*About the front cover:*

“Riding on a Rubble Pile”

Numerical simulations of asteroid disruptions indicate that in many cases of asteroid disruption by a collision with another object, fragment ejection velocities are typically slow enough that most of the fragments reassemble, leading to the formation of rubble piles. It occurred to the artist that during such processes, various irregularly shaped rock shards could fall back at very slow velocities (centimeters per second in some cases) and pile up in grotesque formations not seen on Earth. Here, a large, narrow rock shard has come to rest at an angle on another rock at the surface of the rubble pile. This asteroid also has a rubble-pile satellite (upper left), constituting a binary system. Earth and the Moon are in the distance (upper right). Painting copyright William K. Hartmann, acrylic, mixed with basaltic soil from Tucson.

*About the back cover:*

Haulani impact crater (diameter 35 km) on asteroid (1) Ceres from Dawn’s Framing Camera with a spatial resolution of ~140 m/pixel. The color mosaic is a cut out of the global mosaic in orthographic projection, obtained in August 2015. Haulani (10°E, 6°N) is shown in colors R = 965 nm, G = 555 nm, B = 438 nm. Absolute reflectance values range between 0.025 and 0.055. This young crater, as indicated by its ray system and lack of impact craters on its floor, contrasts in various bright bluish tones sharply from the surrounding brownish background material. At its center, an irregular remnant central peak at the rim of a central pit exists. The unique colors in the crater indicate excavation and deposition of a subsurface layer of potentially hydrated materials.

List of Contributing Authors .....	xiii
Scientific Organizing Committee and Acknowledgment of Reviewers .....	xiv
Foreword .....	xv
Preface .....	xvii

## PART 1: INTRODUCTION

Asteroids: Recent Advances and New Perspectives <i>P. Michel, F. E. DeMeo, and W. F. Bottke</i> .....	3
--	---

## PART 2: PHYSICAL AND COMPOSITIONAL PROPERTIES

### 2.1. Asteroid Composition and Physical Properties

The Compositional Structure of the Asteroid Belt <i>F. E. DeMeo, C. M. O'D. Alexander, K. J. Walsh, C. R. Chapman, and R. P. Binzel</i> .....	13
--	----

Mineralogy and Surface Composition of Asteroids <i>V. Reddy, T. L. Dunn, C. A. Thomas, N. A. Moskovitz, and T. H. Burbine</i> .....	43
--	----

Astronomical Observations of Volatiles on Asteroids <i>A. S. Rivkin, H. Campins, J. P. Emery, E. S. Howell, J. Licandro, D. Takir, and F. Vilas</i> .....	65
--	----

Space-Based Thermal Infrared Studies of Asteroids <i>A. Mainzer, F. Usui, and D. E. Trilling</i> .....	89
---	----

Asteroid Thermophysical Modeling <i>M. Delbo, M. Mueller, J. P. Emery, B. Rozitis, and M. T. Capria</i> .....	107
--	-----

Asteroid Photometry <i>J.-Y. Li, P. Helfenstein, B. J. Buratti, D. Takir, and B. E. Clark</i> .....	129
--	-----

Asteroid Polarimetry <i>I. Belskaya, A. Cellino, R. Gil-Hutton, K. Muinonen, and Y. Shkuratov</i> .....	151
--	-----

Radar Observations of Near-Earth and Main-Belt Asteroids <i>L. A. M. Benner, M. W. Busch, J. D. Giorgini, P. A. Taylor, and J.-L. Margot</i> .....	165
---	-----

Asteroid Models from Multiple Data Sources <i>J. Ďurech, B. Carry, M. Delbo, M. Kaasalainen, and M. Viikinkoski</i> .....	183
--	-----

### 2.2. Populations

The Complex History of Trojan Asteroids <i>J. P. Emery, F. Marzari, A. Morbidelli, L. M. French, and T. Grav</i> .....	203
---	-----

The Active Asteroids <i>D. Jewitt, H. Hsieh, and J. Agarwal</i> .....	221
--	-----

The Near-Earth Object Population: Connections to Comets, Main-Belt Asteroids, and Meteorites <i>R. P. Binzel, V. Reddy, and T. L. Dunn</i> .....	243
---	-----

Small Near-Earth Asteroids as a Source of Meteorites <i>J. Borovička, P. Spurný, and P. Brown</i>	257
--	-----

Meteoroid Streams and Zodiacal Dust <i>P. Jenniskens</i>	281
---	-----

### **2.3. Families**

Identification and Dynamical Properties of Asteroid Families <i>D. Nesvorný, M. Brož, and V. Carruba</i>	297
---	-----

Asteroid Family Physical Properties <i>J. R. Masiero, F. E. DeMeo, T. Kasuga, and A. H. Parker</i>	323
---	-----

Collisional Formation and Modeling of Asteroid Families <i>P. Michel, D. C. Richardson, D. D. Durda, M. Jutzi, and E. Asphaug</i>	341
--	-----

### **2.4. Multiple Systems**

Asteroid Systems: Binaries, Triples, and Pairs <i>J.-L. Margot, P. Pravec, P. Taylor, B. Carry, and S. Jacobson</i>	355
--	-----

Formation and Evolution of Binary Asteroids <i>K. J. Walsh and S. A. Jacobson</i>	375
--	-----

## **PART 3: SPACE MISSIONS**

Hayabusa Sample Return Mission <i>M. Yoshikawa, J. Kawaguchi, A. Fujiwara, and A. Tsuchiyama</i>	397
---	-----

The Dawn Mission to Vesta and Ceres <i>C. T. Russell, H. Y. McSween, R. Jaumann, and C. A. Raymond</i>	419
---	-----

The Flybys of Asteroids (2867) Šteins, (21) Lutetia, and (4179) Toutatis <i>M. A. Barucci, M. Fulchignoni, J. Ji, S. Marchi, and N. Thomas</i>	433
---	-----

Phobos and Deimos <i>S. L. Murchie, P. C. Thomas, A. S. Rivkin, and N. L. Chabot</i>	451
---	-----

## **PART 4: EVOLUTIONARY PROCESSES**

### **4.1. Dynamical Evolution**

New Paradigms for Asteroid Formation <i>A. Johansen, E. Jacquet, J. N. Cuzzi, A. Morbidelli, and M. Gounelle</i>	471
---	-----

The Dynamical Evolution of the Asteroid Belt <i>A. Morbidelli, K. J. Walsh, D. P. O'Brien, D. A. Minton, and W. F. Bottke</i>	493
--	-----

The Yarkovsky and YORP Effects <i>D. Vokrouhlický, W. F. Bottke, S. R. Chesley, D. J. Scheeres, and T. S. Statler</i>	509
--	-----

### **4.2. Differentiation**

Asteroid Differentiation: Melting and Large-Scale Structure <i>A. Scheinberg, R. R. Fu, L. T. Elkins-Tanton, and B. P. Weiss</i>	533
---	-----

Hydrothermal and Magmatic Fluid Flow in Asteroids <i>L. Wilson, P. A. Bland, D. Buczkowski, K. Keil, and A. N. Krot</i>	553
Early Impact History and Dynamical Origin of Differentiated Meteorites and Asteroids <i>E. R. D. Scott, K. Keil, J. I. Goldstein, E. Asphaug, W. F. Bottke, and N. A. Moskovitz</i>	573
<b>4.3. Physical Evolution</b>	
Asteroid Surface Alteration by Space Weathering Processes <i>R. Brunetto, M. J. Loeffler, D. Nesvorný, S. Sasaki, and G. Strazzulla</i>	597
The Formation and Evolution of Ordinary Chondrite Parent Bodies <i>P. Vernazza, B. Zanda, T. Nakamura, E. Scott, and S. Russell</i>	617
Sources of Water and Aqueous Activity on the Chondrite Parent Asteroids <i>A. N. Krot, K. Nagashima, C. M. O'D. Alexander, F. J. Ciesla, W. Fujiya, and L. Bonal</i>	635
<b>4.4. Collisions</b>	
Global-Scale Impacts <i>E. Asphaug, G. Collins, and M. Jutzi</i>	661
Modeling Asteroid Collisions and Impact Processes <i>M. Jutzi, K. Holsapple, K. Wünneman, and P. Michel</i>	679
The Collisional Evolution of the Main Asteroid Belt <i>W. F. Bottke, M. Brož, D. P. O'Brien, A. Campo Bagatin, A. Morbidelli, and S. Marchi</i>	701
<b>4.5. Surface Geology and Geophysics</b>	
Cratering on Asteroids <i>S. Marchi, C. R. Chapman, O. S. Barnouin, J. E. Richardson, and J.-B. Vincent</i>	725
Asteroid Interiors and Morphology <i>D. J. Scheeres, D. Britt, B. Carry, and K. A. Holsapple</i>	745
Asteroid Surface Geophysics <i>N. Murdoch, P. Sánchez, S. R. Schwartz, and H. Miyamoto</i>	767
<b>PART 5: GROUNDBASED SURVEYS, HAZARDS, AND FUTURE EXPLORATION</b>	
Surveys, Astrometric Follow-Up, and Population Statistics <i>R. Jedicke, M. Granvik, M. Micheli, E. Ryan, T. Spahr, and D. K. Yeomans</i>	795
Orbits, Long-Term Predictions, and Impact Monitoring <i>D. Farnocchia, S. R. Chesley, A. Milani, G. F. Gronchi, and P. W. Chodas</i>	815
Asteroid Impacts and Modern Civilization: Can We Prevent a Catastrophe? <i>A. W. Harris, M. Boslough, C. R. Chapman, L. Drube, P. Michel, and A. W. Harris</i>	835
Human Exploration of Near-Earth Asteroids <i>P. A. Abell, B. W. Barbee, P. W. Chodas, J. Kawaguchi, R. R. Landis, D. D. Mazanek, and P. Michel</i>	855

## **Foreword**

In the founding volume of what would become the Space Science Series, Tom Gehrels (1925–2011) wrote, “We are now on the threshold of a new era of asteroid studies” (*Gehrels*, 1971). These words once again trumpet the state of the field four decades later with the release of *Asteroids IV*. Yet why do asteroids captivate our curiosity in a way that so greatly exceeds their small total mass relative to the rest of our solar system? It is because asteroids matter. Now more than ever before, we realize how much asteroids matter to scientists, to explorers, and to the future of humanity. As evidenced throughout this volume, scientists across broad disciplines recognize that understanding asteroids is essential to discerning the basic processes of planetary formation, including how their current distribution bespeaks our solar system’s cataclysmic past. For explorers, the nearest asteroids beckon as the most accessible milestones in interplanetary space, offering spaceflight destinations easier to reach than the lunar surface. For futurists, the prospects of asteroids as commercial resources tantalize as a twenty-first-century gold rush, albeit with far greater challenges and less certain rewards than faced by nineteenth-century pioneers. For humanity as a whole, it is not a question of if — but when — the next major impact will occur. While the disaster probabilities are thankfully small during any one lifespan (and minuscule within the time horizons typically considered by funding agencies), fully cataloging and characterizing the potentially hazardous asteroid population remains unfinished business. While the motivation to “know thy enemy” may ultimately prompt a dedicated spacebased asteroid survey, the richness of the overall scientific return and their exploration/utilization potential will prove that these little worlds are actually our friends.

*Asteroids IV* sets the scientific foundation upon which all these topics and more will continue to be built upon for the foreseeable future. Herein our expert authors lay out what we know, how we know it, and where we go from here. Through this approach, our collective goal is to provide a gateway for new researchers and students of all ages to enter this field by ascertaining the current state. Challenge what doesn’t make sense, resolve what is contentious, and most importantly, fearlessly pursue new ideas that can break through to new paradigms in our understanding. Dare boldly enough to be wrong while being modest enough to reshape or abandon ideas that fail. Only in this way can we soar through the threshold on which we currently stand.

It is my privilege to thank the editors, scientific organizing committee, and authors who crafted this work. Leading the effort with boundless energy and enthusiasm is Patrick Michel. Shining throughout is the careful organization and integrative thinking of Francesca DeMeo. Holding this project steady by his *Asteroids III* editorial experience, Bill Bottke brought his creative thinking as the capstone. Less visible, but whose quality and presence grace every page, are Renée Dotson and colleagues at the Lunar and Planetary Institute (LPI), who brought this volume to physical reality. The ongoing success of the Space Science Series would not be possible without the unfailing support of LPI Director Dr. Stephen Mackwell and the professionalism of the University of Arizona Press.

- Gehrels T. (1971) Preface to *Physical Studies of Minor Planets* (T. Gehrels, ed.). NASA SP-267, U.S. Government Printing Office, Washington, DC. 687 pages.

## Preface

Asteroids are fascinating worlds. Considered the building blocks of our planets, many of the authors of this book have devoted their scientific careers to exploring them with the tools of our trade: ground- and spacebased observations, *in situ* space missions, and studies that run the gamut from theoretical modeling efforts to laboratory work. Like fossils for paleontologists, or DNA for geneticists, they allow us to construct a veritable time machine and provide us with tantalizing glimpses of the earliest nature of our solar system. By investigating them, we can probe what our home system was like before life or even the planets existed.

The origin and evolution of life on our planet is also intertwined with asteroids in a different way. It is believed that impacts on the primordial Earth may have delivered the basic components for life, with biology favoring attributes that could more easily survive the aftermath of such energetic events. In this fashion, asteroids may have banished many probable avenues for life to relative obscurity. Similarly, they may have also prevented our biosphere from becoming more complex until more recent eras. The full tale of asteroid impacts on the history of our world, and how human life managed to emerge from myriad possibilities, has yet to be fully told.

The hazard posed by asteroid impacts to our civilization is low but singular. The design of efficient mitigation strategies strongly relies on asteroid detection by our ground- and spacebased surveys as well as knowledge of their physical properties. A more positive motivation for asteroid discovery is that the proximity of some asteroids to Earth may allow future astronauts to harvest their water and rare mineral resources for use in exploration. A key goal of asteroid science is therefore to learn how humans and robotic probes can interact with asteroids (and extract their materials) in an efficient way. We expect that these adventures may be commonplace in the future.

Asteroids, like planets, are driven by a great variety of both dynamical and physical mechanisms. In fact, images sent back by space missions show a collection of small worlds whose characteristics seem designed to overthrow our preconceived notions. Given their wide range of sizes and surface compositions, it is clear that many formed in very different places and at different times within the solar nebula. These characteristics make them an exciting challenge for researchers who crave complex problems. The return of samples from these bodies may ultimately be needed to provide us with solutions.

In the book *Asteroids IV*, the editors and authors have taken major strides in the long journey toward a much deeper understanding of our fascinating planetary ancestors. This book reviews major advances in 43 chapters that have been written and reviewed by a team of more than 200 international authorities in asteroids. It is aimed to be as comprehensive as possible while also remaining accessible to students and researchers who are interested in learning about these small but nonetheless important worlds. We hope this volume will serve as a leading reference on the topic of asteroids for the decade to come.

We are deeply indebted to the many authors and referees for their tremendous efforts in helping us create *Asteroids IV*. We also thank the members of the *Asteroids IV* scientific organizing committee for helping us shape the structure and content of the book. The conference associated with the book, “Asteroids Comets Meteors 2014” held June 30–July 4, 2014, in Helsinki, Finland, did an outstanding job of demonstrating how much progress we have made in the field over the

last decade. We are extremely grateful to our host Karri Muinonen and his team. The editors are also grateful to the *Asteroids IV* production staff, namely Renée Dotson and her colleagues at the Lunar and Planetary Institute, for their efforts, their invaluable assistance, and their enthusiasm; they made life as easy and pleasant as possible for the editors, authors, and referees. They also thank Richard Binzel, the General Editor of the Space Science Series, for his strong support and advice during this process, as well as the staff at the University of Arizona Press.

Finally, editor Patrick Michel would like to thank his wife Delphine, who married him on June 14, 2013, almost at the birth of the book process. He is grateful that she was willing to put up with him as he spent many of his nights and weekends working on the book. Thanks to her support, their trajectories are as bounded as a perfectly stable asteroid binary system, and this was probably the best way to experience from the start what her life would be like with a researcher! Co-editor Bottke would also like to thank his wife Veronica and his children Kristina-Marie, Laura, and Julie, who make up his own favorite asteroid family. Since *Asteroids III*, the size distribution of the family members has been steadily changing, and who knows how many tiny new members it will contain by *Asteroids V*! Co-editor DeMeo would like to thank her husband Alfredo for his support and encouragement throughout the process of creating this book. They met at the beginning of her career in research, becoming an asteroid pair and now continuing on the same orbit in life.

## 1. INTRODUCTION

Asteroids are thought to be leftover planetesimals that are closely related to the precursor bodies that formed both the terrestrial planets and the cores of the giant planets. The most primitive ones contain a record of the original composition of the solar nebula in which the planets formed. The organic matter and properties of water that some contain provide us with critical clues about how life started on Earth. Moreover, some of them cross the trajectory of our planet and therefore pose a risk to humanity.

The sizes, shapes, and rotational, internal, and surface properties of asteroids are the outcome of collisional and dynamical evolution that has molded them since they formed. Understanding the processes they experienced, how these mechanisms changed their properties, and how these factors in turn influenced their evolution can serve as a tracer to tell us the story of the solar system.

In 2005, the European Space Agency published its report *Cosmic Vision: Space Science for Europe in 2015–2025*, which contained two questions related to asteroid research: (1) what are the conditions for planet formation and the emergence of life? (2) How does the solar system work?

Similarly, in 2012, the committee on the planetary science decadal survey appointed by the U.S. National Research Council published a list of questions intimately related to asteroid research. We repeat here those that help put into context the work that is presented throughout *Asteroids IV*: (1) What were the initial stages, conditions, and processes of solar system formation and the nature of the interstellar matter that was incorporated? (2) What solar system bodies endanger Earth's biosphere, and what mechanisms shield it?

In addition, the decadal survey indicated the goals for research on primitive bodies for the next decade: (1) Decipher the record in primitive bodies of epochs and processes not obtainable elsewhere, and (2) understand the role of primitive bodies as building blocks for planets and life.

Important questions related to asteroids in various areas were then indicated, some of which include:

- Which classes of meteorites come from which classes of asteroids, and how diverse were the components from which asteroids were assembled?
- Did asteroid differentiation involve near-complete melting to form magma oceans, or modest partial melting?
- What are the internal structures of Jupiter's Trojan asteroids? Are there systematic chemical or isotopic gradients in the solar system, and if so, what do they reveal about accretion?
- Do we have meteoritic samples of the objects that formed the dominant feeding zones for the innermost planets?
- How did Earth get its water and other volatiles? What is the mechanical process of accretion up to and through the formation of meter-size bodies?
- Which classes of asteroids participated in the late heavy bombardment of the inner planets and the Moon, and how did the current population of asteroids evolve in time and space?
- What are the sources of asteroid groups (e.g., Trojans) that remain to be explored by spacecraft?

It is clear that the solutions to these questions will allow us to glean insights into many fundamental planetary science problems, in particular those connected to the formation and evolution of our solar system.

Since the last book in this series, *Asteroids III*, we have made tremendous advances in our knowledge of asteroids, thanks to the combined efforts of ground- and spacebased observations, space mission rendezvous and flybys, laboratory analysis of returned samples, and theoretical and numerical modeling. In *Asteroids IV*, major strides have been made in the long journey that will eventually lead us to a much deeper understanding of our planetary ancestors. In the words of the classic Californian science fiction radio show *Hour 25*, our progress has all of us now “standing on the verge of new worlds, new ideas, and new adventures.”

This book reviews these major advances in 42 chapters, with the aim of being as exhaustive as possible while also

remaining accessible to students and researchers who are interested to learn about these fascinating bodies and what they tell us about solar system history. Here we introduce the major concepts and topics of this book and highlight some of the major advances that have been made since *Asteroids III*. This introduction does not include references except from the chapters themselves.

## 2. ASTEROID FORMATION AND SOLAR SYSTEM EVOLUTION

Many major improvements have been achieved in solar system dynamical studies since *Asteroids III*. As discussed in the review chapter by Johansen et al., new modeling work on the very early phases of planetesimal growth, together with constraints derived from meteorites and protoplanetary disks, have inspired next-generation scenarios of how the largest asteroids originated. Simulations of the evolution of turbulent gas and dust in protoplanetary disks demonstrate that 100- to 1000-km-diameter asteroids may have formed directly from the gravitational collapse of small particles that organize themselves in dense filaments and clusters. Although many open questions remain, these models provide a potential solution to the long-standing issue regarding the passage from centimeter-sized particles to asteroidal bodies in planetary growth studies, bypassing the long-standing “meter-size barrier.”

In effect, laboratory experiments have shown that micro-meter-scale dust readily aggregates into millimeter- or even pebble-sized agglomerates. On the largest scales, impact simulations have shown that self-gravity among two colliding protoplanets ensures net growth, although the efficiency of two planetesimals combining is often less than 100% (see the chapter by Asphaug et al.). The situation is still murky for objects ranging in size from millimeters to kilometers. In fact, macroscopic dust particles (millimeter or larger) have poor sticking properties in particle-particle collisions, while gravity between the components is too low to act as a “glue” between them. Johansen et al. discuss how the self-gravity of a sufficiently massive particle clump may be capable of growing bodies in this size range.

Several dynamical scenarios have also emerged to describe the early phases of the solar system, with the observed properties of the asteroid belt acting as a constraint (see chapter by Morbidelli et al.). They indicate that the asteroid belt has been sculpted by one or possibly a series of processes, and that this evolution can be characterized by three phases.

The first phase starts during the lifetime of the gaseous protoplanetary disk when the giant planets formed. Here the giant planets may have undergone migration as they gravitationally interacted with the solar nebula. One of the new scenarios describing this phase, which involves the migration of Jupiter through the asteroid belt, is called the “Grand Tack.” It is capable of producing dynamical excitation among the existing asteroids, forcing many out of the region where the main belt currently lies, while also introducing new low-albedo asteroids into the main belt from the Jupiter-Saturn

zone. This could have left the population in a state similar to the observed main belt, with a low-mass population having a wide range of eccentricities, inclinations, and compositions.

The second phase occurs later, possibly as late as ~4 G.y. ago or nearly 500 m.y. after the removal of the gaseous protoplanetary disk. Once again, the giant planets became temporarily unstable, such that some of them may have strongly interacted with a large primordial disk of comet-like planetesimals located in the outer reaches of the solar system. This allowed the giant planets to migrate from an initial resonant and compact configuration to their current configuration. The instability may also have led to the additional loss of asteroids from the main-belt region. The so-called “Nice model” provides a description of this evolutionary phase. The strength of this model is that it naturally reproduces various observed constraints within a single model, such as the current semimajor axes, eccentricities, and inclinations of giant planets; the curious existence of Trojan asteroids, a population that is reviewed by Emery et al.; and the structure of the Kuiper belt beyond Neptune. The Nice model also provides a possible explanation to the origin of the so-called late heavy bombardment, which some argue produced numerous younger basins on the Moon and terrestrial planets.

The studies of these first two phases provide us with new insights into how and where planets formed, with implications for the dynamical history of the asteroid belt and the diversity of compositions observed in the relatively narrow ~1-AU-wide main asteroid belt, as reviewed by DeMeo et al. These new scenarios together describe an evolutionary process that could lead to a solar system with properties that are consistent with the observed one. The aforementioned constraints, however, are challenging, and it is possible that the new scenarios will founder as they are tested in detail. Therein lies the new science that will comprise *Asteroids V* in the decade or more to come.

The third phase, reviewed by Morbidelli et al., covers the interval between late giant planet migration until today. Potentially as much as half the asteroid population was lost via depletion taking place at unstable resonances with the giant and terrestrial planets, mostly during the subsequent 100 m.y. after late planet migration took place.

Additional constraints on these ideas come from models of the collisional evolution of the asteroid belt. As reviewed by Bottke et al., the latest generation of model results suggests that the main belt’s wavy size-frequency distribution describes a primordial population dominated by 100-km-diameter and larger objects (see Johansen et al.) that undergoes sufficient comminution to create much of the observed population of <100-km bodies. The shape of the size distribution created in this process can then be considered something of a fossil-like remnant of a violent early epoch. This left the main-belt size distribution in a collisional quasisteady state, and it has possibly been that way for billions of years.

Insights from collisional evolution models, however, rely strongly on our understanding of the physics of collisional disruption events. Scaling laws are needed to define the results of two-body collision results, and precise expressions are

needed to define the nature of the fragment size frequency and ejection velocity distributions. As reviewed by Asphaug et al. and Jutzi et al., numerical modeling has become an important method for studying global-scale impacts and asteroid collisions. Moreover, impact experiments remain an important activity that has greatly improved our understanding of the impact process at small scales.

Since *Asteroids III*, computational resources, numerical methods, and impact experiments have all led to a new understanding of the impact process at both large and small scales. Several material models introduced in shock physics codes, with some of their results validated by comparison with laboratory hypervelocity shot experiments, now allow us to better account for the diversity of asteroid properties that affect collision outcomes. In particular, porosity models have been introduced to account for the influence of microporosity in the fragmentation process. Porosity helps to dissipate a portion of the impact energy into the crushing of pores, which results in compaction. This makes porous asteroids more resistant to disruption against impact than expected (see Jutzi et al.). The importance of the shear strength, and its dependency on the confining pressure produced by asteroidal self-gravity, is reviewed by Asphaug et al. They find that when this kind of friction is introduced, the impact energy threshold for disruption can increase by a factor of 5 to 10. The disruption threshold further increases by a factor of 2 to 3 when the energy dissipation by compaction (pore crushing) is taken into account.

The implications of these results are that many collision events previously considered catastrophic, defined as half the combined mass of the projectile and target flying away at escape velocity, are instead more likely to produce a shattered target that remains in possession of much of its mass. As collisional evolution models begin to take these results into account, new possible evolutionary histories of the asteroid belt may reveal themselves.

### 3. ASTEROID DIFFERENTIATION

Another issue that has made major advances since *Asteroids III* is asteroid differentiation. It was originally expected that asteroids that formed early and large enough to heat up enough from the decay of short-lived radioactive isotopes such as  $^{26}\text{Al}$  and melt would eventually form an iron core, olivine-rich mantle, and basaltic crust. Thus all differentiated bodies, large or small, would look like little Vesta. Observational evidence for the mantle material among the known asteroids was lacking, thereby raising the question of “Where is the missing mantle material?” Scheinberg et al. describe differentiation models, including the possibility of partial differentiation, whereby some asteroids may have experienced enough melting to form differentiated interiors but still preserve primitive surface layers. The salient point here is that not all magmas are buoyant; some are happy to reside at depth rather than propelling themselves to the surface. Thus, the old adage that one cannot judge a book by its cover may be particularly appropriate here.

The possible sources of asteroid heating in the early solar system are summarized by Wilson et al. They describe the physical transport of magma in an asteroid during the differentiation process. Because most of our evidence of and information about asteroid differentiation comes from meteorite fragments of differentiated asteroids, these samples can be used to establish a chronology for asteroid formation, differentiation, and subsequent disruption of these differentiated bodies (see chapter by Scott et al.).

### 4. ASTEROID FAMILIES

Collisional evolution models have various constraints that they must reproduce to be validated, as Bottke et al. discuss in their review chapter. A critical one is the number and precise nature of asteroid families. An asteroid family is a group of asteroids that share similar orbital and compositional properties. They have long been thought to originate from the collisional disruption of parent asteroids. It is only in the last decade, however, that the collisional origin of asteroid families has been directly demonstrated by numerical simulations, as reviewed by Michel et al. By including both physical and dynamical effects, such as fragmentation and the gravitational self-atraction of components after a disruption, runs from these codes show that the catastrophic disruption of bodies larger than a few hundred meters in diameter will lead to reaccumulation of debris and the formation of large gravitational aggregates. This potentially solves the mystery of how very large members within asteroid families might form. Without this reaccumulation process, family members produced solely by the fragmentation phase would tend to be very small because the impact energy needed to reproduce the observed ejection speeds is too high to create large monolithic fragments.

Numerical simulations also benefit from the identification of very young families whose properties are the direct outcomes of parent body disruption events. These properties can be directly compared with numerical simulation outcomes, while the dispersion of older families is affected more by post-collision and dynamical processes. Through a careful comparison, we can obtain constraints on the internal structure of family members and the initial state of the parent body from which they came, while also probing the initial dynamical state of the new family. The results of this exercise show that the outcome of a parent body disruption depends strongly on the nature of its internal structure.

Since *Asteroids III*, the inventory of asteroid families has been steadily increasing as surveys continue to find new main-belt bodies. At the same time, several dedicated programs and sky surveys have produced an abundance of physical observations; nearly 2 orders of magnitude more asteroids have been characterized in some fashion than had been done a little more than a decade ago. This has set the stage for huge advances in our knowledge of families, as reviewed in the chapters by Nesvorný et al. and Masiero et al. Progress includes the discovery of several very young families, new data to better understand the full reach of

specific families, and new tools that allow us to determine the dynamical evolution of families by nongravitational forces and date their approximate age.

A key advance in this work has been the comprehensive measurements of asteroid colors by the Sloan Digital Sky Survey and albedos by the Wide-field Infrared Survey Explorer (WISE) infrared telescope. These spectacular datasets also allow us to search for how the surface properties of different family members might vary from object to object. This could help us identify heterogeneity in the composition of the parent body. More critically for impact simulations aiming to reproduce the initial size frequency and ejection velocity distributions of family members, diameter measurements lead to improved estimates of the size-frequency distribution of family members as well as estimates of the original parent body sizes. These data are a rich and diverse source of new information about this history of the main belt.

## 5. ACTIVE ASTEROIDS

One of the more remarkable observational discoveries of the last decade is that some main-belt bodies eject small particles that lead to transient, comet-like comae and tails. These peculiar objects are called active asteroids, and are discussed in Jewitt et al. They are particularly remarkable for being an entirely new population located in one of the closest and most intensively studied regions of the solar system.

There are many plausible causes of this activity. They include impact ejection and disruption, rotational instabilities, electrostatic repulsion, radiation pressure sweeping, dehydration stresses and thermal fracture, as well as ice sublimation. The evidence suggests that one size does not fit all, and a good physical mechanism for activity for one object may not be a good fit for another. We expect substantial advances will be made in this area over the years between the publications of *Asteroids IV* and *V*. These processes also imply that the difference between asteroids and comets in terms of surface activity may be smaller than previously thought, supporting the idea of an asteroid-comet continuum.

## 6. WATER IN ASTEROIDS

While the search for extraterrestrial water has always been a priority in solar system science, particularly with NASA's "follow the water" space mission priorities, it has only recently become a big topic in asteroid science. Even though evidence of aqueous alteration on asteroids has long been known, the direct evidence of water or ice has been limited. *Asteroids IV* has a number of chapters dedicated to recent advances in understanding the role of water on or in asteroids. As described above, the discoveries of activated asteroids covered by Jewitt et al. have great implications for better understanding the relationship between asteroids and comets. Rivkin et al. present observational evidence for water and hydration on asteroids detected from visible to mid-IR wavelengths. They also discuss possible explanations for the presence of water or hydroxyl detections on asteroid surfaces; these explana-

tions include not only the formation of those asteroids in an ice-rich environment, but also space weathering processes and the delivery of exogenic material. Among chondrites that accreted ices during formation, the chapter by Krot et al. describes the degree of aqueous alteration among chondrite types, their implications for the likely locations of the snow line early in solar system history, and the probable location of chondrite formation relative to this snow line.

## 7. ASTEROID PHYSICAL AND COMPOSITIONAL PROPERTIES

The available data on the sizes and shapes of asteroids has grown by exponentially since *Asteroids III*. Mid-infrared surveys, including WISE, have provided diameter and albedo estimates for more than 150,000 asteroids, increasing the characterized population by orders of magnitude (see the chapter by Mainzer et al.). From these data, the first "albedo map" of the main belt was created.

The abundance of thermal infrared data motivated advances in asteroid thermophysical modeling. This modeling has not only improved albedo estimates but has also constrained thermal inertia and surface roughness among different bodies. These parameters in turn constrain the grain sizes at the surface, as discussed in the chapter by Delbo et al. Moreover, a new mechanism for regolith production has been identified: thermal cracking through repeated temperature changes on an asteroid surface. We also have identified more shapes of asteroids than ever before via radar studies (chapter by Benner et al.), direct asteroid imaging, lightcurve inversion into shape models, and the combination of multiple data sources (see the chapter by Durech et al.). So far, these shapes have proven to be reliable, as demonstrated by spacecraft imaging the same targets.

In their review chapter, Reddy et al. review revised equations to constrain mineralogy and describe diagnostic features in the mid-infrared spectroscopy of asteroids, for which there were little data in previous books. Belskaya et al. discuss how our growing sample of polarimetric measurements has helped constrain the refractive index, particle size, packing density, and optical heterogeneity. Advances in photometry were led by spacecraft observations as well as theory and laboratory measurement (see the chapter by Li et al.).

For three decades we have sought to understand why the most common meteorite type, ordinary chondrites, does not spectrally match the most common asteroid taxonomic type, the so-called S-type asteroid. This has been known as the ordinary chondrite paradox. It was the Hayabusa mission returning samples from (25143) Itokawa that finally settled and resolutely revealed that these two sets are in fact a compositional match (see chapters by Yoshikawa et al. and Brunetto et al.). Significant progress has been made in understanding the primary cause of the spectral mismatch, i.e., the space weathering process. Brunetto et al. review what we have learned about space weathering over the past decade. Vernazza et al., in light of the link between ordinary chondrites and S-type asteroids, review the compositions of

ordinary chondrites and what they tell us in the context of the formation and evolution of S-type parent bodies. It has been scientifically rewarding to resolve this longstanding puzzle with the first sample return mission to an asteroid.

## 8. ASTEROID GEOPHYSICS

Before the first asteroid images were sent from space, our knowledge of asteroids relied entirely on groundbased observations, meteorite analysis, and analytical/numerical modeling studies. Now, *in situ* images from flyby and rendezvous missions have revolutionized our knowledge of their physical properties. Since *Asteroids III*, space missions have closely studied an extreme range of asteroid sizes. For example, NASA's Dawn mission, reviewed by Russell et al., orbited (4) Vesta, the second largest asteroid (530 km diameter), and is now orbiting (1) Ceres, the largest (950-km diameter). These two worlds provide potential windows into the nature of the protoplanets that accreted into the terrestrial planets and perhaps those strange large bodies found today in the Kuiper belt.

On the opposite end of the size distribution, Japan's Hayabusa mission visited a 320-m-sized near-Earth asteroid (NEA) named (25143) Itokawa, which turns out to be a rubble pile, and successfully returned a sample to Earth, as reviewed by Yoshikawa et al. The European Space Agency's (ESA) Rosetta mission performed flybys of the E-type asteroid (2867) Steins, discovering that it had the shape of a "diamond in the sky," and the M-type asteroid (21) Lutetia, which was found to have an intriguingly high density of  $3.4 \text{ g cm}^{-3}$ . Rosetta then continued on to Comet 67P/Churyumov-Gerasimenko, where it successfully performed the spectacular and successful landing of Philae. These encounters, as well as that with the contact binary (4179) Toutatis by China's Chang'e mission, are reviewed by Barucci et al.

Finally, Murchie et al. discuss what we have learned about Phobos and Deimos, two bodies in orbit around Mars. These satellites have several traits in common with low-reflectance bodies, and they arguably resemble some of the typical denizens found in the outer asteroid belt. The origins of Mars' satellites have long been debated. Some believe their physical properties point to them being captured asteroids. The problem is that the low inclinations of Phobos and Deimos are hard to match by any known capture mechanism. Instead, it can be argued they are more likely to be the byproduct of a disk of debris formed near Mars by some potential mechanism (e.g., similar to the preferred theory of the formation of Earth's Moon). Comparisons between Phobos/Deimos and what is known about low-albedo asteroids may ultimately provide us with solutions to this longstanding problem.

These missions showed us that asteroids are not only incredibly diverse in size, shape, structure, composition, and rotational properties, but have also been subjected to a wide range of processes. Each encounter/rendezvous provided us with a taste of how granular mechanics, landslides, earthquakes, faulting, and impact cratering affect worlds of

many different sizes. The way in which matter behaves on an asteroidal surface, as well as the way in which the surface material will respond to different processes, depends drastically on a body's surface gravity. It is therefore no surprise that the 34-km-long asteroid (433) Eros, the primary target of the Near Earth Asteroid Rendezvous (NEAR) mission, and the 535-m-long asteroid (25143) Itokawa have very different surface properties, despite the fact that they are the same taxonomic type.

Over the past decade, remote and *in situ* observations have revealed that the surfaces of asteroids are generally covered by loose unconsolidated material called regolith. Regolith is present on asteroids of all sizes, from the largest to those as small as a few hundreds of meters, such as Itokawa. As a result of the unique microgravity environment that the smaller (and most populous) components of the asteroid population possess, complex and varied geophysical processes have given birth to fascinating features that we are just now beginning to understand. These processes were first described through detailed spacecraft observations, but recently have been studied in detail using theoretical, numerical, and experimental methods that combine several scientific disciplines. Murdoch et al. provide a summary of what the scientific community has learned so far about granular materials on the surfaces of these small planetary bodies using both experimental techniques and numerical simulations. Studies of how regolith evolves and responds to different processes (e.g., impacts, shaking, etc.) in low-gravity environments are vital to our understanding of observations as well as the design of future space missions.

Other ubiquitous features of asteroid surfaces are impact craters. As discussed by Marchi et al., crater populations are a powerful tool to trace back an asteroid's surface history and constrain its age. Large craters excavate deep inside the asteroid and produce reverberating stresses that cause global surface modifications, massive faulting, and overturn. Of the known asteroid craters, only the ~500-km Rheasilvia and ~400-km Veneneia craters, the two largest craters on (4) Vesta (see the chapter by Russell et al.), show clear evidence for gravitational rebound and central peak formation. These two basins overlap in Vesta's southern hemisphere, providing a distinct challenge for modeling efforts (see the chapter by Asphaug et al.). Understanding the formation of these giant craters is critical to interpreting Vesta's history, the nature of its associated asteroid family, and the origin of the howardite, eucrite, and diogenite (HED) meteorites that are almost certainly samples from Vesta itself.

While many broad questions were posed in the *Asteroids III* chapter on asteroid interiors, we are now able to delve more deeply into these. In this volume, authors leverage what has been learned from observations across a huge range of asteroid sizes and from our greater understanding of the processes that contribute to their interior properties (see the chapter by Scheeres et al.). As an example, consider that giant craters act as probes of interior geology (see Asphaug et al.), while bodies smaller than 100 km in diameter may increasingly originate from cratering and disruption events

among larger bodies (see Bottke et al.). Consequently, most smaller bodies should be fractured, shattered, or rubble-pile bodies. Moreover, according to simulations, all bodies larger than a few hundred meters extracted from a larger body through a catastrophic disruption experienced reaccumulation during the ejection/gravitational phase of the collision (see Michel et al.).

Along these lines, Scheeres et al. review our current understanding of asteroid interiors and morphology. This includes a discussion of the strength of asteroid materials as inferred from meteors and meteorites, the density and porosity of asteroids as derived from remote observations, global constraints on asteroid strength and morphology based on ground- and spacebased observations, analytical theories of asteroid strength and evolution, and the current state of numerical simulation techniques of asteroid strength.

Despite these efforts, however, it is clear that many issues and questions remain. For example, we do not yet have a clear and detailed view of how to define the interior of an asteroid, even though we can approximately infer its strength based on its spin rate and on how it evolves. We are also lacking a robust theory of tidal dissipation within such rubble-pile bodies, as well as a way to characterize the critical parameters of rubble piles (e.g., rigidity, tidal Love number). Compared to the extent of knowledge at the time of *Asteroids III*, major advances have been made, but we still have a long way to go. It is here that direct measurements of asteroid interiors using techniques such as radar tomography or seismic experiments could provide us with new and strongly needed insights.

## 9. YARKOVSKY AND YORP EFFECTS

During the current and relatively calmer phase of main-belt history (i.e., the last 3 G.y. or so), we have become increasingly aware of slow but steady dynamical mechanisms that contribute to the evolution of asteroid physical properties, the modification of the orbits of asteroid family members, and the transport of asteroids from the main belt to resonances that can take them into near-Earth space. Vokrouhlický et al. review recent progress in our understanding of the Yarkovsky and Yarkovsky-O’Keefe-Radzievskii-Paddack (YORP) thermal forces that modify the orbits and spin rates of small asteroids. At the time of *Asteroids III*, the Yarkovsky effect had been explored theoretically, but it had not yet been directly detected. (6489) Golevka was the first asteroid for which an unambiguous signature of the Yarkovsky effect was detected in its orbit. Other detections, as well as upcoming possibilities, are reviewed in the chapter by Vokrouhlický et al.

Additional progress has also been made concerning the “sunlight alters spin” mechanism called the YORP effect. Analyses of small-asteroid populations indicate clear evolutionary differences due to the YORP effect, both in rotation rate and obliquity. Vokrouhlický et al. discuss the direct measurements of this effect as well as how sensitive it is to small-scale surface topography. YORP can either decrease or increase an asteroid’s spin rate. In the latter case, YORP

spinup can lead to a fission event and/or to the formation of a binary system. For such a system, a variant of the YORP effect has been proposed, called binary YORP (BYORP), that can potentially cause interesting effects to the newly formed satellite. It has not been directly observed as of yet, although some predictions stemming from this effect have been confirmed.

Both the Yarkovsky and YORP effects have many implications for asteroid properties, family structures, distribution of asteroid spin properties, transport of asteroids out of the main belt, and formation of asteroid binaries (Walsh and Jacobson), and could be an intriguing tool to probe the nature of individual asteroids.

## 10. MULTIPLE SYSTEMS

Multiple systems (e.g., binary and triple asteroids) are a nonnegligible fraction of the asteroid population. Their formation and evolution have been the subject of intensive work and discoveries over the past decade. The observational aspects of these systems are reviewed by Margot et al., while Walsh and Jacobson review how they have been modeled to date.

Since *Asteroids III*, the number of known binary NEAs has also more than quadrupled, while the number of known large main-belt asteroids with satellites has doubled. Half a dozen triple asteroids have been discovered. Moreover, populations of so-called asteroid pairs, defined as asteroids that have lost companions, have now become a flourishing field of research. Even small main-belt binaries have been identified, which is quite an achievement given how difficult it is to study small main-belt asteroids of any type.

These systems provide a natural laboratory in which to study many different types of physical processes acting on asteroids and how their dynamics provide a valuable probe of their physical properties — otherwise only possible with *in situ* spacecraft missions. Observations of small binary systems (with diameters of the primary body <10 km) have motivated theoretical work showing that YORP torques can efficiently drive the rotational disruption of small asteroids. Constraints on the dynamical evolution of those systems have also been obtained; they account for the effect of tides, thermal forces, and rigid body physics. The split pairs have then pushed theorists to explore a wide range of evolutionary end-states.

## 11. NEAR-EARTH ASTEROIDS

Asteroids that cross Earth’s trajectory pose a threat to humankind. The explosion of a 20-m bolide over Chelyabinsk in Russia on February 13, 2013, and the realization that even relatively small impact events can cause human injuries, served as a valuable reminder of this fact. The inventory of potentially hazardous asteroids (PHAs) has driven the development of mitigation strategies; there are very low probabilities of Earth impact in the near future, but if a large asteroid does hit, the impact could have major consequences for life on Earth.

The proximity of asteroids in the PHA class of bodies also offers us with the opportunity for exploration via robotic and human missions. Abell et al. review the current status of ongoing projects to fulfill the dream of a human mission to an asteroid by NASA and other space agencies. These asteroids may also be a potential source of rare minerals, although there is still much to learn and to be done before we can fully exploit them.

The recent advances in asteroid surveys are reviewed in the chapter by Jedicke et al. To date, the vast majority of the known asteroids have been discovered by dedicated surveys funded by NASA. The ability of these surveys to find small asteroids has also steadily improved, with 8× more near-Earth objects (NEOs) and 10× more main-belt asteroids found in the last 5 years than in the 5 years leading up to *Asteroids III*. In particular, the NASA directive to discover 90% of NEOs greater than 1 km in diameter is estimated to have been achieved, and now the new challenge is to do the same for the smaller NEOs, which still pose serious regional threats to Earth.

Once an object is discovered, its orbit must be computed. Despite a well-consolidated theory of orbit determination, the increasing number and ever higher quality of observational data, together with the goal of pushing forward the horizon for ephemeris predictions, pose new challenges in estimating asteroid trajectories. Farnocchia et al. review the methods currently in use to compute asteroid orbits, predict their evolutions, and assess the impact hazard to Earth. Considerable activity has taken place regarding the hazard caused by asteroids. The goals of these studies are to increase the number of identified potentially hazardous objects and better understand the efficiency of various mitigation techniques. International institutions, such as the United Nations (UN), have also begun to organize a response to this risk. These activities are reviewed in the chapter by Harris et al.

Another field that has flourished since the time of *Asteroids III* is the study of subkilometer-sized asteroids. There are more than 9000 of these that have been discovered to date among NEOs. Binzel et al. summarize the current understanding of NEO spectroscopic properties.

Another method that can be employed to study the smallest asteroids is the use of meteoroid observation networks, which detect and measure fireballs, typically centimeter- to meter-sized bodies that enter Earth's atmosphere. Emission measurements provide compositional information, and additional data is provided by the fireball's path, which can constrain the body's orbit prior to entry.

Spectacular fireballs from the past decade that have resulted in meteorite recovery include the Chelyabinsk and Almahata Sitta (2008 TC<sub>3</sub>) events (see the chapter by Borovička et al.). The case of Almahata Sitta is particularly fascinating. As reviewed by Borovička et al., in October 2008, a small asteroid with a flat (gray) spectrum at 550–800-nm wavelengths and a weak pyroxene absorption band around 900 nm — asteroid 2008 TC<sub>3</sub> — entered the atmosphere and exploded over the Nubian desert, depositing material in a strewn field in northern Sudan. Searches to date

have recovered >600 fragments, but the net collected mass is still <1% of the expected mass of the roughly 3–4-m-diameter bolide. Most of this missing mass was almost certainly lost in the atmosphere. These materials are collectively named Almahata Sitta (AHS), and represent the first recovered meteorites from a spectrally observed asteroid. The ensuing wave of work on AHS revealed an enormous diversity of components. None of this was predicted from the remote spectral observations of the asteroid in space, showing that our interpretation of asteroid physical and compositional properties from remote observations must always be treated with due caution.

Smaller bodies in the form of micrometeorites also reach Earth. Interplanetary matter falls to Earth at a rate of 10,000–40,000 tons per year, mostly in the form of meteoroids with sizes ranging from 10 μm to 1 mm. Most of this material appears to come from disrupted Jupiter-family comets, which would explain the dynamical signatures of these bodies as well as their predominately primitive compositions. Jenniskens reviews the considerable progress made in this area, as well as what we have learned in charting meteoroid streams at Earth and understanding the mechanisms of meteoroid stream formation and evolution.

Several ongoing fragmentation cascades of comets and primitive asteroids manifest themselves as multiple meteoroid streams at Earth. Evidence is mounting that recently released meteoroids fall apart on timescales of 100–10,000 years, breaking into smaller meteoroids that survive for another ~100,000 years to form the zodiacal dust cloud. Main-belt asteroids are thus thought to contribute only a small fraction of the cloud's material. For asteroid-like material, the active asteroid (3200) Phaeton is perhaps the most significant source of the infall to Earth of freshly ejected meteoroids.

## 12. PERSPECTIVES

During the next decade, our knowledge of asteroids should undergo major improvements and possibly substantial revisions, thanks to both current and future space missions, groundbased observations, and future advances in numerical and theoretical works.

Dawn's visit to (1) Ceres will be completed by the time this book is released, but most of the science learned from that part of the mission will be in the realm of *Asteroids V*.

Two sample return space missions — Hayabusa-2 and the Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) — will visit their respective asteroid targets at nearly the same time. The Japan Aerospace Exploration Agency's (JAXA) Hayabusa-2 mission, launched successfully on December 3, 2014, will arrive at the primitive C-type NEA 1999 JU<sub>3</sub> in 2018. It will orbit the body for approximately one year before returning a sample to Earth in 2020. A small lander, the Mobile Asteroid Surface Scout (MASCOT), will perform *in situ* investigations, while a small carry-on impactor will perform a 2 km s<sup>-1</sup> impact and will create a crater on the asteroid's surface — allowing us to test numerical impact models and

scaling laws on a real asteroid surface — in which a sample will possibly be collected in addition to at least one other sample in a different area.

The counterpart of Hayabusa-2, NASA's OSIRIS-REx mission, will be launched in September 2016 and will arrive at the primitive B-type asteroid (101955) Bennu in 2018. It will also orbit its target for nearly a year before collecting a sample. The samples will then arrive on Earth in 2023. These two missions will allow us to make huge strides in our understanding of primitive asteroids while also helping us place into context our knowledge of certain types of carbonaceous chondrite meteorites. It will also be novel to compare and contrast the physical nature and compositional properties of two different C-complex asteroids (or see if they are from the same parent family).

ESA and NASA are also now performing a Phase A study of the Asteroid Impact and Deflection Assessment (AIDA) mission. AIDA is a joint ESA-NASA cooperative project that entered into the 15-month Phase A in 2015 and aims to be the first kinetic impactor test if approved in fall 2016 for launch in 2020. The characterization of its target — the secondary of the binary NEA (65803) Didymos — by ESA and the kinetic impact test by NASA would take place in 2022 and would allow us to have a first direct measurement of an asteroid internal structure by radar tomography and an asteroid's response to an impact.

It is also hoped that a new Discovery-class mission will be selected with asteroids as a target. Several proposed projects intend to survey and discover asteroids, visit particular or several asteroids in the main belt, perform seismic experiments on a NEA, and visit Trojan or active main-belt asteroids. The Japanese are studying a sample return from a Trojan asteroid using a novel solar sail for propulsion.

The 2029 Apophis encounter at 5.6 Earth radii from Earth's center is close enough for the body's spin to be affected by tidal forces. This will be a grand experiment in asteroid seismology that nature is performing for us. It would thus be interesting to see if tidal effects are enough strong to trigger some kind of surface or interior motion. This opportunity is so unique that it may ultimately motivate a space agency or an international effort to devote a small space mission to it.

The next generation of groundbased and spacebased telescopes is also underway. The space mission Gaia (ESA)

is an all-sky astronomic space survey launched in 2013 that will measure the positions and colors of all sources down to a magnitude of V = 20. By the end of the mission in 2020, Gaia is expected to provide absolute astrometric positions for 350,000 asteroids that will be 2 orders of magnitude more precise than currently exist. We will also gain huge improvements in the accuracy of asteroid orbit determinations, and the masses of the largest 100 asteroids will be well established. Using spectra in visible wavelengths, Gaia will also provide a more refined taxonomic classification for many asteroids. Overall shapes, spins, and pole coordinates for various asteroids will also be part of the Gaia output.

The Large Synoptic Survey Telescope (LSST) also promises to discover large numbers of NEOs and other small bodies in the solar system. The James Webb Space Telescope (JWST), scheduled to launch in 2018, is the successor to the Hubble and Spitzer telescopes; it will feature a 6.5-m primary mirror. The next generations of groundbased telescopes are also in design or at early stages of construction. These include 30–40-m-class telescopes such as the Thirty Meter Telescope (TMT) to be built in Hawaii and the Giant Magellan Telescope (GMT) and European Extremely Large Telescope (E-ELT) to be built in Chile. These telescopes will provide opportunities for research on asteroids not currently possible and will allow discoveries we have not yet imagined.

Finally, our knowledge of asteroids is crucial to understanding the surroundings of other stars. We now have discovered more than 1800 confirmed extrasolar planets, plus more than 4500 Kepler planet candidates. The number of discoveries regarding exoplanets and debris disks will only increase, although we will not be able to observe the detailed properties of these systems in the near future. Asteroids carry information that is key to understanding planetary formation, as explained in several chapters of this book. They, along with comets, are the closest analog we have to the types of objects involved in planet formation. By exploring how asteroids formed and evolved, we glean insights into the history and properties of debris disks and planetary systems around other stars. Asteroids are therefore fascinating not only because they tell us about our own solar system's provenance and evolution, but also because they can help us better interpret what is going on in newly discovered planetary systems.

The past decade has brought major improvements in large-scale asteroid discovery and characterization, with over half a million known asteroids, more than 100,000 of which have some measurement of physical characterization. This explosion of data has allowed us to create a new global picture of the main asteroid belt. Put in context with meteorite measurements and dynamical models, a new and more complete picture of solar system evolution has emerged. The question has changed from “What was the original compositional gradient of the asteroid belt?” to “What was the original compositional gradient of small bodies across the entire solar system?” No longer is the leading theory that two belts of planetesimals are primordial, but instead those belts were formed and sculpted through evolutionary processes after solar system formation. This chapter reviews the advancements on the fronts of asteroid compositional characterization, meteorite measurements, and dynamical theories in the context of the heliocentric distribution of asteroid compositions seen in the main belt today. This chapter also reviews the major outstanding questions relating to asteroid compositions and distributions and summarizes the progress and current state of understanding of these questions to form the big picture of the formation and evolution of asteroids in the main belt. Finally, we briefly review the relevance of asteroids and their compositions in their greater context within our solar system and beyond.

## 1. INTRODUCTION

By the early 1990s, in the era of *Asteroids II*, roughly 10,000 asteroids had been discovered, only a fraction of the total number of asteroids that are now known to exist. At that time, asteroids were discovered by visually inspecting photographic plates for light trails. In the 1990s, many of the major automated discovery surveys came online. By the year 2000, around the time of *Asteroids III*, ~20,000 asteroids were known (see Fig. 1). Today (in 2015, *Asteroids IV*) there are roughly 700,000 asteroids with known orbits, revealing much new information about the asteroid belt’s dynamic past. About 100,000 asteroids have measurements that tell us about their surface compositions (Ivezic et al., 2001; Szabo et al., 2004; Nesvorný et al., 2005; Carvano et al., 2010), providing a broader view of the asteroid belt than ever before. With the explosion of asteroid discoveries over the past decade (Fig. 1) and the conclusion of two of the largest asteroid physical measurement surveys, the Sloan Digital Sky Survey (SDSS)

(Ivezic et al., 2001) and the Wide-field Infrared Survey Explorer (WISE) (Mainzer et al., 2011), it is timely to reflect upon recent advances, leaving us well poised for the next generation of major surveys, including Gaia (Mignard, 2007) and the Large Synoptic Survey Telescope (LSST) (Ivezic et al., 2007; Jones et al., 2009).

This chapter reviews our current understanding of the compositions of asteroids in the main belt from asteroidal, meteoritic, and dynamical perspectives. Our view of the asteroid belt has changed dramatically since the “big picture” chapters from *Asteroids* and *Asteroids II* (Chapman, 1979; Gradie et al., 1989; Bell, 1989). In the context of this chapter, the use of the term “compositional trends” is more akin to taxonomic rather than mineralogical trends, and the “compositions” discussed here refer more to broad trends of observational data than any derived mineralogical information. In section 2, we review the current tools used to compositionally (taxonomically) characterize and classify asteroids and meteorites, and the dynamical tools that help us interpret the current orbital distribution of the

**Fig 1.** The cumulative number of known asteroids and the yearly discovery rate are plotted above. The surveys responsible for spikes in detection are marked: Palomar-Leiden (P-L), Trojan (T-1, T-2, T-3), Spacewatch, and LINEAR. Recent years have seen an explosion in asteroid discoveries due to automated telescopic surveys with advanced detection algorithms. As of the year 2015, nearly 700,000 asteroids have been discovered.

asteroids. We also review the current distribution of asteroid classes in the main asteroid belt. Section 3 focuses on how the current observational constraints strengthen or weaken leading dynamical theories. In section 4, we summarize the meteoritic evidence for asteroid compositions, as well as when and how asteroids formed. In section 5, we compile the major compositional questions in asteroid science and review the progress made toward answering many of them to provide a broad view of asteroid compositions and their locations in the belt. Section 6 looks at asteroids in their greater context for Earth, the solar system, and beyond. Appendix A lists the major outstanding questions relevant to asteroid compositions and distributions. Appendix A also briefly summarizes the current state of knowledge and suggests future work to solve these problems. Many of these questions are noted specifically in this chapter and are addressed, and most are covered in more detail in other chapters.

## 2. THE OBSERVATIONAL PERSPECTIVE

### 2.1. Asteroid Composition Tools

The surface properties (grain size, mineralogy, degree of space weathering, etc.) of an asteroid can be inferred through spectral and photometric measurements at wavelengths from the ultraviolet (UV) to the infrared (IR). Thermal emission at longer wavelengths is used to calculate surface albedos that are related to surface compositions (see the chapter by Mainzer et al. in this volume). Absorption features in reflectance spectra from UV to mid-IR wavelengths and emission features in the mid-IR range can be used to identify minerals and other compounds on the surface of an asteroid or meteorite (see the chapter by Reddy et al. in this volume). For example, olivine and pyroxene have readily identifiable absorption features located at 1  $\mu\text{m}$  and, for pyroxene, 2  $\mu\text{m}$ .

While mineralogical analysis is most appropriate for detailed studies of bodies with distinct features, relatively few asteroids have the high-quality spectra that are required for this. On the other hand, taxonomic classifications can be made using lower-quality or lower-resolution spectra, providing a rapid characterization of asteroid spectra and a common language for comparing them. Hence, taxonomic information is available for orders of magnitude more than the number of asteroids for which detailed spectra have been measured. At the time of *Asteroids III*, the majority of reflectance spectra were taken at visible wavelengths to 1  $\mu\text{m}$ , and were classified according to the Bus or Tholen taxonomies (*Bus and Binzel*, 2002b; *Tholen and Barucci*, 1989). The mafic silicate-rich asteroids with available near-IR spectra at the time were classified mineralogically by the Gaffey system (*Gaffey et al.*, 1993). By the early 2000s, near-IR spectrometers became available, such as SpeX on the NASA Infrared Telescope Facility (IRTF) (*Rayner et al.*, 2003). An extension of the Bus taxonomy, the so-called Bus-DeMeo taxonomy, was created to classify both the visible and near-IR data in such a way as to be as consistent with the Bus taxonomy as possible (*DeMeo et al.*, 2009). A comparison of each of these major taxonomies is presented in Table 1.

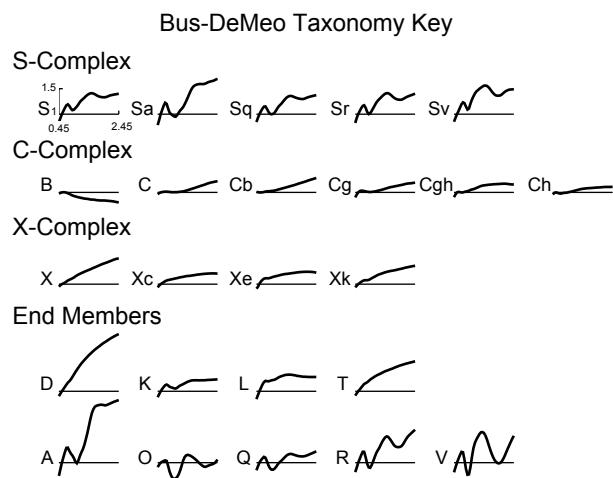

Asteroid spectra are traditionally divided into three major complexes and each of the complexes is divided into individual classes (also called “types”). The S-complex, originally named for its expected silicaceous composition (*Chapman et al.*, 1975), is characterized by spectra with moderate silicate absorption features at 1 and 2  $\mu\text{m}$ . The C-complex, historically named in connection with carbonaceous chondrite meteorites, has low-albedo surfaces with spectra that have flat or low slopes and are subtly featured to featureless. Subtle features have absorptions of only a few percent, one of the most notable being the 0.7- $\mu\text{m}$  feature indicating the presence of phyllosilicates likely due to aqueous alteration (*Vilas and Gaffey*, 1989). The X-complex is characterized by moderately sloped and subtly featured or featureless spectra. It has long been known that the X-complex is compositionally degenerate because it comprises the darkest and brightest surfaces of all asteroids, with albedos as low as a few percent to as high as 50%. The Tholen taxonomy distinguished the X-complex by albedo, breaking it up into the E, M, and P classes, ranging from high to low albedo.

Additionally, there are spectral classes that do not fit within these three main complexes. These spectra typically have more extreme or distinct characteristics and are much less common than the major complexes. These include the spectrally featureless and very red-sloped D-types; the spectrally olivine-dominated A-types with the broad, deep 1- $\mu\text{m}$  feature; and the spectrally pyroxene-dominated V-types with a deep, narrow 1- $\mu\text{m}$  feature and a deep, broad 2- $\mu\text{m}$  feature. Additionally, there are the K-, L-, T-, O-, Q-, and R-types. A visual summary of the visible and near-IR spectral classes is provided in Fig. 2. A description of the spectral features can be found in *Bus and Binzel* (2002b) and *DeMeo et al.* (2009).

TABLE 1. Comparison and explanation of the progression of spectral taxonomies.

Taxonomic System	Tholen (1984)	Gaffey (1993)	Bus (2002)	Bus-DeMeo (2009) (B-D)	Taxonomy Notes	Relevant Minerals and Possible Meteorite Analogs
Wavelength Range	0.33–1 μm	0.35–2.50 μm	0.45–0.90 μm	0.45–2.45 μm		
S-complex		S	SI SII SIII SIV SV SVI SVII	S Sa Sq Sr Sk Sl	 Tholen: Defined only S. Gaffey: 7 mineralogic classes based on Band I center and Band II/Band I area ratio. Primarily separates olivine to orthopyroxene ratio. Bus: Separates based on strength of 0.9-μm drop, indicative of 1-μm band. B-D: Definition largely preserved from Bus. Now includes full 1- and 2-μm feature in near-IR. Sl, Sk, and Ld are removed, Sv is added.	Minerals: olivine, pyroxene Meteorites: S(I): pallasites?, R chondrites, brachinites S(IV): many are ordinary-chondrite-like S(V): primitive achondrites? S(VII): basaltic achondrites
C-complex				B C Cb Cg Cgh Ch	 Tholen: Primarily distinguished by the 0.3–0.5-μm UV dropoff region. Bus and B-D do not cover this region, thus do not make these distinctions. Bus: Defined by UV dropoff and/or by 0.7-μm Cgh, Ch feature. B-D: Definition largely preserved from Bus. Near-IR is largely degenerate.	Minerals: opaques, carbon, phyllosilicates, some have weak features indicating olivine, pyroxene Meteorites: carbonaceous chondrites (except CV), possibly impact melts from ordinary chondrites and HEDs?
X-complex		E M P		X Xc Xe Xk	 Tholen: EMP are spectrally degenerate. Distinguished by high (E), med (M), and low (P) albedo. Bus: X class defined by shape of curve and/or 0.49-μm Xe feature. B-D: Definition largely preserved from Bus. Near-IR is largely degenerate.	Minerals: M,P: opaques, carbon, low-Fe pyroxene. E: enstatite, oldhamite Meteorites: M,P: carbonaceous chondrites (not CV). M w/high radar albedo: irons, CB chondrites, silicate-rich irons E: enstatites
Other: End members, outliers				T D Q O R V A K L Ld	 Definitions for each of these classes are relatively consistent among taxonomies as they are each spectrally distinct.	D: opaques, organics Q: mostly LL OCs O: pyroxene, olivine R: olivine, pyroxene V: HEDs, pyroxene, plagioclase feldspar A: pallasite, brachinite, R chondrites, olivine K: CO, CV, olivine L: CAI-rich, spinel-rich

A simple description of relevant minerals and meteorites for each class is presented. For meteorite and mineral details see Burbine et al. (2002).

**Fig 2.** The 24 spectral classes of the Bus-DeMeo taxonomy key measured over visible and near-infrared wavelengths. Based on work from DeMeo *et al.* (2009).

The accuracy of an asteroid's classification depends on the quality of the data. Also, repeated observations of a single object may show spectral (hence perhaps taxonomic) differences that may be intrinsic (due to rare mineralogical or grain size variations on different portions of the body), may reflect real but uncorrected variations due to photometric viewing geometry, or may reflect instrumental or observational artifacts. We emphasize the advice from the chapter by *Bus et al.* (2002) in *Asteroids III*, “We should not feel compelled to decide which label is ‘correct,’ but should rather accept these distinct labels as a consequence of our growing knowledge about that object.” For example, an object classified by visible wavelength measurements alone may “change its type” when the wavelength coverage is extended to the near-IR, or when an albedo measurement becomes available. An improved answer as more information becomes available is simply the scientific method at work.

One of the biggest challenges remains how to determine surface compositions from asteroid spectra and spectral types. Most materials on an asteroid's surface do not produce distinct, identifiable features in a reflectance spectrum. Furthermore, an asteroid spectrum is not only a product of composition, but is also affected by factors such as grain size, temperature, viewing geometry, and space-weathering processes (see the chapter by Reddy *et al.* in this volume). The compositional interpretation of many asteroid classes has broadened over time. While the S-complex has been linked to ordinary chondrite meteorites and the C-complex to carbonaceous chondrites, there is strong evidence that these spectral classes are not compositionally uniform. There is a range of different types of ordinary and carbonaceous chondrites, and there are additional meteorite classes that also may comprise subsets of the S- and C-complexes. This must be accounted for when interpreting spectra.

In addition to the visible and near-IR, asteroid spectra are now also measured beyond 2.5  $\mu\text{m}$  and into the mid-IR.

Asteroid spectra at these wavelengths are categorized by the presence of and shape of a 3- $\mu\text{m}$  absorption feature indicating hydrated minerals or phyllosilicates (*Takir and Emery*, 2012; see also the chapter by Rivkin *et al.* in this volume). There are four distinct spectral groups of 3- $\mu\text{m}$  features. Beyond the 3- $\mu\text{m}$  feature, the mid-IR range (7–25  $\mu\text{m}$ ) holds a wealth of information (*Emery et al.*, 2006) because many minerals have diagnostic features at these wavelengths. There are multiple deterrents to analyzing these longer wavelengths: Instrument design sensitivity requirements are challenged by measurements taken at ambient temperatures, observations are constrained by the lower solar flux, and available laboratory experimentation to interpret the spectra is currently limited in number (e.g., *Vernazza et al.*, 2010, 2012).

## 2.2. The Historical Perspective

Initial measurements from the 1940s through the 1970s found that the surface brightness and colors of asteroids trend from medium-albedo and moderate spectral slopes (S-complex) for bodies in the inner part of the main asteroid belt to lower-albedo and neutral spectral slopes (C-complex) toward the outer part of the main belt (*Fisher*, 1941; *Kitamura*, 1959; *Wood and Kuiper*, 1963; *Chapman et al.*, 1971, 1975). The diversity was a great surprise and the trend with distance motivated further observations.

The hundreds of observations available with even greater wavelength coverage in the 1980s then revealed distinct peaks in relative abundance for each of the major classes of asteroids at certain distances throughout the belt (*Zellner et al.*, 1985; *Gradie and Tedesco*, 1982; *Gradie et al.*, 1989). Because the asteroids were grouped systematically with heliocentric distance, it was concluded that the asteroids formed close to their current locations. In the context of a relatively static solar system, where the asteroids were assumed to have formed nearly in place, the variation in the compositions of these asteroids was interpreted to represent the original thermal gradient across the main belt from the time of planetesimal formation (see question C1 of Appendix A). While this fundamental trend among the largest asteroids has remained robust, both our interpretation of surface properties and the dynamical models explaining this structure have evolved.

Two major surveys from the late 1990s to early 2000s (*Bus and Binzel*, 2002a; *Lazzaro et al.*, 2004) provided spectroscopic data for around 2000 asteroids. While much of the ensuing analysis focused on asteroid families, two works investigated taxonomic distributions with orbital properties. *Bus and Binzel* (2002b) note a more detailed distribution than Gradie and Tedesco, finding double peaks for the S- and C-complex with distance from the Sun. *Mothé-Diniz et al.* (2003) found that the distribution of C-complex objects was different for higher vs. lower inclinations. These authors were also the first to show the presence of S-complex asteroids at distances as far as 3 AU in their dataset of asteroids larger than 15 km and found a fairly even distribution of S-complex out to that distance.

### 2.3. Recent Progress

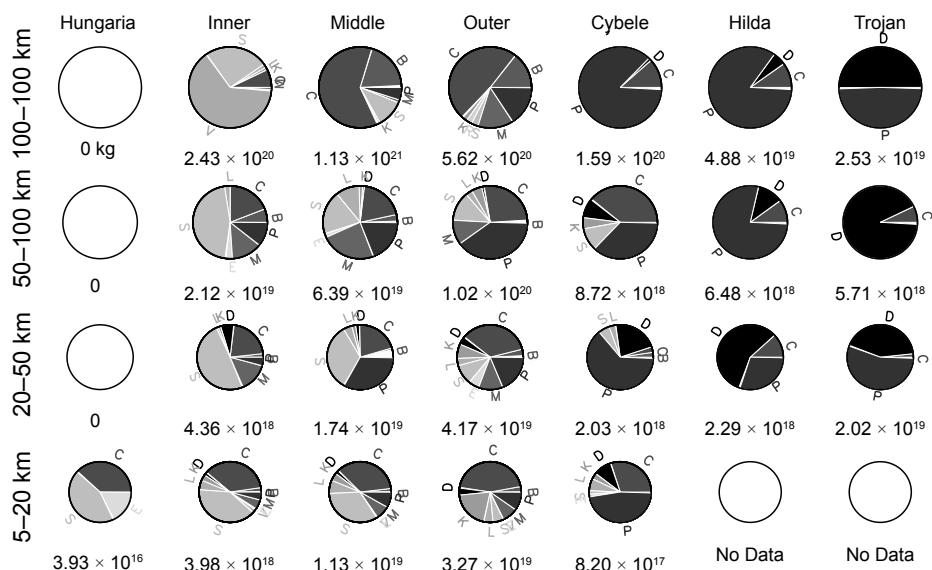

The next major survey released was the Sloan Digital Sky Survey. Although it was designed for extragalactic studies, it made crude spectral observations of more than 100,000 moving objects in the field. These data were released in several Moving Object Catalogs (*Ivezic et al.*, 2001; *Parker et al.*, 2008). Combined with the more recent Near-Earth Object Wide-field Infrared Survey Explorer (NEOWISE) survey, which produced over 100,000 diameters and albedo estimates (*Mainzer et al.*, 2011; *Masiero et al.*, 2011), there now exists a treasure trove of physical measurements to analyze. Many of the advances in understanding the compositions of asteroids in the main belt since *Asteroids III* have stemmed from these datasets, as well as targeted spectroscopic surveys or targeted follow-up studies of objects in these two large datasets. Here we describe taxonomic trends beginning in the Hungaria region and extending out to the Jupiter Trojans. Figure 3 shows the distribution of the asteroid class in each heliocentric distance region and multiple size regimes. We use the terms “inner,” “middle,” and “outer” main belt to refer to the three regions of the main belt carved by the  $v_6$  secular, 3:1, and 5:2 mean-motion resonances (the  $v_6$  starts near 2 AU and the 3:1 and 5:2 are located at 2.5 and 2.82 AU, respectively).

The Hungaria region ( $1.8\text{--}2.0$  AU,  $i \sim 20^\circ$ ) is dominated by high-albedo [ $>0.3$  (*Tholen and Barucci, 1989*)] E-type

asteroids that have moderate spectral slopes and often display a 0.49- $\mu\text{m}$  absorption feature (*Gradie and Tedesco*, 1982; *Bus and Binzel*, 2002b). These E-types are considered members of the Hungaria asteroid family (*Gaffey et al.*, 1992) with (434) Hungaria being the brightest member. In the Hungaria region, however, there are a variety of compositional types, including S- and C-complex objects (*Carvano et al.*, 2001).

In the inner main belt (2.0–2.5 AU), the dominant players are (4) Vesta (V-type) and a number of large S-complex asteroids. C-complex asteroids are rare in the inner belt at large sizes ( $D > 100$  km) where they comprise only 6% of the total mass, but they make up a quarter of the mass at medium sizes ( $20 \text{ km} < D < 100 \text{ km}$ ), and are almost equal to the S-complex by mass at the smallest sizes ( $5 \text{ km} < D < 20 \text{ km}$ ). At the same time, the fractions of medium-sloped spectral types (M and P) decrease at smaller sizes. Newly discovered in the inner main belt are D-type asteroids defined by their very red spectral slopes, which had only previously been seen at larger distances aside from a few near-Earth objects (NEOs) that have dynamical origins in the outer belt and beyond (Carvano et al., 2010; DeMeo and Carry, 2014; DeMeo and Binzel, 2008). These objects are discussed later in section 5.2.

An interesting effect of viewing the inner main belt by mass (previous analyses have viewed such statistics by number, not by mass) is the relative insignificance of the Vesta family, the products of a large collision with Vesta, in the inner belt

**Fig 3.** The distribution of asteroid classes by mass in distinct size ranges and distances from the Sun. Asteroid mass is grouped according to objects within four size ranges, with diameters of 100–1000 km, 50–100 km, 20–50 km, and 5–20 km. Seven zones are defined as in Fig. 1: Hungaria, inner belt, middle belt, outer belt, Cybele, Hilda, and Trojan. The total mass of each zone at each size is labeled and the pie charts mark the fractional mass contribution of each unique spectral class of asteroid. The total mass of Hildas and Trojans are underestimated because of discovery incompleteness. The top row is consistent with results from *Gradie and Tedesco* (1982) and *Gradie et al.* (1989). Figure from *DeMeo and Carry* (2014).

(Binzel and Xu, 1993). Indeed, when excluding Vesta itself, only a handful of all Vesta family members, called vestoids, are larger than 5 km, so their mass contribution even among 5–20-km-diameter bodies is minuscule [1% of that size range and region (DeMeo and Carry, 2014)]. Vestoids are significant contributors to the inner belt in terms of the total number observed (Parker et al., 2008; Masiero et al., 2013), but it is their high albedo, close distance, and spectral distinctiveness that have biased their discovery and classification.

In the middle main belt (2.5–2.82 AU), (1) Ceres (C-type in the Bus-DeMeo taxonomy) and (2) Pallas (B-type) are the largest objects and they comprise roughly 31% and 7%, respectively, of the entire main belt by mass. The broad taxonomic makeup of the inner and middle belt at the smallest sizes is essentially identical.

In the outer main belt (2.82–3.3 AU), the C-complex dominates by mass, with (10) Hygiea being the largest and most massive member. Despite the fact that the relative fraction of S-complex asteroids is small in the outer main belt, their total mass is still quite significant given that the mass in the outer belt is 2–10× greater than in the inner belt at each size range.

A- and V-types, respectively olivine-dominated and basaltic asteroids, are present in small numbers throughout the main belt, aside from those associated with Vesta (Lazzaro et al., 2000; Moskovitz et al., 2008; Sanchez et al., 2014). Their discovery in the middle and outer belts was surprising since differentiated bodies or fragments of them were not expected in the context of the classical understanding of asteroid differentiation. Significant advances have been made since *Asteroids III* in understanding the complexity of both the asteroid differentiation process and the mechanisms that displace material throughout the solar system (see the chapters by Scheinberg et al., Scott et al., and Morbidelli et al. in this volume).

Families play a very important role in the architecture and composition of the main belt. The chapter by Masiero et al. in this volume covers this topic in detail. It will be valuable for future work to incorporate the size-frequency distribution of asteroid families into studies of the radial distance distribution of asteroids in the main belt to fully interpret the results, particularly at small asteroid sizes.

The taxonomic makeup of the largest Hildas (~4 AU) and Trojans (5.2 AU) remain predominantly P-type and D-type, respectively. The trends at smaller sizes are discussed in section 5.2. The chapter by Emery et al. in this volume is dedicated to the Trojan population, covering the compositional and physical characteristics as well as the dynamical history.

### 3. THE DYNAMICAL PERSPECTIVE

#### 3.1. Dynamical Tools

Determination of an asteroid's orbit immediately tells you where it is currently spending its time in the solar system, and the combination of the distributions of known orbits and

physical properties provide powerful clues to the evolution of the solar system (questions A2 and A3 in Appendix A). However, there are many more asteroids with known orbits than there are with physical characterization, and at times we are left to gain context based on their orbits alone. The dominant perturber in the solar system is Jupiter, and its effects are made clear by the large depleted Kirkwood gaps in the asteroid population owing to its mean-motion resonances. Given the dominance of Jupiter's perturbations for asteroid orbits, one can take advantage of its similarity to the restricted three-body problem to generate some quasi-conserved quantities. The most common measure is the Tisserand parameter  $T_J$ , which is calculated with respect to Jupiter and can help to distinguish between different classes of small body orbits. This is primarily used to separate Jupiter-family comets ( $2 < T_J < 3$ ) from nearly isotropic comets ( $T_J < 2$ ), but is also commonly used to try to uncover dormant comets in the NEO population (Levison et al., 1994; Bottke et al., 2002b; DeMeo and Binzel, 2008) and separate main-belt comets from the ordinary comet population (see the chapter by Jewitt et al. in this volume).

Orbits are typically calculated and reported for what the asteroid's Keplerian orbit would be at a specific epoch in the presence only of the Sun. This calculated "osculating orbit" does not incorporate any information about short- or long-term oscillations of the orbit owing to the perturbations of the giant planets. The "proper elements" of an asteroid represent quasi-integrals of motion, meaning that they are nearly constant in time, and can be calculated or estimated using various numerical and analytical tools (Knežević et al., 2002). The difference between an asteroid's osculating and proper orbital elements can be substantial — tens of percent in  $a$ ,  $e$ , and  $i$ . The proper elements of an asteroid are representative of its long-term orbit and are essential in studies of dynamically related clusters or families of asteroids (see the chapter by Nesvorný et al. in this volume; Bendjoya et al., 2002; Zappalà, 2002).

An important dynamical process affecting the entire main asteroid belt is the Yarkovsky effect (see Bottke et al., 2002a, 2006). This is a size-dependent drift in a body's semimajor axis caused by the reemission of absorbed solar radiation. It is the main driver that pushes main-belt asteroids into resonances and they can then become NEOs or be driven to extreme orbits that could have them impact a planet or the Sun, or be ejected from the solar system. Smaller objects move more rapidly, where drift rates scale roughly as  $1/D$ , which means that where we find smaller objects now may simply be a waypoint on a drift across the asteroid belt (where a 1-km body might drift roughly  $10^{-4}$  AU in 1 m.y.). A similar point of confusion for small objects is that the collisional lifetimes are much shorter than the age of the solar system at sizes smaller than 10–30 km (see the chapter by Bottke et al. in this volume). Between the effects of the Yarkovsky drift and collisional evolution, we can really trust the orbits of only the 500 or so largest bodies ( $D > 50$  km) as tracers of the early structures of the asteroid belt.

As the Yarkovsky effect pushes asteroids around, some will inevitably reach an orbital resonance [a mean-motion resonance with Jupiter or other powerful secular resonances (see Nesvorný *et al.*, 2002)]. While the effects of this may vary, a typical response is an increase in the asteroid's orbital eccentricity. As the eccentricity increases to large values, it can cause the body to cross the orbit of Jupiter, which can easily result in its ejection from the solar system. If the asteroid first has an interaction with the terrestrial planets, it is possible that its orbit can be altered in a way to pull it out of the main asteroid belt and reside almost entirely within the inner solar system. In near-Earth space, the orbital dynamics are controlled by the chaotic interactions with the terrestrial planets and thus the population is transient, with only a 10-m.y. lifetime (Gladman *et al.*, 2000). Numerical models of the evolution from the main belt to near-Earth orbits have largely recovered the flux of bodies moving through different resonant passageways and can explain the size of the NEO population (Bottke *et al.*, 2000, 2002b). Furthermore, the NEO model of Bottke *et al.* (2002b) provides a dynamical tool to make statistical links between NEAs and the most likely resonant pathway they traveled from the main asteroid belt. Some NEOs can be probabilistically linked to specific regions of the main belt, allowing for links to be made between bodies and their regions or possible parent asteroid families (e.g., Campins *et al.*, 2010).

Even the orbits of the largest bodies have likely been altered substantially early in solar system history. As models of solar system evolution have matured, the effects of the possible "late" (after ~400 m.y. or so) movements of the giant planets have been studied in the most detail (see the chapter by Morbidelli *et al.* in this volume). Specifically, some traces of giant planet migration are still found in the main asteroid belt by way of depletions near primordial mean-motion resonances with Jupiter (Minton and Malhotra, 2009), although some types of migrations can be ruled out by clear patterns of depletion and orbital changes that would still be noticeable in today's asteroid belt (Morbidelli *et al.*, 2010). As the possible late migration of the giant planets has been studied in more detail, it is clear that many small bodies could be affected. The violent instability of the giant planets has been found to provide ideal dynamical pathways to capture the Trojan asteroids at Jupiter (Morbidelli *et al.*, 2005; Nesvorný *et al.*, 2013), capture the irregular satellites of the giant planets (Nesvorný *et al.*, 2014), implant D- and P-type asteroids from the primordial Kuiper belt into the main asteroid belt (Levison *et al.*, 2009), and sculpt the Kuiper belt (Levison *et al.*, 2008; Batygin *et al.*, 2012). An example of the effects that planetary migration would have on small bodies and the asteroid belt is shown in Fig. 4.

The distribution of asteroid orbits, their physical properties, and the total mass depletion in the asteroid-belt region are all used as constraints on early solar system evolution, as discussed below (and in more detail in the chapter by Morbidelli *et al.*).

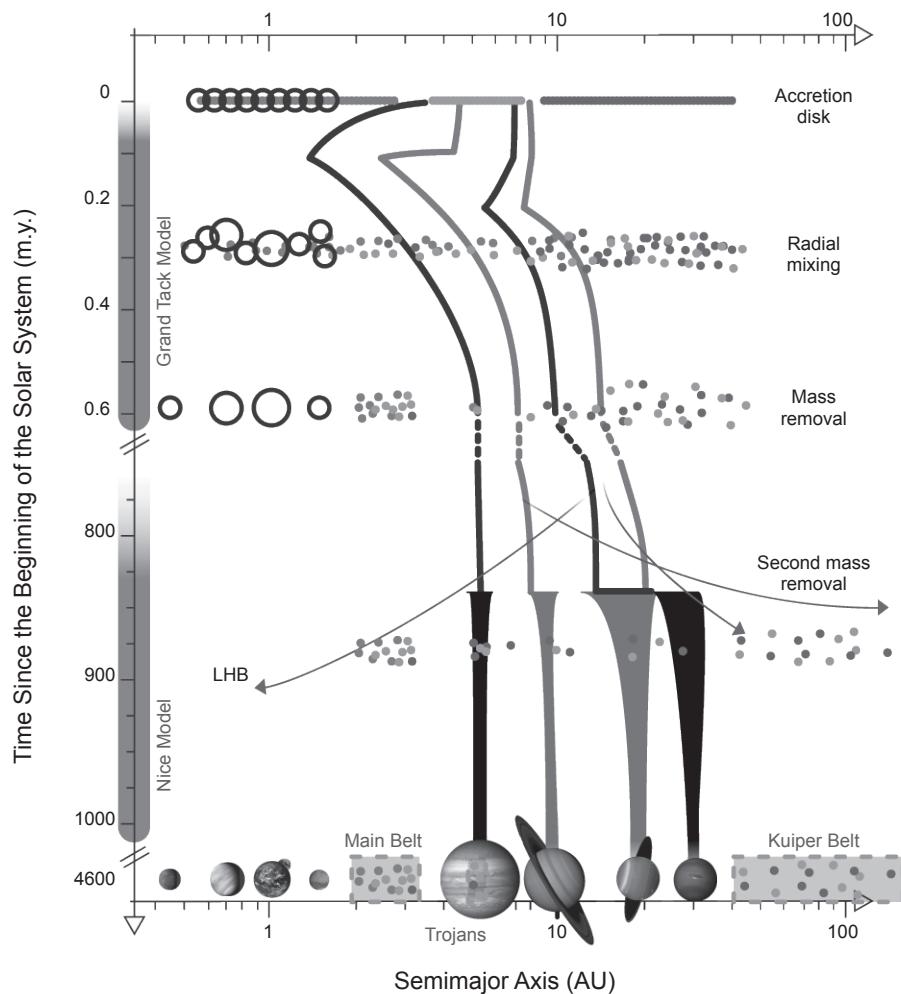

### 3.2. Dynamical Overview of the Main Belt

The asteroid belt today is estimated to contain approximately  $\sim 5 \times 10^{-4}$  Earth masses ( $M_{\oplus}$ ), which is approximately  $3\times$  the mass of its most massive asteroid, (1) Ceres (Krasinsky *et al.*, 2002). This is in contrast to the nearly  $1 M_{\oplus}$  of material that would be expected to inhabit this region given a smooth distribution of the solid material found in the planets (Weidenschilling, 1977). Similarly, classical models of planetesimal formation suggest that the current mass in the asteroid belt today would not be enough to have grown the largest asteroids, and thus there has been a depletion of mass since the asteroid belt formed (see Weidenschilling and Jackson, 1993). As discussed in detail in the chapter by Morbidelli *et al.* (and below), there are multiple proposed methods to remove so much mass from the asteroid belt, and there are also new models for planetesimal formation that may allow the formation of large asteroids directly from small "pebbles" in the solar nebula (see the chapter by Johansen *et al.* in this volume).

The orbital distribution of the asteroid belt finds that most of the dynamically stable phase space of  $a$ ,  $e$ ,  $i$  is filled, with orbital eccentricities ranging from 0 to 0.35 and inclinations from  $0^{\circ}$  to about  $30^{\circ}$ . Meanwhile, every theory for planetesimal formation relies on the damping effects of the gaseous solar nebula to reduce relative velocities and increase accretion rates (see the chapter by Johansen *et al.*). This implies that, at least immediately following their formation, planetesimals would have been on circular and coplanar orbits and were dynamically excited into their current orbits at some later time.

The loss of mass, observed dynamical excitement, and taxonomic mixing are presumed to be closely linked to the dynamical evolution of the solar system — including the formation and migration of the terrestrial and giant planets. As described in more detail in the chapter by Morbidelli *et al.*, models typically attack all three constraints with one mechanism. Studies of sweeping secular resonances due to the dissipation of the solar nebula suffer dual problems of needing long (20 m.y.) timescales of gas dissipation to deplete enough bodies, and then typically failing to reproduce the inclination distributions (see O'Brien *et al.*, 2007). The inclination distribution is also a problem for models that invoke stranded planetary embryos that excite and deplete the primordial asteroid belt (see O'Brien *et al.*, 2006). Here there is depletion of low-inclination bodies owing to their low-velocity encounters with planetary embryos, and again a mismatch with the observed distributions. Collisional processes are also important constraints. While even very massive asteroid belts (e.g., with 1000 times more mass than today) would have collisionally ground away most mass and reached a total mass similar to that found today (Chapman and Davis, 1975), the remnants and scars of such dramatic and long-term collisional evolution would likely be more visible in our studies today (see also the chapter by Bottke *et al.*).

Partly due to the inability of models to simultaneously match constraints with the terrestrial planets (the mass of

**Fig 4.** This cartoon depicts major components of the dynamical history of small bodies in the solar system based on models. These models may not represent the actual history of the solar system, but are possible histories. The figure displays periods of radial mixing, mass removal, and planet migration — ultimately arriving at the current distribution of planets and small-body populations. Figure from DeMeo and Carry (2014).

Mars) and with the asteroid belt (orbital distributions and water delivery), a recently proposed model, the Grand Tack model, invokes a scattering implantation of nearly the entire asteroid belt population from different parent populations (Walsh *et al.*, 2011). This dramatic migration of the giant planets causes widespread depletion and then mixing of remnant populations into the dynamically stable asteroid belt. When Jupiter is migrating inward, it completely depletes all objects native to the current asteroid belt. During its outward migration it scatters some remnants of this population back into the asteroid belt, and then during the outermost stretches of its migration it also scatters in bodies from more primitive reservoirs between and beyond the formation region of the giant planets. This mechanism is distinct from others as it implies separate parent populations for some of the major different compositional classes found in the asteroid belt, and also because it results in a low-mass asteroid belt from

very early on in solar system history. While it provides first-order matches to these three asteroid belt constraints (mass depletion, orbital distributions, and taxonomic distributions), they were not a prediction of the model — rather, they were a necessary constraint for the model to be viable. Going forward, each of these can be investigated more closely and hopefully limit or rule out some of the free parameters in the current Grand Tack scenario (growth and migration parameters of the giant planets).

Already, the Grand Tack model relies on some assistance from what is thought to follow in solar system history. The eccentricity distribution in the Grand Tack model is elevated compared to what is observed today (Walsh *et al.*, 2012). However, the motion of the giant planets during the “Nice model,” which might have happened roughly 400 m.y. later, will alter the orbits of the asteroid belt while having minimal affect on taxonomic distributions or total mass

[eccentricities are the primary orbital element altered, and total mass is only depleted by a factor of 2–3 (*Morbidelli et al.*, 2010), although the Nice model is credited with implanting D- and P- types bodies in the main belt]. In fact, *Minton and Malhotra* (2011) find that a very excited asteroid belt (elevated eccentricities) is a good fit when considering very simple models of giant planet migration that could come later. However, the models regarding later giant planet migration is a field of active study, and so each new iteration may require a reinvestigation of this aspect of the Grand Tack model’s asteroid belt fits.

If the Grand Tack model relies on later events, it begs the question of how much we can use different mechanisms to explain different constraints — and are there ways to mesh asteroid belt constraints with other models of planet formation? Already planet-formation models are increasingly using the asteroid belt as a constraint for their model outcomes, both for delivering water-rich asteroid material to the growing planets (*Morbidelli et al.*, 2000), and also for using their orbits to rule out other modes of planet migration (*Minton and Malhotra*, 2009; *Walsh and Morbidelli*, 2011).

Meanwhile, recent advances in planetesimal formation (see the chapter by Johansen et al. in this volume) imply the possibility of a different initial distribution of mass in the early solar system than previously considered. It is possible that planetesimal formation relies on clumps of “pebbles” collapsing, which could lead to a small number of planetesimals amid a huge number of remnant pebbles — where only a few of the formed planetesimals are large enough to rapidly accrete the remaining pebbles (see *Ormel and Klahr*, 2010). One could envision scenarios in which the asteroid belt never had much mass, and thus dynamical and taxonomic stirring would be constraints independent of mass loss.

#### 4. THE METEORITE PERSPECTIVE

##### 4.1. Meteorite Composition Tools

The parent asteroids of most meteorites would have formed at different times and/or places in an evolving solar nebula. This will have had profound effects on the initial compositions and subsequent histories of the asteroids that are reflected in the way meteorites are classified.

Radial thermal gradients in the disk will have dictated gross differences in compositions upon accretion, such as rock/ice ratios. However, it is evident from the meteorite record that more transient processes were also important in the thermal processing of dust and that radial transport brought together materials with different thermal histories. The thermal processing of dust has left its imprint on the major- and trace-element compositions that show clear variations associated with their volatility. Estimates of the relative volatilities of the elements are traditionally based on thermodynamic equilibrium calculations of their 50% condensation temperatures from a gas of solar composition at a total pressure of  $10^{-4}$  bar (e.g., *Lodders*, 2003). There

is also evidence in meteorites for the fractionation of elements in the nebula according to their chemical affinities (lithophile — rock-loving, siderophile — Fe-metal-loving, and chalcophile — sulfide-loving). Physical processes that separated solid/melt from gas and silicates from metal seem the most likely causes for these variations.

After accretion, asteroids were subject to internal heating, largely due to the decay of the short-lived radionuclide  $^{26}\text{Al}$  ( $t_{1/2} \approx 720,000$  yr) that was inherited from the protosolar molecular cloud. Thus, asteroids that formed early will tend to have been more internally heated than those that formed later, although other parameters will also have influenced internal temperatures. The least-heated meteorites ( $<150^\circ\text{C}$ ) normally exhibit varying degrees of aqueous alteration. Thermally metamorphosed meteorites have been more severely heated (up to  $800^\circ\text{--}900^\circ\text{C}$ ), which will have dehydrated them if they were not dry already, and they exhibit varying degrees of recrystallization and chemical reequilibration between minerals. Finally, there are meteorites that came from bodies that underwent melting and, in many cases, differentiation that produced metal-sulfide cores and silicate mantles.

The classification of meteorites has recently been reviewed in considerable depth (*Krot et al.*, 2014), and so is only briefly summarized here. The most basic separation of meteorites is into unmelted meteorites (chondrites) and melted meteorites (nonchondrites). The chondrites are generally assumed to come from parent bodies that were smaller and/or formed later than those of the nonchondrites, although it is possible that some chondrites are the unmelted crusts of differentiated bodies (*Weiss and Elkins-Tanton*, 2013). For further subdividing meteorites, the most useful classification tools reflect the meteorites’ nebular (primary) and parent body (secondary) characteristics — both physical and chemical. It is important to note that the causes of the variations in primary and secondary features are not always well understood, but that makes them no less useful as classification tools. Superimposed on the primary and secondary characteristics can be shock features and brecciation associated with later large impacts, as well as terrestrial weathering. A complete classification scheme must also account for these effects, but they will not be considered here.

For classification based on bulk chemistries, it is usually sufficient to use a few representative element ratios that reflect the major fractionations that influenced meteorite compositions. The CI chondrites enjoy a unique status among meteorites because their bulk compositions are identical within error to the rock-forming component of the solar photosphere. Since all objects are thought to have ultimately evolved from the solar composition, elemental compositions and ratios are usually normalized to (divided by) the CI composition.

Oxygen isotopes have proved to be a very useful classification tool because, in addition to the mass-dependent fractionations produced by most physical and chemical processes, meteorites exhibit mass-independent variations (changes in  $^{16}\text{O}$  abundance relative to  $^{17}\text{O}$  and  $^{18}\text{O}$ ).

Recently, other isotope systems, most notably Cr, have begun to be used as additional classification tools.

A significant number of meteorites do not fit easily into the established groups. Since by convention groups must be composed of five or more members, these meteorites are classified as ungrouped. Each meteorite group is generally assumed to come from a single asteroidal parent body that had a uniform composition at the time of its formation. Nevertheless, it cannot be ruled out that members of a group come from a number of asteroids that formed at similar times and places (e.g., Vernazza *et al.*, 2014) (see also question B2 in Appendix A). Assuming that a group comes from a single parent body and that ungrouped meteorites come from separate parent bodies, meteorites appear to be samples of 100–150 distinct parent bodies (Burbine *et al.*, 2002) (see also question B1 in Appendix A).

**4.1.1. Chondrites.** The chondrites are composed of three major components — refractory inclusions and chondrules, both of which formed at high temperatures, are embedded in a fine-grained matrix. Refractory inclusions are a diverse group of objects, broadly divided into calcium-aluminum-rich inclusions (CAIs) and amoeboid olivine aggregates (AOAs). The inclusions are the oldest known solar system solids and, in some cases, formed by condensation from a hot gas, while others formed by melting and evaporation of preexisting solids (MacPherson, 2014). Chondrules appear to have typically formed 1–3 m.y. after refractory inclusions as molten silicate-metal droplets in brief (hours to days) heating events in very “dust-rich” environments. Being so fine grained, the matrix is very susceptible to parent-body modification, but seems to originally have been dominated by a mix of fine-grained (<5–10 µm) crystalline and amorphous silicates. Matrix also contains the bulk of the most volatile elements in chondrites, as well as all the organic matter and presolar circumstellar grains found in them, and probably originally contained the ices accreted by most chondrite groups.

Almost all chondrites belong to one of five classes that have been further subdivided into a number of groups (Table 2). Each group is defined by a narrow range of primary physi-

cal features (e.g., chondrule sizes, abundances, types, etc.), elemental compositions, and O (and Cr) isotopic compositions.

After accretion, varying degrees of aqueous alteration and/or thermal metamorphism in the parent bodies led to the modification of the primary features of all chondrites. The extent of this modification is reflected in a chondrite’s petrologic type — a chondrite that was unaffected by either aqueous alteration or thermal metamorphism is assigned a petrologic type of 3.0, while petrologic types 3–6 reflect increasing degrees of thermal metamorphism and types 3–1 reflect increasing extents of aqueous alteration. A meteorite’s petrologic type is normally given after its chemical group (e.g., CI1, LL3.0, and H6).

**4.1.2. Nonchondrites.** As with the chondrites, the non-chondritic meteorites are classified according to the properties of their components (mineralogy, grain size, etc.), as well as by their bulk chemical and isotopic compositions (Table 3). Except for those from the Moon and Mars, it is generally assumed that nonchondritic meteorites evolved from originally chondrite-like objects. They are divided into (1) primitive achondrites that have seen very intensive metamorphism, as well as relatively low degrees of partial melting and melt extraction; and (2) differentiated meteorites that underwent extensive melting and differentiation. The differentiated meteorites are further divided on the basis of their Fe-metal contents into achondrites (metal-poor), stony-irons, and irons.

Primitive achondrites sometimes contain relict chondrules, which are chondrules that have survived metamorphism and partial melting of its host rock. However, they have not been conclusively linked to any known chondrite groups. Only one primitive achondrite, the ungrouped Tafassasset, has geochemical affinities to carbonaceous chondrites (Gardner-Vandy *et al.*, 2012). Similarly, only one achondrite, the ungrouped basaltic achondrite Northwest Africa (NWA) 011 and several paired specimens from the same fall, seems to have formed by melting of a carbonaceous chondrite-like body (Warren, 2011).

**4.1.2.1. Stony irons.** Mesosiderites are breccias composed of diverse silicate clasts that are intimately mixed with roughly equal amounts of Fe,Ni-metal and sulfide. Pallasites

TABLE 2. Summary of the recognized chondrite classes and groups.

Class	Groups	
Enstatite (E)	EH, EL	Highly reduced, metamorphosed types 3–6
Rumuruti (R)		Metamorphosed types 3–6, some OH-bearing minerals
Ordinary (O)	H, L, LL	Metamorphosed types 3–6, evidence for H <sub>2</sub> O activity
Carbonaceous (C)	CI, CM, CR CO, CV CK CH, CB	Aqueously altered types 1–3 Metamorphosed types 3, evidence for H <sub>2</sub> O activity Metamorphosed types 3–6, evidence for H <sub>2</sub> O activity Metal-rich, impact products
Kakangari (K)		

TABLE 3. Summary of the nonchondrites.

Meteorite Type	Composition
<i>Primitive achondrites</i>	
Winonaites	Related to IAB irons
Acapulcoites and lodranites	
Brachinites	
<i>Achondrites</i>	
Aubrites	Broadly basaltic compositions, related to E chondrites
Ureilites	Contain veins of graphite and diamond
Angrites	Basaltic compositions
HEDs	From (4) Vesta
Howardites	Eucrite and diogenite breccias
Eucrites*	Basaltic compositions
Diogenites	Coarse pyroxene and olivine
<i>Stony irons</i>	
Mesosiderites	Impact breccias
Pallasites	Core-mantle boundary material (?)
Main group	Related to IIIAB irons (?)
Eagle Station group	Related to C chondrites
Pyroxene group	
<i>Irons</i> <sup>†</sup>	
Magmatic	IVAs related to L/LL chondrites
IC, IIAB, IID, IIC, IIF, IIG, IIIAB, IIIE, IIIF, IVA, IVB	
Non-magmatic	IIES related to H chondrites,
IAB, IIE, IIICD	IABs related to winonaites

\* A few anomalous eucrites may not be from (4) Vesta.

† 15% of irons remain ungrouped.

are composed of Fe,Ni-metal/sulfide that is intergrown with similar proportions of relatively coarse-grained olivine and pyroxene crystals. There are three recognized subtypes that probably came from at least three different parent bodies. Traditionally, it has been assumed that pallasites are core-mantle boundary samples. However, recent studies indicate that the main-group pallasites experienced a range of cooling rates, which would not be expected if they come from the core-mantle boundary of a single body (Yang et al., 2010b).

**4.1.2.2. Irons.** Iron meteorites are divided into 14 chemical groups, although ~15% of irons remain ungrouped. The chemical groups fall into one of two categories, magmatic and nonmagmatic. The magmatic irons exhibit intragroup chemical variations that are consistent with fractionation between solid and liquid metal that presumably occurred during crystallization of planetesimal cores. The chemical variations within the nonmagmatic iron groups are more difficult to understand and they tend to contain abundant silicate clasts. These irons may have formed in melt pools during failed core formation, but are more likely the products of impacts. Many of the ungrouped irons are also probably impact melts, particularly the smaller ones.

## 4.2. When and How Big Did Asteroids Form?

As discussed in detail below, the formation of chondrites seems to have occurred between roughly 2 and 4 m.y. after CAIs (question A1 in Appendix A). Calcium-aluminum-rich inclusions are the oldest dated objects in meteorites [4567.3 ± 0.2 m.y. (Connelly et al., 2012)] and are generally considered to provide the best estimate of the time of solar system formation, although Boss et al. (2012) have suggested that most CAIs formed toward the end of the Fu Orionis outburst phase of young stellar evolution. Meteorites from differentiated objects seem to have formed slightly earlier than chondrites, although the uncertainties in their ages do allow for significant overlap with chondrite formation and it is possible that some chondrites represent the unmelted crusts of differentiated objects. Some carbonaceous chondrites, such as the CKs, formed roughly contemporaneously with the other chondrite classes, but others may have formed up to 1 m.y. later. The absence of chondrites that formed later than 3–4 m.y. after CAIs suggests that planetesimal formation effectively ceased at this time in the chondrite-forming regions, possibly marking the dissipation of the gas disk. If the carbonaceous chondrites were scattered into the asteroid belt from the outer solar system, this must have occurred after the formation of the youngest carbonaceous chondrites.

At present, there is no way to measure the accretion ages of chondrites directly, although there is evidence from their short-lived <sup>53</sup>Mn-Cr systematics that the H and EH chondrite parent bodies had formed ~2 m.y. after CAIs (Polnau and Lugmair, 2001; Shukolyukov and Lugmair, 2004). In principle, the youngest chondrules in a chondrite group provide an upper limit to the age of their parent body. Most studies have dated individual chondrules using the <sup>26</sup>Al-Mg system on the assumption that the <sup>26</sup>Al/<sup>27</sup>Al ratio of ~5 × 10<sup>-5</sup> seen in most undisturbed CAIs represents the homogeneous initial ratio of the solar system (e.g., Bizzarro et al., 2004; Hutchison et al., 2009; Jacobsen et al., 2008; Kita and Ushikubo, 2012; Ushikubo et al., 2013; Villeneuve et al., 2009). The assumption of a homogeneous <sup>26</sup>Al/<sup>27</sup>Al ratio in the solar nebula has been questioned by some (Larsen et al., 2011; Schiller et al., 2015), but at present the balance of evidence supports a homogeneous distribution (Kita et al., 2013; Wasserburg et al., 2012). A few chondrule studies have also used the <sup>53</sup>Mn-Cr (Kita et al., 2005), <sup>182</sup>Hf-W (Kleine et al., 2008), and Pb-Pb systems (Amelin and Krot, 2007; Amelin et al., 2002; Connelly et al., 2012; Krot et al., 2005) to date chondrules. Together, these studies suggest that (1) most chondrules in ordinary and CO chondrites and the ungrouped carbonaceous chondrite Acfer 094 formed between 1 and 3 m.y. after CAIs, (2) formation of CV chondrules began almost contemporaneously with CAIs and continued for >3.4 m.y., and (3) chondrules in CR chondrites began forming at about the same time as ordinary and CO chondrules, but the youngest ages are >3–4 m.y. after CAIs. Chondrules in the CB chondrites, which are different from those in other

chondrite groups, have average ages of  $4.6 \pm 0.5$  m.y. after CAIs ( $2\sigma$  standard error) and seem to have formed in an impact (Krot *et al.*, 2005; Yamashita *et al.*, 2010).

Taken at face value, these chondrule ages imply that all chondrite parent bodies formed  $>3$ – $4$  m.y. after CAIs. However, the apparent spreads in chondrule ages are problematic. Chondrules in a particular chondrite group exhibit a limited range of physical and chemical properties that vary from group to group. At the levels of turbulence that are thought to exist in disks, even in a so-called dead zone, chondrules would be mixed over many astronomical units on timescales of 1–3 m.y. (Alexander, 2005; Alexander and Ebel, 2012; Cuzzi *et al.*, 2010). Thus, either chondrite formation was dispersed over a large fraction of the solar nebula, as in the Grand Tack and Nice models, or the quoted ranges in chondrule ages are not real. The latter must be ruled out before concluding the former. Indeed, it has been suggested that most of the reported ranges in Al-Mg ages simply reflect the uncertainties in the measurements (i.e., most chondrules in a chondrite group could have the same age or a narrow range of ages) (Alexander and Ebel, 2012; Kita and Ushikubo, 2012), and that the youngest ages, indeed perhaps all chondrule ages, have been disturbed by parent-body processes (Alexander, 2005; Alexander and Ebel, 2012). It remains to be seen if the range in chondrule Pb-Pb ages also reflect parent-body disturbance.

Given that parent-body processes can disturb the radiometric systems that are used to date chondrules, it is essential to study only the least-metamorphosed and aqueously altered members of a chondrite group. Even in these chondrites, it is essential to take care to select only those chondrules that can be shown to have undergone no secondary modification. The most careful Al-Mg study of chondrule ages conducted to date has been for the ungrouped carbonaceous chondrite Acfer 094, where 9 of the 10 chondrule ages are within error of a mean of  $2.3^{+0.5}_{-0.3}$  m.y. ( $^{26}\text{Al}/^{27}\text{Al} = 5.7 \pm 1.0 \times 10^{-6}$ ) after CAIs (Ushikubo *et al.*, 2013). Selecting only similar (type I) chondrules from a previous study of a primitive CO (Kurahashi *et al.*, 2008) gives a mean age of  $2.0^{+0.3}_{-0.2}$  m.y. ( $^{26}\text{Al}/^{27}\text{Al} = 7.1 \pm 0.8 \times 10^{-6}$ ) after CAIs. The Al-Mg system is more susceptible to modification in the chondrules analyzed in Semarkona, the ordinary chondrite that has been least affected by parent-body processes, but the chondrules have a mean age of  $2.0^{+0.5}_{-0.3}$  m.y. ( $^{26}\text{Al}/^{27}\text{Al} = 7.3 \pm 1.4 \times 10^{-6}$ ) after CAIs (Kita *et al.*, 2000; Villeneuve *et al.*, 2009), which is very similar to those for CO and Acfer 094 chondrules. This Semarkona average chondrule age is consistent with an average age of  $1.7 \pm 0.7$  m.y. after CAIs for H-chondrite chondrules obtained using the  $^{182}\text{Hf}-\text{W}$  system (Kleine *et al.*, 2008).

Additional constraints on the timing of accretion can potentially come from the thermal histories of chondrites since the abundance of the radioactive heat source,  $^{26}\text{Al}$ , will have been a function of accretion time. Modeling of mineral ages with different closure temperatures during metamorphism has been used to estimate the accretion time ( $\geq 2$ – $3$  m.y. after

CAIs) and size ( $\sim 100$  km in diameter) of the H ordinary chondrite parent body (Harrison and Grimm, 2010; Henke *et al.*, 2013; Kleine *et al.*, 2008; Trieloff *et al.*, 2003). Alternatively, assuming that the maximum peak temperatures estimated for any member of a chondrite group represents the peak central temperature achieved in their parent body, along with a diameter of 60 km, Sugiura and Fujiya (2014) estimated accretion ages for all chondrite groups (Table 4), including one for the ordinary chondrites of  $\sim 2.1$  m.y. after CAIs. If this accretion age for the ordinary chondrites is approximately correct, it constitutes further evidence that many measured chondrule ages (e.g., those  $>2.1$  m.y.) are disturbed. Such estimates depend on many assumptions, not the least of which are that we have samples from all depths in the chondrite parent bodies, that the peak temperatures have been accurately determined, that accretion temperatures and initial water ice contents are known, and that the parent body sizes are known. A lack of samples from the deep interior of the CO parent body, for example, could explain why the estimated accretion age of the COs ( $\sim 2.7$  m.y. after CAIs) is younger than for the ordinary chondrites despite their average chondrule ages being so similar.

Further complicating these estimates, some have questioned the simple internal heating models and argue that at least the ordinary chondrite parent bodies are rubble piles produced by early collisions while the bodies were still hot (Ganguly *et al.*, 2013; Scott *et al.*, 2014). Also, there is the suggestion that the CV chondrites, at least, formed in the presence of magnetic fields generated by dynamos in their planetesimal cores (Weiss and Elkins-Tanton, 2013), i.e., that these chondrites are the unheated crusts of differentiated bodies. If true, the accretion age of the CV parent body would have to have been significantly earlier than estimated by Sugiura and Fujiya (2014). However, to date, no achondrites or iron meteorites have been linked to the CVs.

Constraints on the timing of aqueous alteration can be established in some chondrites because two products of alteration, fayalitic olivine and carbonates, incorporated short-lived  $^{53}\text{Mn}$ . Fayalitic olivine in ordinary chondrites formed at  $2.4^{+1.8}_{-1.3}$  after CAIs, while in CV and CO chondrites it formed at  $4.2^{+0.8}_{-0.7}$  and  $5.1^{+0.5}_{-0.4}$  after CAIs, respectively (Doyle *et al.*, 2015). Four to 5 m.y. after CAIs is also about the time that carbonates formed in CM and CI chondrites and the ungrouped chondrite Tagish Lake (Fujiya *et al.*, 2012, 2013; Jilly *et al.*, 2014). Thermal modeling suggests that the parent bodies of these meteorites formed 3–4 m.y. after CAIs.

Thermal modeling of differentiated bodies is even more problematic than for chondrites because, for instance, the initial bulk composition is not known, and how the melts segregate within the bodies can have a profound affect on thermal histories (e.g., Moskovitz and Gaidos, 2011; Neumann *et al.*, 2014). Nevertheless, models of varying degrees of sophistication have been used to estimate their accretion times. For instance, core formation on the IIAB, IIIAB, IVA, IVB, and IID iron meteorite parent bodies occurred at  $0.7 \pm 0.3$ ,  $1.2 \pm 0.3$ ,  $1.4 \pm 0.5$ ,  $2.9 \pm 0.5$ , and  $3.1 \pm 0.8$  m.y.

TABLE 4. Average ages and estimates of the accretion ages of chondrites and various nonchondrites from *Sugiura and Fujiya* (2014) unless otherwise indicated.

Group	Chondrules	Time After CV CAI	Other
<i>Chondrites</i>			
E		$1.8 \pm 0.1$	
O	$2.0 + 0.5, -0.3^*, 1.7 \pm 0.7^\dagger$	$2.1 \pm 0.1, \geq 2-3^\ddagger$	
R		$2.1 \pm 0.1$	
CK		$2.6 \pm 0.2$	
CO	$2.0 + 0.3, -0.2^\S$	$2.7 \pm 0.2$	
CV		$3.0 \pm 0.2$	
CI, CM, CR, TL		$3.5 \pm 0.5$	
<i>Nonchondrites</i>			
Angrites	—	$0.5 \pm 0.4$	$\leq 1.5^\#$
HEDs	—	$0.8 \pm 0.3$	$\leq 2.5 \pm 1^{**}, \leq 0.6 + 0.5, -0.4^{\dagger\dagger}, < 1^{\ddagger\ddagger}$
Magmatic irons	—	$0.9 \pm 0.3$	$1.0 \pm 0.6, 1.3 \pm 0.5, 1.5 \pm 0.5^{\$\$}$
Stony irons	—	$0.9 \pm 0.3$	
Ureilites	—	$1.0 \pm 0.3$	
Acapulcoites + lodranites	—	$1.3 \pm 0.3$	
Aubrites	—	$1.5 \pm 0.1$	
NWA 011	—	$1.5 \pm 0.1$	
Tafassasset	—	$1.9 \pm 0.2$

§§ Kruijer et al. (2013).

Ages are in millions of years after CV CAI formation.

after CAIs, respectively (Kruijer et al., 2014). Previous modeling suggested that the accretion of the IVA, IVB, and IID parent bodies occurred, respectively, at  $1.0 \pm 0.6$ ,  $1.3 \pm 0.5$ , and  $1.5 \pm 0.5$  m.y. after CAIs (Kruijer et al., 2013). However, Kruijer et al. (2014) have significantly revised the accretion age estimates to  $\sim 0.1$ – $0.3$  m.y. after CAIs for the parent bodies of all these iron meteorites. Estimates for the timing of differentiation and the onset of magma ocean crystallization of the HED parent body [(4) Vesta] of  $2.5 \pm 1.0$  m.y. (Lugmair and Shukolyukov, 1998, 2001; Trinquier et al., 2008) and  $\leq 0.6^{+0.5}_{-0.4}$  (Schiller et al., 2011), respectively, are broadly consistent with estimates of accretion times for Vesta of  $< 1$  m.y. after CAIs (Neumann et al., 2014). Core formation in the angrite parent body occurred  $\leq 2$  m.y. after CAIs, and its accretion must have occurred  $\leq 1.5$  m.y. after CAIs (Kleine et al., 2012).

Metallographic cooling rates have been used to argue that the iron meteorites formed in still hot cores that had been stripped of their silicate mantles by impacts (Yang et al., 2007, 2008, 2010a,b). The estimated parent-body diameters for the best-studied groups are IVA =  $300 \pm 100$  km and IVB =  $140 \pm 30$  km, and, assuming roughly chondritic compositions, the sizes of the original bodies with their silicate mantles would have been roughly twice these estimates. Thus, the formation of relatively large asteroids

began quite early. There is geochemical evidence that an even bigger object, Mars, had reached  $\sim 50\%$  of its present mass in  $\leq 1.8^{+0.9}_{-1.0}$  m.y. after CAIs (Dauphas and Pourmand, 2011; Tang and Dauphas, 2014), i.e., contemporaneously with most chondrites.

#### 4.3. How Did Asteroids Form?

Of the chondrites, only the CI chondrites lack clear evidence for chondrules, although even in these highly altered and brecciated rocks, mineral fragments suggest that some chondrules or chondrule fragments may have been present at the time of accretion. It is much harder to say if chondrules were as abundant in the parent bodies of the nonchondritic meteorites, but relict chondrules have been reported in the primitive achondrites, and in silicate inclusions in IIE irons (tentatively linked to H chondrites). Ordinary, R and enstatite chondrites only contain 10–15 vol.% matrix and refractory inclusions are rare in them. It cannot be ruled out that chondrules dominated the dust in their formation regions, but it is also possible that chondrules were preferentially concentrated during planetesimal formation, as predicted by turbulent concentration (Chambers, 2010; Cuzzi et al., 2010) and possibly streaming instability models (see the chapter by Johansen et al. in this volume).

However, the rarity of primitive meteorites with few or no chondrules suggests another intriguing possibility — that chondrule formation and planetesimal formation were linked in some way (Alexander *et al.*, 2008). Metzler (2012) has argued that chondrules in ordinary chondrites were accreted within hours of their formation while they were still hot and plastic. Such a scenario would be consistent with reaccretion of chondrules produced in hit-and-run collisions between partially molten planetesimals (Asphaug *et al.*, 2011), for instance. However, such a model must overcome some serious problems: (1) Accretion of hot chondrules is difficult to reconcile with the contemporaneous accretion of thermally labile material, such as organic matter and water ice; (2) there are a number of geochemical/petrologic objections to making chondrules this way; and (3) it is not clear why only primitive objects that formed in this way are present in our collections. Johnson *et al.* (2015) also propose that chondrules were produced in collisions, although not rapidly reaccreted, i.e., they are byproducts of planetesimal formation rather than being intimately linked to it. If correct and turbulent concentration and the streaming instability need chondrules to work, then the dominant mechanism(s) for planetesimal formation has still to be identified (question A1, Appendix A).

#### 4.4. Where Did Asteroids Form?

There is clear isotopic evidence in O, Ti, Cr, Mo, and Ru for a distinction between the carbonaceous chondrites and almost all other inner solar system objects (including Earth, Moon, and Mars) for which we have samples (Burkhardt *et al.*, 2011; Warren, 2011). With the exception of O, the subtle isotopic variations appear to be nucleosynthetic in origin. The causes of these differences are still not understood, but presumably they reflect subtle differences in the materials from which the planets/planetesimals formed (question A1, Appendix A). These differences are certainly consistent with formation of the carbonaceous chondrites in the outer solar system (beyond the initial orbit of Jupiter), as in envisioned by the Grand Tack and Nice models, but at present other explanations may also be possible.

Since objects at or beyond the orbit of Jupiter tend to be water ice-rich, water contents are a potential means for distinguishing between meteorites/asteroids with inner and outer solar system origins. Some carbonaceous chondrites (CI, CM, and Tagish Lake) were relatively water-rich when they formed, as is evident in the abundant clay minerals that they contain. Other carbonaceous chondrites seem to have accreted some water (CR and CV), but evidence for accretion of water ice in others is limited (CO) or lacking (CK, CH, CB). Further confusing this issue is that ordinary (Alexander *et al.*, 1989; Grossman *et al.*, 2000) and R chondrites (McCanta *et al.*, 2008) also seem to have accreted water ice.

If water contents cannot be used to determine whether the carbonaceous chondrite parent bodies formed at greater radial distances than other meteorite parent bodies, perhaps

the H isotopes of the water can. There is expected to have been a radial gradient in the D/H ratio of water ice in the disk that reflected mixing between interstellar water (high D/H) and water with low D/H that had reequilibrated with H<sub>2</sub> in the hot inner disk (Albertsson *et al.*, 2014; Jacquet and Robert, 2013; Yang *et al.*, 2013). The D/H ratios of water in all comets are similar to or greater than the terrestrial ratio (Lis *et al.*, 2013), and the terrestrial ratio is almost an order of magnitude higher than the bulk solar value. The only other outer solar system planetesimals with measured D/H ratios are Saturn's moons Enceladus, whose water like most comets is enriched in D relative to Earth (Waite *et al.*, 2009), and Titan, whose atmospheric methane D/H is Earth-like (Nixon *et al.*, 2012). On the other hand, the N isotopes of Titan's atmosphere are <sup>15</sup>N-enriched compared to Earth (Mandt *et al.*, 2014), like comets (Rousselot *et al.*, 2014; Shinnaka *et al.*, 2014). While it is still not certain where and how the comets and Saturn's moons formed, their compositions suggest that ice in the outer solar system had D/H ratios that were greater than or equal to terrestrial. However, except for the CR chondrites, the best estimates of the D/H ratios of water in carbonaceous chondrites at the time of accretion were subterrestrial (Alexander *et al.*, 2012). Rather surprisingly, the D/H ratios for water in ordinary and R chondrites are similar to those of the more enriched comets. This probably does not mean that they formed in the outer solar system. It more likely reflects isotopic fractionation associated with the loss of H<sub>2</sub> generated by the oxidation of metal by water in their parent bodies. The effect may have been larger in the ordinary and R chondrites because they had lower initial water/metal ratios. Nevertheless, this process should also have affected the carbonaceous chondrites, so that their initial water D/H ratios were probably somewhat lower than estimated by Alexander *et al.* (2012).

In summary, while carbonaceous chondrites and their asteroidal parent bodies are geochemically distinct from other inner solar system objects that we have samples of, at present there is no direct evidence that they formed at much greater radial distances from the Sun than other meteorite parent bodies.

### 5. ASTEROID COMPOSITIONAL TRENDS

In this section, we explore questions related to the taxonomic distribution of asteroids at both the large and small sizes. A number of questions listed in Appendix A are discussed here.

#### 5.1. What is the Source of the Compositional Gradient in the Main Belt?

For the largest asteroids ( $D > \sim 100$  km), the trend of taxonomic types as a function of distance from the Sun, in the order of S, C, P, D, remains robust. The canonical interpretation of this gradient is that it reflects the compositional variation with distance from the Sun of the dust in

the solar nebula (*Chapman et al.*, 1971, 1975; *Gradie and Tedesco*, 1982) (question C1, Appendix A). At the time, it was anticipated that (1) dynamical processes might have smeared an originally sharper division between asteroids of different composition, and (2) different materials, condensing and accreting earlier or later, might have formed at the same solar distance, also smearing the gradient (*Ruzmaikina et al.*, 1989; *Petit et al.*, 2002).

These ideas have not been ruled out entirely, but it is now apparent that other processes may have played a greater role in producing this gradient. The largest source of uncertainty is the ongoing challenge to associate many of the asteroid taxonomic types with specific types of meteorites or compositions (*Burbine et al.*, 2002). There are ~40,000 meteorites in our collections, yet only ~100–150 distinct parent bodies have been identified from the collections. There are more than 700,000 known asteroids, but only ~100 asteroids with diameters greater than 100 km and 122 notable families (see the chapter by Nesvorný et al. in this volume) that may be considered indicators of the number of parent bodies existing in the main belt today (question B1, Appendix A). It is also possible, but not yet firmly established, that more than one asteroid could be the source of a single meteorite group (e.g., *Vernazza et al.*, 2014) (question B2, Appendix A). There is certainly more work needed to understand the links between meteorites and their asteroidal sources. Next, we briefly summarize some of the known and proposed associations.

It is now clear that a fraction of S-complex objects are ordinary chondrites and that the HEDs are mostly associated with Vesta and its family, but most taxonomic types cannot be robustly associated with specific meteorites or mineralogies. Many asteroid spectra are simply not diagnostic of unique mineral assemblages. E-types have been associated with enstatite chondrites or achondrites, M-types with metallic meteorites, A-types with pallasites or olivine-rich achondrites, L-types with CAIs, etc., but these connections are not unique or robust (*Burbine et al.*, 2002). It is generally understood that some of the C-complex asteroids (including P- and D-types) are likely associated with carbonaceous chondrites, of which there are many subtypes. It is probable that many of these asteroids do not supply meteorites to Earth because their distant orbits are less likely to be perturbed into Earth-crossing, or if their fragments do enter the atmosphere, they may be too fragile and/or arrive at too high a velocity to survive as a meteorite.

A major advance toward interpreting the taxonomic gradient is the understanding of processes that move asteroids and their fragments about. Since the time of *Asteroids* and *Asteroids II*, there is far better understanding of major and minor resonances in the main belt (*Nesvorný et al.*, 2002), of how the Yarkovsky effect (and associated YORP effect) works (*Bottke et al.*, 2006), of past dynamical regimes (e.g., the Grand Tack or Nice models) that may have had profound effects on the distributions of small bodies in the inner and outer solar system (see the chapter by Morbidelli et al. in this volume), and of how asteroid families produced by

catastrophic collisions evolve. It has also been suggested that some inner belt asteroids were emplaced as debris from the terrestrial planet region (*Bottke et al.*, 2006), that comets can be implanted into the main belt, and even that Ceres might have been implanted from the outer solar system (*McKinnon*, 2008).

The gradient is less obvious for smaller main-belt asteroids than for larger ones, but this could be attributed to the fact that several processes act more readily on smaller bodies. The idea that the larger asteroids retain some element of a primordial gradient is more tenable, but clearly only one of a number of possibilities, given recent models (*Walsh et al.*, 2011, 2012). It is uncertain whether astronomical observations together with dynamical scenarios can uniquely solve this problem. We need to measure actual compositions as a function of location in the solar system, whether through better understanding from meteoritical research or from *in situ* studies, to resolve the matter. It is still not understood in any quantitative way how meteorites with different oxygen isotopes were distributed in the early solar system, nor from where they are derived in the modern epoch. Short of a wholly impractical mineralogical and isotopic assay of dozens of asteroids and comets, there does not appear to be a way for this question to be robustly resolved in the near term.

## 5.2. Distribution Changes with Size

While the smallest asteroids are the least studied due to observational biases, there are some interesting possible trends and discoveries that have been noted in the past decade (question C2, Appendix A). Among the Hildas and Trojans the relative frequency of D- and P-types changes as a function of size. *Grav et al.* (2012) find a decrease in spectral slope with decreasing size, which translates to more P-types at smaller sizes. *DeMeo and Carry* (2014) also note a change in relative fraction between the D- and P-types. The cause of this change in spectral slope as a function of size is not yet understood. Possible explanations could include space weathering (*Lantz et al.*, 2013; *Brunetto et al.*, 2014), compositional differences, or grain size effects (e.g., *Cloutis et al.*, 2011a,b).

Additionally, among the smallest asteroids ( $D < \sim 15$  km) we find very red asteroids, D-types, in the inner belt where they were previously not expected (*DeMeo et al.*, 2014). The compositional makeup of these bodies and how they arrived in their current locations are under debate. They could have been scattered farther than expected during the late-stage migration modeled by *Levison et al.* (2009). Perhaps they arrived through another mechanism such as an earlier migration, other planetary scattering, or Yarkovsky drift across the resonances. Ultimately, we cannot rule out the possibility that they are compositionally distinct from other D-types and thus do not require an implantation mechanism.

*DeMeo and Carry* (2013, 2014) reported that the relative abundance of C-complex asteroids in the inner main belt is greater at the smaller sizes. There are multiple possible explanations for asteroids of different compositional types to

have different size distributions. It could be related to the size-frequency distribution of families; for example, C-complex objects may survive longer if they have high porosity, as in the case of (253) Mathilde. Bodies with an ice component may have shorter lifetimes, as both sublimation and collisions are at play (Rivkin *et al.*, 2014). Shocked S-complex objects that have suppressed absorption features could be masquerading as other taxonomic types, including the C- or X-complex (Britt and Pieters, 1989; Reddy *et al.*, 2014; Kohout *et al.*, 2014). Differences could also be attributed to the primordial size distributions of asteroids of different compositional types.

### 5.3. What Processes Can Mix Wildly Different Meteorite Types into a Single Tiny Body?

There has been increased focus recently on asteroids in the size range for meteorite delivery, partly due to recent spectacular events such as the fall of 2008 TC<sub>3</sub> (Almahata Sitta), the airblast from the Chelyabinsk meteorite in 2013, and several asteroid close approaches, such as 2012 DA<sub>14</sub>.

Almahata Sitta presents a new puzzle to the meteorite and asteroid communities because of the diversity of meteorite types that have been mixed into a single small body (question B6, Appendix A). Almahata Sitta is predominantly made of ureilitic lithologies, but contains an unprecedentedly large fraction of a variety of other meteorite types, including enstatite chondrites, ordinary chondrites, and even carbonaceous chondrites (Zolensky *et al.*, 2010). Gayon-Markt *et al.* (2012) concluded that it could not have been assembled by low-velocity collisions among asteroids of diverse types in the Nysa-Polana family region (the suspected source region of Almahata Sitta) in the current dynamical environment. The mixture of two or three different meteorite types could be ascribed to unusual but possible coincidental encounters at the low-velocity tails of their dynamical parameters, but the variety of different materials in this case is so large that it is difficult to appeal to such low-probability events. In addition, Almahata Sitta is not a regolith breccia (it does not contain implanted solar-wind particles), so it was not lying on the surface of an asteroid for an extended period of time. Hence, Gayon-Markt *et al.* (2012) suggest that the diverse pieces must have been assembled in early times when collisional velocities were much lower.

Asteroid 2008 TC<sub>3</sub> exhibited a seemingly flat reflectance spectrum most closely, but not convincingly, resembling F-types (Jenniskens *et al.*, 2009) (F-types are from the Tholen taxonomy and would fall under the C-complex in the Bus and Bus-DeMeo taxonomies; see Table 1), where the spectral data had large error bars and did not contain diagnostic absorption features. Ureilites are fairly dark and some of the other incorporated meteorite types exhibited shock-darkening, thus a fairly featureless reflectance spectrum is not unexpected. A wide variety of mineralogies, so long as they contain a fraction of low-albedo materials or shock-darkened grains, might show such a spectrum. Thus there is no strong basis for arguing that other asteroids with

similar spectra should be similarly composed of heterogeneous materials the way Almahata Sitta is.

This mystery might be addressed if we could identify a larger proportion of meteorites that resemble Almahata Sitta. Is there a bias against finding meteorites of this type? The Sudanese desert was an especially good background for picking up pieces of the meteorite. Maybe these kinds of meteorite conglomerates are typically even weaker than Almahata Sitta and fragment even higher in the atmosphere, lessening the chance of recovery on the ground (e.g., similar to reasons for why we apparently lack samples of comets). If this is a more common kind of assemblage than we now think, we would be forced to abandon some of our ideas about asteroid family homogeneity (e.g., from the similar colors and albedos of asteroid family members) or about relative velocities among asteroids during early epochs of solar system history. Given the mismatch in scale between astronomical observation of asteroids and the centimeter-to-meter-scale heterogeneities within Almahata Sitta and other meteorites such as Kaidun (Zolensky, 2003), asteroid astronomical techniques are less likely to resolve this mystery than are techniques of meteor and fireball observation and meteorite research in the laboratory.

### 5.4. The Missing Mantle Problem

The canonical view of asteroid differentiation has been that a fully differentiated body should form an iron core, a silicate mantle, and a basalt crust. Olivine and pyroxene are the spectrally dominant materials in the mantle and crust, respectively. Meteorite collections include a diversity of iron meteorites that imply the existence of more than 60 distinct parent bodies (Wasson, 1995; Burbine *et al.*, 2002). However, the meteorite and asteroid records lack a substantial population of olivine-dominated or pyroxene-dominated bodies (Burbine *et al.*, 1996; Bus and Binzel, 2002a; Binzel *et al.*, 2004; Lazzaro *et al.*, 2004; Carvano *et al.*, 2010; DeMeo and Carry, 2013), aside from HEDs and vestoids linked to Vesta (Consolmagno and Drake, 1977; Binzel *et al.*, 1993; Prettyman *et al.*, 2012). This has been known as the “missing mantle problem,” and also as the “missing dunite problem” (question C3, Appendix A). One of the major outstanding questions in asteroid science that has existed for decades has been this perceived shortage of dunite or olivine in the asteroid belt.

Multiple solutions have been proposed to the missing mantle problem. The “battered to bits” scenario was a leading theory from the 1990s, whereby Burbine *et al.* (1996) further explored a proposal by Chapman (1986) that the mantle and crustal material of the original differentiated bodies had been ground down to pieces below the limit of our observational capabilities or even so they were too small to be delivered to Earth as meteorites. The primary weakness of this scenario is that the mantle and crustal components should not be substantially structurally weaker than undifferentiated material such as the C- and S-complexes that have

survived. Additionally, larger-scale spectroscopic surveys have placed even more stringent limits on the abundance of differentiated material and find it exceedingly rare in both the main belt and among NEOs that are sourced from the smaller (meter- to kilometer-sized) main-belt population (Bus and Binzel, 2002a; Binzel et al., 2004; Lazzaro et al., 2004; Carvano et al., 2010; DeMeo and Carry, 2013).

A more recent suggestion is that the classic view of asteroids differentiating into a pyroxene-rich crust, olivine-rich mantle, and iron core may be incorrect or uncommon (Elkins-Tanton et al., 2011). The differentiation models cause an asteroid's interior to heat and melt due to the decay of  $^{26}\text{Al}$ , but the exterior remains unheated and primitive (see the chapter by Scheinberg et al. in this volume). Thus the unheated crust would hide evidence of a differentiated interior from a remote observer. Weiss et al. (2012) propose that asteroid (21) Lutetia's high density, measured by the Rosetta spacecraft, is evidence of a core due to internal differentiation. Also, recent measurements of the primitive CV meteorite Allende find a directionally stable remnant magnetization that could be explained by the presence of a core dynamo in the parent body's past (Carporzen et al., 2011). As for rethinking the olivine-rich mantle model, the smoking gun has been the lack of appreciable olivine on the surface of Vesta from the Dawn mission (Le Corre et al., 2013). Another test of this differentiation scenario could be observations of asteroid families, whereby family members represent pieces of the parent asteroid's interior. The spectra and albedos of asteroid families tend to be very homogeneous (Parker et al., 2008; Masiero et al., 2011); however, the parent bodies of these families may not have been large enough to differentiate in the first place.

In addition to improved differentiation models, there is a new dynamical context for small bodies. It is possible, even likely, that bodies that formed iron cores formed closer to the Sun, in the terrestrial planet region (see the chapter by Scott et al. in this volume). During the tumultuous time of planet formation, these differentiated bodies were catastrophically disrupted, but their remnants were later scattered outward into their current locations in the main belt (Bottke et al., 2006). In addition, the so-called Grand Tack model (Walsh et al., 2011) proposes that within the first few million years of solar system formation, Jupiter migrated inward to the current location of Mars, then due to Saturn's presence turned course and moved back outward, scattering a significant number of bodies out to the location of the main belt today. The orbital distribution of basaltic and olivine-dominated objects spread across the main belt today are consistent with the idea that a small amount of material was scattered into their current locations (e.g., Moskovitz et al., 2008).

### 5.5. The Ordinary Chondrite Paradox

The ordinary chondrite paradox was a longstanding puzzle in asteroid science (question B7, Appendix A), whereby the most common meteorite type, the ordinary chondrites, did

not spectroscopically match the most common asteroids, the S-complex (Bell, 1989). Originally the S-complex asteroids in the inner belt were interpreted as igneous bodies that had undergone significant heating and melting, exposing iron, olivine, and pyroxene on the surface (McCord and Gaffey, 1974; Chapman, 1974). Thus, they were not considered compositionally linked to ordinary chondrites. However, the possibility of an effect, such as space weathering seen on the Moon, that altered ordinary chondrite spectra to look like S-complex asteroids could not be ruled out (Chapman 1979).

By the 1990s, the space weathering hypothesis gained traction. Spectral measurements of tens of NEOs demonstrated that the S-complex NEOs spanned the entire spectral slope range from spectrally flat ordinary chondrites to spectrally red S-complex main belt asteroids (Binzel et al., 1996, 2010). The Galileo mission data for Ida revealed that spectral differences were correlated with the age of surface features, and the discovery of Ida's moon Dactyl allowed density estimates that rejected the hypothesis of a core or other large metal components that may have been produced by large-scale melting and differentiation (Chapman 1996). Images and spectra of asteroid (433) Eros from the NEAR mission showed that dark regolith on the wall of the crater Psyche moves downslope exposing younger, brighter material (Everka et al., 1999; Murchie et al., 2002). The most important result from NEAR-Shoemaker was the conclusion from X-ray fluorescence spectroscopy that the major elemental composition of Eros was that of ordinary chondrites and that body had not differentiated (Nittler et al., 2001). Additional ground-based studies of Itokawa (Binzel et al., 2001) and an increased understanding of the effects of space weathering (Sasaki et al., 2001, Chapman 2004, Brunetto et al., 2006) further strengthened the ordinary chondrite–S-complex link. However, it was not until the sample return from Itokawa by JAXA's Hayabusa spacecraft (Nakamura et al., 2011) that conclusively proved the link. While it became clear that space weathering accounted for much of the spectral slope difference between ordinary chondrites and S-complex asteroids, other factors including grain size and observational phase angle were also determined to affect spectral slope (see chapter by Reddy et al.). For further discussion of the ordinary chondrite problem see the chapter by Brunetto et al.

The ordinary chondrite paradox case is now generally considered closed — ordinary chondrite compositions are part of the S-complex. There are two large problems remaining: (1) to determine which S-complex asteroids are not ordinary chondrites and may supply other meteorite types, and (2) to determine how many original parent bodies the ordinary chondrites come from. The S-complex encompasses a range of spectral characteristics and a diverse set of compositions (e.g., Gaffey et al., 1993; Dunn et al., 2013). Detailed mineralogical modeling of a large quantity of S-complex spectra, combined with a refined understanding of other factors that affect an asteroid's reflectance spectrum, is needed if we are to make further progress. Exploring a

broader wavelength range from the UV to mid-IR would provide additional constraints.

## 6. ASTEROIDS IN THEIR GREATER CONTEXT

Studies of asteroids and meteorites reveal their current compositions and structure as well as how and when they formed, including the conditions of the solar system at the time of planet and planetesimal formation. Asteroids, however, are more broadly relevant in our own solar system and beyond. In this section we explore asteroids and their relevance to Earth and habitability and the topic of asteroids outside our solar system. The field of exoasteroids is growing rapidly and the role asteroids play in creating the conditions for life (particularly the role in delivering water) is now being studied extensively. While these topics play a minor role in this book, one may envision these topics to be mature by the time of *Asteroids V*.

### 6.1. The Relevance of Asteroids to Earth Formation and Conditions for Life

No meteorite group or combination of groups can reproduce both the elemental and isotopic compositions of Earth, the planet for which we have the best data (*Palme and O'Neill*, 2014; *Halliday*, 2014) (question D1, Appendix A). Impact erosion and volatile loss during melting/differentiation of planetesimal precursors may explain some of the differences, but it seems that Earth was at least partially made of materials not present in our meteorite collections.

The abundances of highly siderophile elements in Earth's silicate mantle and crust are much higher than would be predicted since these elements should have gone essentially quantitatively into Earth's Fe-metal core during differentiation (*Walker*, 2009). It has been proposed that these elements were added to Earth after the last major event that enabled exchange between the core and the silicate mantle (*Chou*, 1978), which is normally taken to be the Moon-forming impact. The age of the Moon-forming impact is still uncertain — it must have been earlier than the oldest known lunar crustal rocks that formed 4.36 b.y. ago (*Borg et al.*, 2011), and could be as old as  $4.507^{+0.1}_{-0.01}$  b.y. (*Kleine et al.*, 2009; *Touboul et al.*, 2007). The isotopic composition of the highly siderophile elements Os and Ru suggest that the material responsible for this so-called late veneer was probably ordinary- or enstatite-chondrite-like (i.e., volatile-poor), rather than carbonaceous-chondrite-like (i.e., volatile-rich) (*Walker*, 2009). The fraction of Earth's mass that was accreted as a late veneer was on the order of 0.5% (*Walker*, 2009). The material accreted during the proposed late heavy bombardment (LHB), an increase in the lunar basin formation rate about 4 b.y. ago, would have been a minor component of the late veneer. However, there has been a longstanding debate about how long the LHB lasted or even whether there was a LHB (*Chapman et al.*, 2007; *Morbidelli et al.*, 2012). One model (the Nice model)

proposes that the LHB was caused by an episode of giant planet orbital migration that destabilized the inner edge of the asteroid belt (*Bottke et al.*, 2012).

The LHB, and the late veneer as a whole, was not a significant source of Earth's volatiles. Apart from the Os and Ru evidence, and model support that the LHB and the late veneer material were volatile-poor, there is evidence for oceans 4.4–4.3 b.y. ago (*Cavosie et al.*, 2005; *Mojzsis et al.*, 2001; *Wilde et al.*, 2001), i.e., 300–400 m.y. before the LHB. Earth's atmosphere is probably even older,  $\sim 4.527^{+20}_{-10}$  b.y. (*Avicen and Marty*, 2014), which is of a similar age to or possibly older than the Moon. So volatiles were accreted by Earth quite early and were not lost in any subsequent giant impacts, which is consistent with the new evidence for a wetter Moon than previously suspected (*Saal et al.*, 2013) and with the timing for water accretion measured in eucrites (*Sarafian et al.*, 2014).

It has been argued that Jupiter-family comets (JFCs) like Hartley 2 could have been the main sources of Earth's water because they have roughly terrestrial water D/H ratios (*Hartogh et al.*, 2011), although the water D/H of another JFC is roughly 3× terrestrial (*Altweegg et al.*, 2015). However, at least in the Nice model, objects from the scattered disk, the source of the JFCs, would have been scattered into the inner solar system only during the LHB (*Levison et al.*, 2009), which is too late given the evidence for an atmosphere and oceans hundreds of millions of years before the LHB. Also, as mentioned above, the isotopic compositions of Os and Ru suggest that the late veneer material was dominated by ordinary- and enstatite-chondrite-like material. Finally, it is important to remember that Earth would have accreted whole comets and not just their ice. Comets are organic-rich, and judging by the organics in meteorites and interplanetary dust particles, which may be cometary, cometary organic material is very D-rich. Consequently, the bulk D/H even of comets like Hartley 2 is probably significantly more D-rich than their ice and Earth (*Alexander et al.*, 2012). On the other hand, the bulk H and N isotopic compositions of CI and CM chondrites are quite similar to Earth's (*Alexander et al.*, 2012). In fact, the addition of ~2 wt.% of CI or ~4 wt.% of CM chondrite material can roughly reproduce not only the H and N isotopes, but also the abundances of many of Earth's most volatile elements (H, C, Cl, Br, I, Ne, Ar, and Kr) (*Alexander et al.*, 2012; *Marty*, 2012).

### 6.2. Asteroids Outside Our Solar System

Asteroids play an important role outside our solar system as well (questions D3 and D4, Appendix A). Asteroids are inferred to exist as remnants around white dwarf stars and are used as tracers of the dynamics and physical properties in these systems. Gravitational settling in cool white dwarfs causes all elements heavier than helium to sink to the star's interior. One-fourth to one-third of cool white dwarfs have heavy elements in their atmospheres that accreted from in-

falling asteroids (*Alcock et al.*, 1986; *Jura*, 2008; *Jura and Young*, 2014). These asteroids around white dwarfs are at least 85% by mass oxygen, magnesium, silicate, and iron, resembling rocky planetesimals and bulk Earth in our solar system (*Jura and Young*, 2014). This observational technique of studying white dwarf atmospheres can also detect asteroid differentiation, and evidence of water was detected in “exoasteroid” debris (*Farihi et al.*, 2011, 2013). Studies of cool white dwarfs may enable us to understand asteroid compositions, formation, and evolution in other planetary systems.

Asteroid belts are present around stars, as evidenced by the collisional dust (equivalent to our own zodiacal dust) observed around other mature stars. Debris disks are detected by the light emitted by dust grains in the disk at thermal wavelengths (e.g., *Lawler et al.*, 2009; *Lawler and Gladman*, 2012). The peak flux and wavelength of the emitted light provides an estimate for the mass of the disk and its distance from the star. While most known debris disks are Kuiper-belt-like, located at distances from tens to hundreds of astronomical units, a small number exhibit mid-IR emission indicating warm dust. Most spectral measurements of debris disks have been taken at IR wavelengths where the flux ratio of the disk to star is most favorable. Minerals can be identified by emission features (e.g., *Christensen et al.*, 2000) with silicates being the most common and easiest to identify (e.g., *Beichman et al.*, 2005; *Lisse et al.*, 2012; *Ballering et al.*, 2014). Interpretation of these spectra, however, is challenging because many grain properties other than composition (size, shape) can affect the spectrum. Continued studies of debris disks will reveal the diversity of extrasolar asteroid belt configurations and compositions that will provide context for our own solar system and for understanding the role asteroid belts play in creating the conditions for habitability on Earth-sized planets.

## 7. THE FUTURE: WHAT'S NEXT?

Potential avenues for future work on specific questions addressed in this chapter are given in Appendix A. We highlight a few avenues for future work here:

- In general, for the future of understanding the compositions and distributions of asteroids there are several techniques and topics that hold promise. While the past decades have focused primarily on the visible and near-IR wavelength ranges for spectroscopic study, extending to the UV and mid-IR could potentially provide new constraints for asteroid surfaces.
- The internal structures and geophysics of asteroids remain largely unexplored. Additional studies of

densities and differentiation processes will play an important role in understanding asteroid interiors (*Carry*, 2012).

- Studies of small asteroids (a few kilometers in the main belt and a few tens of meters among NEOs) will be a focus in future years, as there is much progress to make on the processes relevant to these size ranges. Understanding the compositional makeup and mixture of serendipitous meteorite falls is a young and developing field. The study of shock-darkening effects on the surfaces of asteroids and meteorites is another avenue of future work. While the foundations for the shocking process were established decades ago (e.g., *Britt and Pieters*, 1994), there is renewed interest as we observe the smallest asteroids.
- Ongoing and upcoming space missions will also add great value to our understanding of asteroid compositions. Dawn recently completed its study of Vesta and will have studied Ceres by the time this book is published. The Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) and Hayabusa-2 missions are scheduled to return samples of primitive asteroids. Gaia is actively taking visible wavelength spectra of tens to hundreds of thousands of asteroids and will provide a large new set of data to the community.

Just as important as exploring all these interesting avenues of asteroid research is exploring the connections between them. We must understand how each new discovery relates to our current body of knowledge and to the big picture of asteroids, our solar system, and beyond.

## APPENDIX A: MAJOR OUTSTANDING ASTEROID COMPOSITIONAL QUESTIONS

Question	Possible Solutions	What Next?	Related Chapters
<b>A. Formation and Physical Evolution of Asteroids</b>			
1. Where, when, and how did they form?	<p><i>Where:</i> Links between asteroids and meteorites help constrain the conditions and location of formation. Dynamical models link where the asteroids are located now to where they originally formed.</p> <p><i>When:</i> Recent advances dating meteorites have constrained formation ages. For example, igneous meteorites have crystallization ages older than chondritic ones. So bodies that melted, melted early. Bodies that did not melt formed later. <i>How:</i> A second leading theory on formation, through streaming instability, has emerged since <i>Asteroids III</i>.</p>	Isotopic evidence points to carbonaceous chondrites being different from all others. But they are not all more water-rich, and their water H isotopes are not comet/Enceladus-like. Ages of chondrules and secondary minerals can be used to estimate chondrite formation ages. The almost ubiquitous presence of chondrules suggests that they may have played a role in planetesimal formation.	Section 4, this chapter; Johansen
2. How have they evolved physically?	Asteroid compositional changes are caused by early heating, aqueous alteration, and the external environment (space weathering). Physical changes are caused by impacts, radiation pressure (YORP spinup), and close approaches to planets (large tidal force).	Continued work on collisional and thermal modeling, studies of families, spacecraft measurements including surface (crater) observations. <i>In situ</i> measurements and sample return of non-OC-like bodies. Density measurements to understand interiors.	Brunetto, Krot, Scheinberg, Scott, Wilson, Bottke, Asphaug, Jutzi
3. How have they evolved dynamically?	Planetary migration likely plays a leading role in early solar system history. Planetary scattering, collisions, orbital drift, and orbital changes due to resonances dominate later history.	Identify the current spread in semimajor axis of each compositional group and use it to constrain the different migration scenarios. Search for and characterize interlopers for composition. Orbital and mass constraints also continue to inform dynamical history.	Section 3, this chapter; Morbidelli, Vokrouhlický, Bottke
<b>B. Asteroid and Meteorite Compositions</b>			
1. How many original parent bodies are represented in the asteroid belt?	Based on the meteorite record and the assumption that each meteorite group comes from a single parent body, there are at least 100–150 distinct parent bodies.	Meteor observation networks will provide insight on source bodies for meteorites. Continued work linking large main-belt asteroids to meteorites.	Burbine <i>et al.</i> (2002)
2. Can a single meteorite group be represented by more than one parent body?	(a) The simplest assumption is that each meteorite group comes from one parent body. (b) More than one object could have formed at a similar time and a similar distance from the Sun, in which case they might look very similar. For instance, there could be more original (>50–100 km) S-type asteroids than the three needed to explain the three ordinary chondrite groups.	Further research on meteorite composition will yield better understanding of parent bodies. For example, high-precision isotopic measurements may reveal if the OCs separate and demand more than three bodies. Sample return will provide insight, as will a review of how many primary parent bodies (those > 50–100 km) there are in each spectral class.	Burbine <i>et al.</i> (2002)

## APPENDIX A (continued)

Question	Possible Solutions	What Next?	Related Chapters
<b>B. Asteroid and Meteorite Compositions (continued)</b>			
3. How well do meteorites sample the asteroids?	<p>Comparison of meteorites with micrometeorites and breccias suggests meteorites may be fairly representative samples of the major types of asteroids. We still find new types of meteorites (and presumably parent bodies), but differences tend to be subtle. However, the inherent “top-heavy” asteroid size distribution means that rare, large collisions stochastically dominate the ejected fragments by mass, resulting in an inherent possibility of large deviations from direct representation of asteroid types by meteorite collections. If there is more diversity in the spectra of main-belt asteroids than meteorites, could much of this diversity be due to regolith processes (grain size and density sorting) and space weathering? Also, there are biases associated with delivery efficiency from different resonances and the robustness of the samples as they pass through Earth’s atmosphere.</p>	<p>Characterize asteroids at sizes relevant to meteorite falls (~5–50 m) to compare with the meteorite collection. IDPs, micrometeorites, and clasts in meteorite regoliths provide alternative samplings of the asteroid belt — how similar are they to the meteorites?</p>	Borovička, Jenniskens, Binzel
4. How robust are our asteroid-meteorite links?	<p>A few connections are robust: OCs make up part of the S class. HEDs are linked with V-types and the largest group of isotopically linked HEDs are concluded to be from Vesta. Isotopically distinct HEDs, as well as the diversity of other achondrites, point to a wide diversity of differentiation processes that remain poorly understood. The CMs may be linked with Ch and Cgh asteroids. The weaker and fewer bands present in an asteroid spectrum, the less confident we are of its composition. The C and X complexes could be extremely compositionally diverse, but observations are also affected by varying grain size, phase angle, regolith gardening, space weathering, etc. Shock darkening, which also mutes absorption bands, can also disguise the compositional identity of asteroid surfaces.</p>	<p>Dynamical study of asteroid families has the potential for addressing this question. By determining the ages of families and comparing with meteorite shock ages, and by following the plausible dynamical routes from family to Earth, current best guesses of associations of some meteorite types with families might become more robust. The mid-IR may be the next frontier for groundbased observational studies. Meteorite studies of spectral effects not related to composition are needed. Asteroid sample return will provide valuable insight for featureless asteroids. Serendipitous observation and recovery of objects such as 2008 TC<sub>3</sub> will also provide “free sample return.”</p>	Vernazza, Brunetto, Yoshikawa, Reddy, Burbine et al. (2002)

**APPENDIX A: (continued)**

Question	Possible Solutions	What Next?	Related Chapters
<b>B. Asteroid and Meteorite Compositions (continued)</b>			
5. How well do NEOs represent the main belt and beyond?	We now understand that dynamical and weathering processes can be relatively fast, suggesting that NEO flux is just a current snapshot, influenced by stochastic events like more recent disruption events. Size might also matter, and the speed at which an asteroid's orbit drifts due to the Yarkovsky effect increases with proximity to the Sun and with decreasing diameter. Yarkovsky is more effective at the small sizes (10 m or smaller) that might dominate meteorite samples. Additionally, size-dependent delivery mechanisms (Yarkovsky) mean that different size ranges could be dominated by specific asteroid families. NEO lifetimes and the NEO delivery models have helped link NEOs to their main-belt source regions.	Survey main-belt asteroids at sizes similar to NEOs (~1 km). Study dynamical and compositional links between NEOs and main-belt families and specific regions. Dynamics need to be calibrated by observations. New understanding of differentiation processes is also relevant.	Binzel
6. What is the diversity of compositions within individual small asteroids? What processes mix wildly different meteorite types into a single tiny body (e.g., Almahata Sitta, Kaidun)? When did the mixing occur?	Collisional or accretional processes (or both) could potentially bring such diverse materials together.	Implementation of ATLAST-like telescopic surveys of asteroids/meteoroids on their final approach to Earth and increased video surveillance and recovery of fall samples to understand the prevalence of and compositions of these mixes. Physical measurements of the smallest asteroids (5–100-m). Sample return of small asteroids will also provide constraints.	Section 5.3, this chapter; Borovička, Bottke?
7. The ordinary chondrite paradox: Why does the most common asteroid type, S-type, not match the most common meteorite type, OC?	Space weathering is the primary reason for the spectral mismatch. Laboratory experiments plus ground- and spacebased asteroid measurements made great progress. Hayabusa's sample return of Itokawa provided conclusive evidence. Other factors affecting spectral slope include grain properties and observational phase angle.	This question is solved. The follow up questions are: What S-type asteroids are not OCs? What meteorites do they supply? How does the space environment affect other asteroid types?	Section 5.5, this chapter; Vernazza, Brunetto, Binzel, Yoshikawa
8. What are the interior compositions of asteroids?	Density measurements and asteroid families currently provide the most information about asteroid interiors. How compositionally homogenous or differentiated the medium to large asteroids are is largely unknown.	Density measurements particularly from multiple systems. The porosity of asteroid interiors must be better constrained as well.	Margot, Scheeres, Barucci

## APPENDIX A: (continued)

Question	Possible Solutions	What Next?	Related Chapters
<b>C. Asteroid Compositional Distributions</b>			
1. What is the source of the compositional gradient in the main belt? Why are the Hildas and Trojans compositionally homogeneous compared to the main belt?	(a) It is a primordial remnant from the temperature and compositional gradient in the disk.  (b) It is the result of a transplantation of one or more groups of asteroids that formed elsewhere. (3) Hildas and Trojans actually are more compositionally diverse than they appear, but they have significant quantities of low-albedo materials that render diagnostic spectral features nearly invisible.	Progress on early solar system environment models and asteroid formation models. The best although impractical way to solve this is a mineralogical and isotopic assay of dozens of asteroids and comets.	Sections 2.2, 2.3, 5.1, this chapter; Morbidelli, Johansen, Emery
2. How does the distribution of asteroids change as a function of size? What is the significance of that distribution?	Recent work has explored the change in relative abundance of asteroid types as a function of size. Many factors still need to be taken into account, such as (1) the size-frequency distribution of families, (2) the difference in collisional lifetimes per asteroid class, and (3) the fact that some compositions are masked at smaller sizes due to processes such as collisions and “shocking.”	Additional study of the size distribution of families in the inner belt. Groundbased imaging and shape models plus mission visits to primitive bodies. Constrain how prevalent shocking is in the main belt. Larger samples of small asteroids in the main belt (1–20 km) will help determine the distribution at smaller sizes.	Section 5.2, this chapter
3. The missing mantle problem: Where is all the missing mantle material? Additional questions: Why are V- and A-types scattered throughout the entire main belt?	(a) Asteroids differentiate differently than expected — perhaps they don't form large olivine-rich mantles and pyroxene-rich crusts.  (b) The parents of these cores formed in the terrestrial planet region. They were destroyed and only the strongest metallic fragments were subsequently delivered to their current locations in the main belt.  (c) “Battered to bits” — this theory is currently less favored. Collisional modeling, crater counts, and observational evidence do not support an aggressive regime of collisional destruction and battering.  (d) Previous theories postulated olivine was hidden by weathering processes. Recent progress on space weathering disproves this hypothesis.	Further study of dynamical solutions and differentiation modeling. Continued study of meteorites to understand differentiation. Continued search for differentiation in families, including metal within large families.	Section 5.4, this chapter; Scheinberg, Wilson, Scott
4. Where is the water in the asteroid belt? How much is there? Where did these water-rich asteroids form?	Current evidence: main-belt comets, activated asteroids, water absorptions, Ceres outgassing, and possible exposures of ice on Ceres.	Discover additional active asteroids and explore asteroid-comet connections. Continue studies of extinct or dormant comets among NEOs. Visit and map surfaces such as by the Dawn, OSIRIS-REx, and Hayabusa-2 missions. Also, density measurements, radar sounding by spacecraft, etc., might reveal ice buried beneath thick surficial lag deposits.	Jewitt, Rivkin, Krot, Binzel

**APPENDIX A: (continued)**

Question	Possible Solutions	What Next?	Related Chapters
<b>D. Asteroids in Their Greater Context</b>			
1. Importance of the asteroid belt for Earth: Do we have remnants of Earth's building blocks? Do we have remnants of Earth's water source?	Arguments exist for and against enstatites or angrites being primary components of Earth. Water from Earth's oceans is argued to have been delivered from asteroids. Late veneer. Isotopic compositions show that the known chondrites were not the major building blocks of Earth, but the CI + CM-chondrite-like material may have been the sources of Earth's volatile materials as suggested by the SMOW D/H ratio.	Continued studies of D/H ratios of meteorites, comets, and asteroids. Continued theoretical studies of planet formation and dynamical studies of planet and planetary migrations.	Section 6.1, this chapter
2. Importance of the asteroid belt for the rest of our solar system?	Surface ages determined by impacts and cratering rates. Main belt and Kuiper belt orbital architecture and captured Trojans and satellites constrain giant planet migration. Study of solar corona is enabled by asteroids and comets evaporating during close approach to the Sun.	Continue with current progress on crater studies, dynamical studies including migration.	Beyond the scope of this book
3. What role do asteroids play in other planetary systems?	Collisions in massive asteroid belts create debris disks around old stars.	Identify and characterize extrasolar asteroid belts (evolved debris disks). Survey different planetary system architectures including asteroid belt distances and masses.	Section 6.2, this chapter; mostly beyond the scope of this book
4. What role do asteroids play in creating the conditions for habitability on Earth-sized planets?	Asteroids are tracers of dynamics and physical properties in dusty white dwarf systems.	Identify and characterize dusty white dwarf systems, and link those systems to the expected properties of precursor planetary systems.	Beyond the scope of this book
5. What is the importance of asteroids as hazards and resources for Earth?	Meteorites are known to contain water and organics (including amino acids), which could be precursors for life. They represent the initial conditions and compositions for forming terrestrial planets. They could be responsible for water delivery and creating oceans. They could also be responsible for destroying life through impacts.	Understand the link or the gradient between comets and wet asteroids. Measure the D/H ratio of a wider array of water-rich small bodies. Dynamical studies of delivery. Understand consequences of delivery of too much water. Studies of impact and water retention on Earth. Studies of ocean-forming mechanisms unrelated to small-body delivery.	Harris, Jedicke, Farnocchia
	Asteroids as a hazard have motivated increased attention to discovery surveys. Asteroids contain rare-Earth elements, including metals of value. Asteroids contain water or water components useful for space travel.	Discover 90% of PHAs down to 140 m. Understand the size of the small NEA population (<140 m). Evaluate and prepare for deflection strategies or evacuation plans. Continue to explore asteroids as resources.

---

Methods to constrain the surface mineralogy of asteroids have seen considerable development during the last decade, with advancement in laboratory spectral calibrations and validation of interpretive methodologies by spacecraft rendezvous missions. This has enabled the accurate identification of several meteorite parent bodies in the main asteroid belt and helped constrain the mineral chemistries and abundances in ordinary chondrites and basaltic achondrites. With better quantification of spectral effects due to temperature, phase angle, and grain size, systematic discrepancies due to noncompositional factors can now be virtually eliminated for mafic silicate-bearing asteroids. Interpretation of spectrally featureless asteroids remains a challenge. This chapter presents a review of all mineralogical interpretive tools currently in use and outlines procedures for their application.

## 1. INTRODUCTION

Physical characterization of small bodies through the use of reflectance spectroscopy provides insight into the diversity of chemical compositions in the solar system and enables meteorites in our terrestrial collections to be linked to specific parent bodies in space. Since the publication of *Asteroids III*, there have been numerous advances in the mineralogical characterization of asteroid surfaces using visible/near-infrared (VIS/NIR) and mid-IR spectra. One of the most significant developments in groundbased characterization of small bodies over the last decade is the commissioning of the SpeX instrument in the NASA Infrared Telescope Facility (IRTF) on Mauna Kea, Hawai‘i. The ideal spectral resolution (~few hundred), wavelength range (0.8–5 μm), and high altitude of Mauna Kea have facilitated the mineralogical characterization of asteroids down to a visual magnitude of 19.

In addition to groundbased observations, the last decade has been witness to a series of successful spacecraft missions, including flybys of (2867) Šteins, (21) Lutetia, (4179) Toutatis, a rendezvous mission to asteroid (4) Vesta, and a sample return from near-Earth asteroid (25143) Ito-

kawa. These missions have helped study the shape, morphology, and surface composition of asteroids over a wide range of sizes, from Itokawa (535 m) to Vesta, which (at 525 km) is the second most massive object in the asteroid belt. Two more sample return missions are planned for the next decade, both of which are targeting primitive near-Earth asteroids. Hayabusa-2 calls for a sample return of C-type asteroid (162173) 1999 JU<sub>3</sub>, and the Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) mission will return a sample from the potentially hazardous asteroid (101955) Bennu.

Our ability to track meteorite falls back to their possible parent asteroids has benefited from increased interest in the monitoring of fireballs, the streak of light generated as a meteorite comes through the atmosphere. The Chelyabinsk meteorite, which exploded over Russia on February 15, 2013, is the most well-documented fireball in modern history. The combination of all-sky-camera data from networks such as Cameras for Allsky Meteor Surveillance, the Desert Fireball Network in Australia, and NASA’s All Sky Fireball Network with weather radar data has helped in the recovery of several meteorites with accurate orbits in the last decade

(Bland *et al.*, 2009; Fries *et al.*, 2014). Although a rare occurrence, the discovery of Earth impactors prior to impact, such as 2008 TC<sub>3</sub>, has enabled us to compare recovered meteorite samples to Earth-based telescopic observations (Jenniskens *et al.*, 2009).

Advances in the collection and quality of spectral data have necessitated improvements in our ability to interpret these data. New formulas for deriving mineralogies from VIS/NIR spectra with prominent 1- and 2-μm absorption bands have been developed (Burbine *et al.*, 2007; Dunn *et al.*, 2010b; Reddy *et al.*, 2011), and the effects of noncompositional parameters have been well characterized, allowing for more accurate interpretations of asteroid surface mineralogies (e.g., Burbine *et al.*, 2009; Sanchez *et al.*, 2012, Reddy *et al.*, 2012c). For spectra devoid of prominent absorption features at visible and near-IR wavelengths, radiative transfer models can provide insight into mineral compositions and abundances. Another area of focus is the 3-μm region, where hydrated silicates and organics have distinct absorption features. Much progress has also been made on spectroscopy of asteroids and meteorites at mid-IR wavelengths (5–25 μm).

In this chapter we review advances made over the last decade in determining mineralogy and surface composition of asteroids at wavelengths ranging from the visible to the mid-IR. We focus on asteroids showing silicate absorption features, as they have the best laboratory spectral calibrations to derive mineralogy with remote sensing data. We also examine the role that spacecraft have played in improving our understanding of asteroid surface morphology and composition. Finally, we discuss the connections between meteorite groups and potential asteroid sources that have been made as a result of these advances in the collection and interpretation of asteroid spectra.

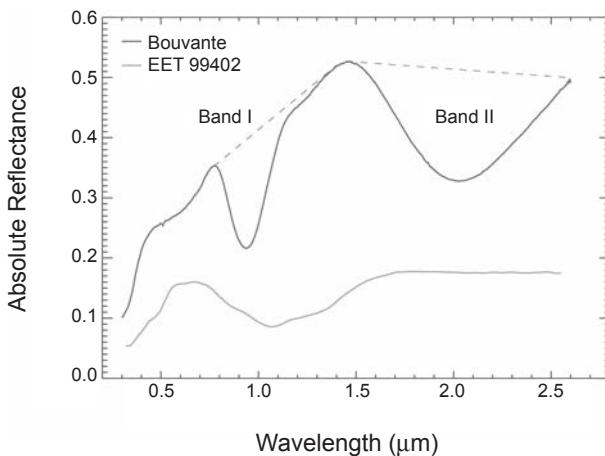

## 2. MINERALOGICAL CHARACTERIZATION

Visible/near-infrared (VIS/NIR) spectra (0.3–2.5 μm) have been widely used to determine mafic mineral abundances and compositions of asteroids since the relationship between spectral properties (i.e., absorption features) and mineralogy in meteorites was first recognized (e.g., Adams, 1975; Burns *et al.*, 1972; Cloutis *et al.*, 1986; Cloutis and Gaffey, 1991). Most previous work examining the spectral properties of silicate minerals has focused on olivine and pyroxene, both of which have diagnostic spectral properties in the VIS/NIR.

Olivine and pyroxene are the primary mineral phases in most primitive meteorites and in many types of non-chondritic meteorites. The structure of olivine consists of individual silicon-oxygen tetrahedra linked by divalent Mg and Fe atoms that occupy the M1 and M2 structural sites. Substitution of Mg and Fe between the M1 and M2 sites results in a solid solution series defined by two compositional endmembers: the Fe-endmember fayalite ( $\text{Fe}_2\text{SiO}_4$ ) and the Mg-endmember forsterite ( $\text{Mg}_2\text{SiO}_4$ ). Pyroxenes are a group of chain silicate minerals that share the chemical formula

$(\text{M}2)(\text{M}1)(\text{Si},\text{Al})_2\text{O}_6$ . Three pyroxene subgroups have been defined based on occupancy of the M2 site. In low-Ca pyroxenes, the M2 site is occupied by Fe or Mg, in high-Ca pyroxenes by Ca, and in sodium pyroxenes by Na. Because high-Ca pyroxenes have monoclinic symmetries, they are often referred to as clinopyroxenes. The term orthopyroxenes is commonly used when referring to the orthorhombic low-Ca pyroxene endmembers, enstatite ( $\text{Mg}_2\text{Si}_2\text{O}_6$ ) and ferrosilite ( $\text{Fe}_2\text{Si}_2\text{O}_6$ ). For a more in-depth discussion of the structure and composition of the olivine and pyroxene groups, we refer the reader to Deer *et al.* (1966).

The primary diagnostic feature in olivine is a composite absorption feature at ~1 μm, which consists of three distinct absorption bands. The composite 1-μm band, which is attributed to electronic transitions of  $\text{Fe}^{2+}$  occupying both the M1 and M2 crystallographic sites (Burns, 1970), moves to longer wavelengths as FeO content increases (King and Ridley, 1987; Sunshine and Pieters, 1998). Pyroxenes have two absorption bands at ~1 μm and ~2 μm that are associated with crystal field transitions in  $\text{Fe}^{2+}$ , which preferentially occupies the M2 site (Clark, 1957; Burns, 1970) (Fig. 1). Low-calcium pyroxenes, which are conventionally defined as having less than 11 mol%  $\text{CaSiO}_3$  (wollastonite, or Wo) (Adams, 1974), show a well-defined relationship between absorption band positions and composition, as both Band I and Band II positions increase with increasing ferrous iron content (Adams, 1974; Burns *et al.*, 1972; Cloutis and Gaffey, 1991). There is also a correlation between composition and band positions in high-calcium pyroxene, although the relationship is complicated by the presence of calcium in addition to iron. In spectral type B clinopyroxenes (<Wo<sub>50</sub>), there is a positive correlation between calcium content and Band I and II position, regardless of iron content (Cloutis and Gaffey, 1991). However, there does not appear to be a systematic relationship between Band I or Band II position

**Fig. 1.** Laboratory-measured spectra of olivine ( $\text{Fa}_{35}$ ) in the brachinitite EET 994012 (Burbine *et al.*, 2007) and pyroxene ( $\text{Fs}_{53}\text{Wo}_{14}$ ) in the eucrite Bouvante (Burbine *et al.*, 2001). The area underneath the dashed lines is the band area. The band area ratio is the area of Band II/area of Band I.

and Ca and Fe content in spectral type A clinopyroxenes ( $>\text{Wo}_{50}$ ) (Cloutis and Gaffey, 1991; Schade et al., 2004). In mixtures of orthopyroxene and clinopyroxene, spectral shape and band positions are dominated by the orthopyroxene component, as clinopyroxene only begins to affect the band positions at abundances  $>75$  wt% (Cloutis and Gaffey, 1991).

### 3. NONCOMPOSITIONAL SPECTRAL EFFECTS

Prior to mineralogical interpretation, spectral band parameters of S-type and V-type asteroids must be corrected for noncompositional effects, such as temperature, phase angle, and grain size. Phase angle is defined as the Sun-target-observer angle, and is typically less than  $25^\circ$  for main-belt asteroids but can be much higher for near-Earth asteroids. With increasing or decreasing phase angle the slope of a reflectance spectrum generally becomes redder or bluer respectively, an effect known as phase reddening. Particle size primarily affects the depth and slope of an absorption feature and overall reflectance, with absorption bands reaching the greatest depth at a grain size bin that provides maximum spectral contrast (deepest absorption bands). Larger particle size typically means deeper bands, bluer (more negative) spectral slope, and lower overall reflectance. Analysis of particles returned by the Hayabusa spacecraft from near-Earth asteroid (25143) Itokawa have shown that a majority of the 1534 particles have a size range between 3 and 40  $\mu\text{m}$ , with most of them smaller than 10  $\mu\text{m}$  (Nakamura et al., 2011). This would suggest that spectra of laboratory meteorite samples with grain sizes  $<100$   $\mu\text{m}$  would best represent spectra of asteroid regolith, although the method of sampling likely biased the grain size distribution of the collected material. Temperature differences between asteroid surfaces and room temperature measurements produce changes in absorption band centers, band depths, band widths, and band area ratios (BAR). Of these three factors, temperature corrections of band centers have a large impact on mineralogical characterization, whereas phase angle corrections are important for constraining space weathering on small bodies, as they affect spectral slope, albedo, and band depth. Ignoring these effects could lead to erroneous interpretations of asteroid surface mineralogy and space weathering effects (Sanchez et al., 2012).

#### 3.1. Temperature-Induced Spectral Effects

The rationale behind applying corrections for temperature-induced spectral effects is motivated by the fact that current laboratory spectral calibrations for the interpretation of asteroid spectra are derived using room-temperature mineral/meteorite spectra ( $\sim 300$  K). In contrast, the surface temperatures of asteroids can range from 140 to 440 K depending on the object's heliocentric distance. This temperature difference produces changes in absorption band centers, band depths, band widths, and BARs, which in turn can lead to over- or underestimation of iron/calcium content in silicates and variations in BAR. Several calibrations for correcting spectral band parameters of specific minerals or meteorite

types have been developed in recent years (e.g., Burbine et al., 2009; Reddy et al., 2012c; Sanchez et al., 2012).

The first step in temperature correction of asteroid spectral band parameters is an estimation of the subsolar equilibrium surface temperature, T (Burbine et al., 2009)

$$T = \left[ \frac{(1 - A)L_0}{16\eta\varepsilon\sigma r^2} \right]^{1/4} \quad (1)$$

where A is the bolometric Bond albedo of the asteroid,  $L_0$  is the solar luminosity ( $3.827 \times 10^{26}$  W),  $\eta$  is the beaming parameter (assumed to be unity) (e.g., Cohen et al., 1998),  $\varepsilon$  is the asteroid's infrared emissivity (assumed to be 0.9),  $\sigma$  is the Stefan-Boltzman constant ( $5.67 \times 10^{-8}$  J s $^{-1}$  m $^{-2}$  K $^{-4}$ ), and r is the asteroid's distance from the Sun in meters. If the asteroid albedo A is unknown, a value can be assumed based on its taxonomic classification. The typical variation in the calculated temperature due to changes in the assumed parameters is in the range of  $\pm 10$  K (Burbine et al., 2009).

Burbine et al. (2009) developed equations to correct for temperature-induced spectral effects in V-type asteroids using spectra of bronzite and enstatite measured at various temperatures by Moroz et al. (2000). Reddy et al. (2012c) improved those temperature corrections by developing equations based on spectra of howardite-eucrite-diogenite (HED) meteorites over a range of temperatures (equations (2)–(5) in Table 1). These equations help derive a correction factor that is added to the Band I and II centers to obtain values at 300 K. Sanchez et al. (2012) derived similar equations for ordinary chondrites using temperature series from Moroz et al. (2000) and Hinrichs and Lucey (2002). They noted that the Band I center changes due to temperature are negligible and can be essentially ignored, and derived a temperature correction for the Band II center (equation (6) in Table 1). For monomineralic-olivine or olivine-rich A-type asteroids, Sanchez et al. (2014) derived temperature corrections using data from Hinrichs and Lucey (2002). Similar to previous equations, the Band I center correction is added to the Band I center before analysis (equation (8) in Table 1).

Band depth is also affected by changing temperature and causes an increase or decrease in BAR. Sanchez et al. (2012) derived equations to correct for temperature effects on BAR of ordinary chondrites. The correction derived using the equation below must be added to the calculated BAR value (equation (7) in Table 1). For olivine-dominated asteroids, the depth of the 1- $\mu\text{m}$  band changes with temperature. We derived an equation to correct Band I depth (%) for temperature effects using data from Hinrichs and Lucey (2002) (equation (9) in Table 1).

#### 3.2. Phase-Angle-Induced Spectral Effects

Phase-angle-induced spectral effects can be exhibited as phase reddening, which is characterized by an increase in spectral slope (reddening) and variations in albedo and absorption band depth with changing phase angle (Gradie

TABLE 1. Calibrations for correcting noncompositional effects.

Effect	Analog	Operation	Equation	Equation No.
Temperature	Howardites and eucrites*	Add to Band I Center	$\Delta BI(\mu\text{m}) = 0.01656 - 0.0000552 \times T (\text{K})$	(2)
		Add to Band II Center	$\Delta BI(\mu\text{m}) = 0.05067 - 0.00017 \times T (\text{K})$	(3)
	Diogenites*	Add to Band I Center	$\Delta BI(\mu\text{m}) = 1.7 \times 10^{-9} \times T^3 (\text{K}) - 1.26 \times 10^{-6} \times T^2 (\text{K}) + 2.66 \times 10^{-4} \times T (\text{K}) - 0.0124$	(4)
		Add to Band II Center	$\Delta BI(\mu\text{m}) = 0.038544 - 0.000128 \times T (\text{K})$	(5)
	Ordinary chondrites†	Add to Band II Center	$\Delta BI(\mu\text{m}) = 0.06 - 0.0002 \times T (\text{K})$	(6)
		Add to Band Area Ratio	$\Delta BAR = 0.00075 \times T (\text{K}) - 0.23$	(7)
	Olivine-rich A-type asteroids‡	Add to Band I Center	$\Delta BI(\mu\text{m}) = -(1.18 \times 10^{-7})T^2 + (2.15 \times 10^{-5})T + 0.004$	(8)
		Add to Band I Depth	$BI_{\text{depth corr}} = 0.0057 \times T (\text{K}) - 1.71$	(9)

\*Reddy *et al.* (2012c).†Sanchez *et al.* (2012).‡Sanchez *et al.* (2014).

*et al.*, 1980; Gradie and Veverka, 1986; Clark *et al.*, 2002; Mann *et al.*, 2011; Shepard and Cloutis, 2011) (Fig. 2). This effect, caused by a wavelength dependence of the single-scattering albedo, has been observed in both groundbased (e.g., Gehrels, 1970; Millis *et al.*, 1976; Lumme and Bowell, 1981; Nathues *et al.*, 2005; Nathues, 2010; Reddy *et al.*, 2012c) and spacecraft observations (Clark *et al.*, 2002; Bell *et al.*, 2002; Kitazato *et al.*, 2008) of small bodies. Asteroid observations need to be corrected for phase-angle effects because they can influence spectral slope and band depth, which are both nondiagnostic parameters. The equations de-

veloped to correct spectral band parameters for phase angle effects normalize them to 0° phase angle.

Reddy *et al.* (2012c) observed Vesta at different phase angles and quantified the effect on spectral slope. Based on these observations, they developed an equation to correct the visible spectral slope (0.4–0.7 μm) for phase angle effects

$$S_c = S - \gamma \alpha \quad (10)$$

where  $S_c$  is the phase angle corrected spectral slope,  $S$  is the measured spectral slope,  $\gamma = 0.0198\%/\mu\text{m}/\text{deg}$ , and  $\alpha$  is the phase angle in degrees. However, data from Dawn predict a similar trend but with less phase reddening (Li *et al.*, 2013) than that observed by Reddy *et al.* (2012c).

Similarly, Reddy *et al.* (2012c) developed an equation to correct the BAR for phase reddening based on groundbased near-IR spectral observations of Vesta

$$BAR_c = BAR - \gamma_3 \alpha \quad (11)$$

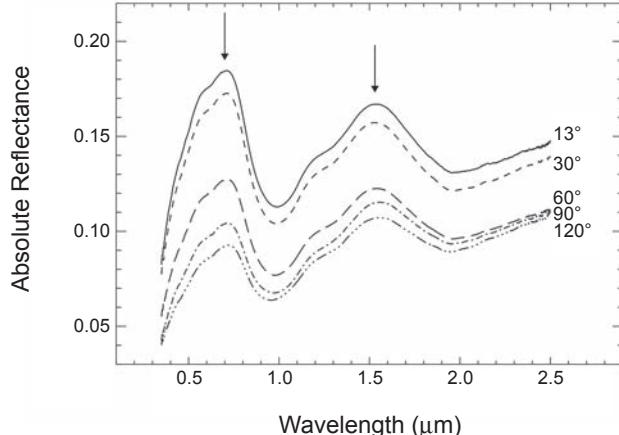

where  $BAR_c$  is the phase-angle-corrected BAR,  $\gamma_3 = 0.0292/\text{deg}$ , and  $\alpha$  is the phase angle in degrees.

Sanchez *et al.* (2012) did not find any systematic changes in BAR due to phase angle for ordinary chondrites. They did develop a phase angle correction for correcting Band I and II depths of olivine-pyroxene assemblages

$$BI_{\text{dep}} = BI_{\text{dep}} - 0.066 \times (\alpha) \quad (12)$$

$$BII_{\text{dep}} = BII_{\text{dep}} - 0.093 \times (\alpha) \quad (13)$$

where  $BI_{\text{dep}}$  and  $BII_{\text{dep}}$  are the corrected band depths (%) and  $\alpha$  is the phase angle. The phase angle range in which these equations are valid are between 2° and 70° for Band I and 2° and 55° for Band II. While these equations are valid for smaller grain sizes (<45 μm), a plethora of observational data of asteroids and laboratory studies of meteorites have shown that asteroid regolith contains, at a minimum, an optically dominant amount of fine grains.

**Fig. 2.** Laboratory near-IR spectra of Dhurmsala meteorite (LL6 ordinary chondrite) at different phase angles  $\alpha = 13^\circ$  (solid line),  $30^\circ$  (short dashed line),  $60^\circ$  (long dashed line),  $90^\circ$  (dot-short dashed line), and  $120^\circ$  (dot-long dashed line) from Sanchez (2012). The figure shows spectra that are not normalized or offset from each other. As the phase angle increases the overall reflectance decreases, and the two arrows show the dramatic decrease in reflectance at the two reflectance peaks of the spectra. The reflectance in the shorter wavelength end (blue region) of the spectrum decreases faster than the longer wavelength end (red) of the spectra with increasing phase angle creating the observed red slope (phase reddening).

## 4. FORMULAE FOR DERIVING ASTEROID COMPOSITIONS

### 4.1. Mafic Mineral Compositions

The correlation between mafic silicate compositions (i.e., mol% Fa in olivine and mol% Fs in pyroxene) and band centers is commonly used to determine asteroid compositions from VIS/NIR spectra. Because of the complex nature of the composite olivine band, most work has focused on the correlation between band centers and pyroxene composition. Gaffey *et al.* (2002) devised a set of equations defining the relationships between band centers and pyroxene compositions, where compositions are expressed as the calcium endmember wollastonite (Wo) and iron endmember ferrosilite (Fs). Although both pyroxene and olivine composition affect the position of Band I, the Gaffey calibrations removed the effect of olivine, thus allowing a single pyroxene composition to be measured.

The Gaffey *et al.* (2002) calibrations, while pioneering, have recently been shown to only work on a limited range of pyroxene compositions and are restricted to mineral assemblages containing a single pyroxene (Gaffey, 2007; McCoy *et al.*, 2007). This is a limitation when attempting to use these formulas on meteorite or asteroid mineralogies. For example, no formulas are available for Fs compositions above 50 mol%, which is the range of most Fe-rich eucrites (Burbine *et al.*, 2009). Also, these formulas can greatly overestimate the Fs content in samples containing more than one pyroxene, such as the ordinary chondrites (Gaffey, 2007; McCoy *et al.*, 2007). To address the problem of derived pyroxene compositions, Gaffey (2007) developed a procedure to correct for two-pyroxene assemblages. In this procedure, the BAR is used to determine an offset for Band I. The Band II position is corrected by compensating for the presence of augite. This is accomplished by subtracting a predetermined value from the measured Band II position (0.065  $\mu\text{m}$  for H chondrites, 0.062  $\mu\text{m}$  for L, and 0.076  $\mu\text{m}$  for LL) (Gaffey, 2007). The new Band I and Band II centers are then applied to the original Gaffey *et al.* (2002) equations, resulting in a single low-Ca pyroxene composition for H, L, and LL chondrite analogs. The correct analog is selected when the derived Fs and Wo values are consistent with measured values.

We tested the Gaffey *et al.* (2002) equations and subsequent corrections using 38 ordinary chondrites with pyroxene compositions analyzed by Dunn *et al.* (2010a). As per the guidelines established by the calibration, we selected the equations that satisfied each set of constraints (in terms of Wo and Fs content). In most cases, this was equations (2b) and (3a) from Gaffey *et al.* (2002). With corrections applied, the difference between measured and derived Wo values ranges from -8.3 mol% to +9.3 mol%, and 63% of derived Wo values are negative. This would suggest the Band I position is being overcorrected. Calculated Fs values are dependent on whether one is testing for H, L, or LL chondrites. Calculated Fs values do not differ substantially between the H and L chondrites, but LL chondrites values are always lower

(due to the higher correction factor). The difference between measured Fs values and Fs values calculated using the L chondrite correction range from -7.2 mol% to 9.1 mol%. Often the Fs content is either too low or too high to correctly classify the sample as H, L, or LL. Only 30% of H chondrites, 29% of L chondrites, and 43% of LL chondrites were classified correctly.

Despite the issues associated with using the Gaffey *et al.* (2002) pyroxene calibrations on ordinary-chondrite-like mineralogies, these calibrations are well suited for single pyroxene assemblages, such as the HED meteorites (e.g., Reddy *et al.*, 2010; Hardersen *et al.*, 2011, 2014). Any calibration for deriving mafic mineral compositions is most successful when designed and implemented for a limited range of mineral assemblages, such as those developed for the HEDs (Burbine *et al.*, 2007), the ordinary chondrites (Dunn *et al.*, 2010b), and olivine-rich meteorites (Reddy *et al.*, 2011) (Table 2). Each of these sets of calibrations is designed with a specific suite of meteorites and potential asteroid analogs in mind. The Burbine *et al.* (2007) calibrations (equations (14–17) from Table 2) were developed using a suite of 13 HED meteorites [basaltic achondrites believed to originate from asteroid (4) Vesta] (McCord *et al.*, 1970). Thus, the Burbine *et al.* (2007) calibrations are useful for deriving pyroxene chemistries of Vesta-like (V-type) asteroids. These calibrations are preferable to those of Gaffey *et al.* (2002) because they are simpler, are applicable to the entire range of pyroxene compositions in HEDs (Fs<sub>23–56</sub>; Wo<sub>2–14</sub>), and are more accurate (to within 3 mol% Fs and 1 mol% Wo).

Dunn *et al.* (2010b) developed formulas for deriving pyroxene and olivine compositions of the ordinary chondrites and asteroids with similar mineralogies (primarily S-types and Q-types). These formulas, one for Fa content in olivine and one for Fs content in pyroxene (equations (18) and (19) from Table 2), have low error (<2 mol%) and were developed based on the suggestion that the Band I center in the ordinary chondrites is controlled almost entirely by the abundance of FeO in olivine and pyroxene, and can therefore serve as a proxy for bulk FeO content. This also suggests that there is no significant correlation between Band I center and CaO content (mol% Wo) in meteorites and asteroids that consist of both olivine and pyroxene. However, we would expect CaO content to have a much more significant effect on band positions in pyroxene-dominated asteroids, such as the vestoids.

Recently, Reddy *et al.* (2011) added another formula to derive forsterite (Fo) content of olivine in meteorites and asteroids composed almost entirely of olivine (equation (22) from Table 2). The relationship between band position and olivine composition was first examined by King and Ridley (1987). Reddy *et al.* (2011) improved this calibration by adding more Mg-rich olivines (Fo<sub>85–93</sub>) to the sample suite. The root mean squared (RMS) error between measured values and laboratory derived Fo content is 5 mol%. This equation is designed to be used with A-type asteroids, which have a weak or nearly absent 2- $\mu\text{m}$  feature consistent with a monomineralic olivine composition.

TABLE 2. Calibrations for various meteorite mineralogies and their asteroid analogs.

Asteroid Type	Analog	Comp. Range	Equation	Error	Equation No.
V-types	HEDs*	$Fs_{23-56}, Wo_{2-14}$	$Fs = 1023.4 \times BIC - 913.82$	$\pm 3$ mol%	(14)
			$Fs = 205.9 \times BIIC - 364.3$	$\pm 3$ mol%	(15)
			$Wo = 396.1 \times BIC - 360.55$	$\pm 1$ mol%	(16)
			$Wo = 79.91 \times BIIC - 148.3$	$\pm 1$ mol%	(17)
S-types	Ordinary chondrites†	$Fa_{17-31}$	$Fa = -1284.9 \times (BIC)^2 + 2656.5 \times (BIC) - 1342.2$	$\pm 1.3$ mol%	(18)
		$Fs_{14-26}, Wo_{1-3}$	$Fs = -879.1 \times (BIC)^2 + 1824.9 \times (BIC) - 921.7$	$\pm 1.4$ mol%	(19)
			$ol/(ol + px) = -0.242 \times BAR + 0.728$	$\pm 0.03$	(20)
A-types	Lodranites/acapulcoites‡		$px/(ol + px) = 0.417 \times BAR + 0.052$		(21)
			$Fo = -1946.6 \times (BIC) - 2139.4$	$\pm 5$ mol%	(22)
			$ol/(ol + px) = -11.27 \times BAR^2 + 0.3012 \times BAR + 0.956$	$\pm 0.003$	(23)

¶Sanchez et al. (2014).

One must use caution when applying any of these calibrations to asteroids, as inaccurate derived mineralogies can lead to misinterpretation of asteroid geologic histories. Such is the case of Itokawa, the target of the Hayabusa mission (see section 6). Abell et al. (2007) suggested that Itokawa had experienced partial melting, based on its high-Fe pyroxene content, while others argued it was compositionally similar to the ordinary chondrites (e.g., Binzel et al., 2001; Abe et al., 2006; Okada et al., 2006). Itokawa's primitive origin (as an LL chondrite) was confirmed by the Hayabusa sample return mission (Nakamura et al., 2011). However, this extremely rare case of obtaining the “ground truth” for specific asteroids is only possible via sample return or terrestrial impact and recovery of an observed asteroid, such as 2008 TC<sub>3</sub>.

Figure 3 shows a decision-making flowchart for interpretation of asteroid spectra based on mineralogical calibrations that are available. In asteroids that show only a 1-μm absorption feature, iron abundance in olivine can be constrained using its Band I center position and equations from Reddy et al. (2011). For asteroids with 1- and 2-μm bands, similar calibrations exist depending on where the asteroid spectral band parameters plot on the Band I center vs. BAR plot (Gaffey et al., 1993). This Band I center vs. BAR plot is broken into S-type subclasses with different zones marking different compositional types. Asteroids in the S(IV) region can be mineralogically characterized using Dunn et al. (2010b) calibrations. Those that fall in the basaltic achondrite zone can be interpreted using calibrations from Gaffey et al. (2002) and Burbine et al. (2009). Meteorite analogs for these three asteroid types (olivine-rich A-type asteroids, S/Q-type asteroids, and V-type asteroids) constitute 91% of all the meteorites in our terrestrial collection (see the chapter by DeMeo et al. in this volume).

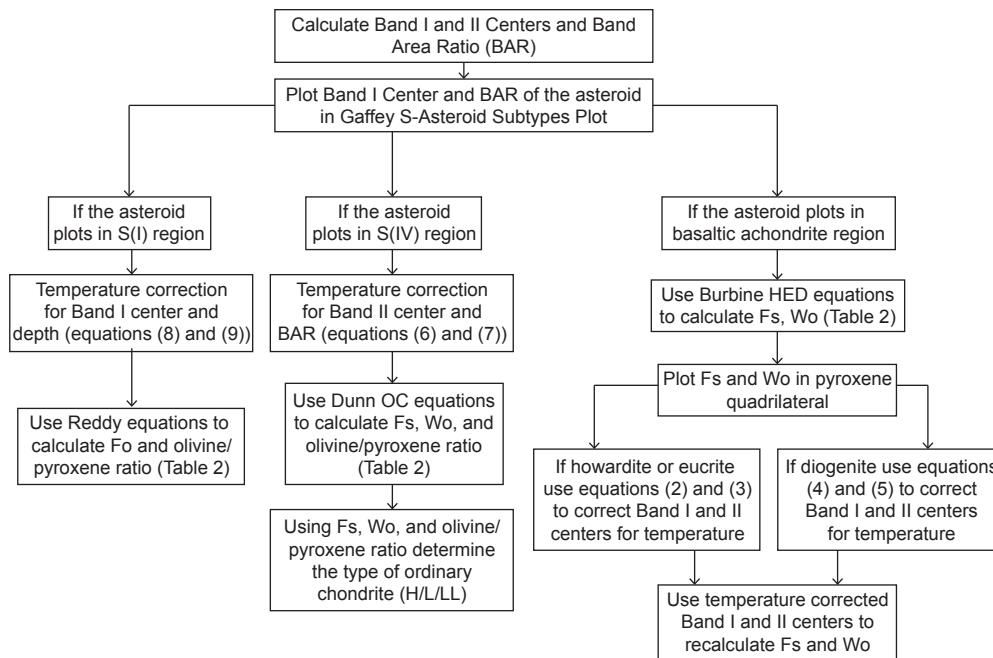

## 4.2. Mafic Mineral Abundances

In spectra containing both olivine and pyroxene absorptions, the combined absorption features near 1 μm (Band I)

and 2 μm (Band II) are also sensitive to the relative proportions of olivine and pyroxene. The ratio of the areas of these two bands (Band II/Band I) is commonly used to estimate olivine and pyroxene abundances in meteorites and asteroids (Cloutis et al., 1986). The linear relationship between BAR and the ratio of pyroxene to olivine + pyroxene [px/(ol + px)] was first recognized by Cloutis et al. (1986) (equation (21) from Table 2). However, the mixtures Cloutis et al. used to derive their equation did not contain clinopyroxene. As a result, their calibrations were not well suited for determining the BARs of mixtures containing more than one pyroxene (i.e., ordinary chondrites).

The Cloutis et al. calibration was initially designed to derive BARs from mixtures of known mineral proportions. However, this relationship between mafic mineral abundances and BAR is also an important tool for determining asteroid mineralogies from VIS/NIR spectra. Gastineau-Lyons et al. (2002) used this relationship to derive mineral abundances from measured BARs of asteroid spectra. However, because the original Cloutis et al. (1986) regression was based on simple mixtures of olivine and orthopyroxene, the presence of more than one pyroxene (or other additional phases) complicated spectral interpretations of asteroids made using this calibration (Gaffey et al., 1993; Sunshine et al., 2004).

In an attempt to develop BAR calibrations that were more useful in asteroid spectroscopy, Burbine et al. (2003) used normative abundances of the ordinary chondrites (abundances calculated from measured bulk chemistry) to derive a calibration for the S-type asteroids. The most recent revision of the calibrations for S-type asteroid mineralogies was produced by Dunn et al. (2010b) (equation (20) from Table 2). Dunn et al. used measured modal abundances of ~50 ordinary chondrite powders to derive their calibrations. Modes were determined using a position-sensitive X-ray diffraction technique (Dunn et al., 2010a), which allows for measurement of phases present at abundances as low as 1 wt% (Cressey and Schofield, 1996). Using this technique, Dunn et al. (2010b) were able to account for pigeonite, the

**Fig. 3.** Flowchart showing a decision making tree for mineralogical characterization of A-, S-, and V-type asteroids using equations from Reddy et al. (2011), Dunn et al. (2010b), and Burbine et al. (2007).

third pyroxene present in the ordinary chondrites. Because this regression was derived using measured abundances (as opposed to abundances calculated using CIPW norms), it provides a more accurate measure of olivine and pyroxene abundances from VIS/NIR spectra.

Gaffey et al. (2002) suggested that pyroxene abundances could be constrained even further by considering the effect of high-Ca pyroxene on Band II position, which they suggested is a linear function of the relative abundance of the two pyroxenes. This assertion requires that the cpx/(opx + cpx) ratio is well-correlated with Band II center in the range of values found in ordinary chondrites. Using XRD-measured pyroxene abundances and Band II centers, Dunn et al. (2010b) derived an equation for establishing the ratio of high-Ca pyroxene to total pyroxene. However, this equation yielded a very low  $R^2$  value of 0.15. The remarkably low  $R^2$  value indicates that there is no significant correlation between Band II position and relative pyroxene abundance in the ordinary chondrites.

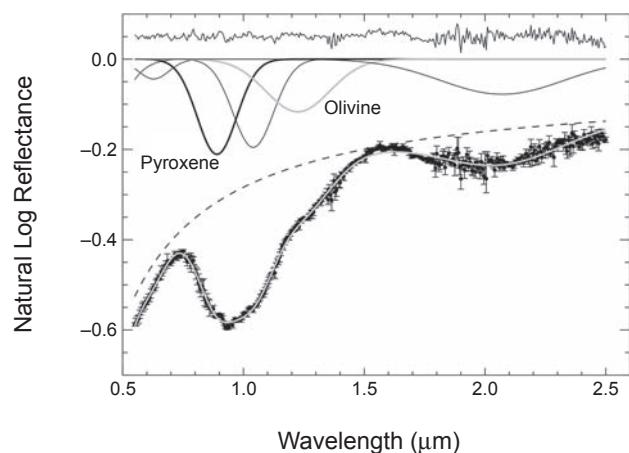

Although the Dunn et al. (2010b) regression formula is well suited for asteroids with ordinary-chondrite-like compositions (e.g., some S-types and Q-types), it is not as equally well suited for asteroids with other mineralogies. For example, the original calibration of Cloutis et al. (1986) is still better suited for asteroids that are compositionally similar to primitive achondrites (lodranites and acapulcoites), which are primarily mixtures of low-Ca pyroxene and olivine (e.g., McCoy et al., 2000). The Dunn et al. (2010b) calibrations would not work well for mineralogies that are dominated by only one mafic phase (i.e., either olivine or pyroxene, but not both). Recently, Sanchez et al. (2014) developed a calibra-

tion for olivine-rich asteroids using the R chondrites (equation (23) from Table 2), which contain higher abundances of olivine than the ordinary chondrites (65–78%) (Bischoff et al., 2011). Initial tests of this calibration yield abundances in strong agreement with previous characterizations. However, it is important to note that this calibration was developed using a limited sample selection (only seven R chondrites). Also, although R chondrites provide a good spectral match with olivine-dominated asteroids, their compositions may differ (Sanchez et al., 2014). Consequently, any interpretations made using the Sanchez et al. (2014) formula should be taken with caution. Additional laboratory measurements will be necessary to improve the robustness of this calibration.

## 5. SPECTRAL MODELING

### 5.1. Modified Gaussian Model

Composite mineral absorption bands can be deconvolved into discrete mathematical functions. The modified Gaussian model (MGM) (Sunshine et al., 1990) constructs a model spectrum from one or more modified Gaussian functions to represent absorption features from individual species (Fig. 4). These modified Gaussians are physically motivated by crystal field theory and represent the relationship between the natural log of reflectance and energy (Sunshine et al., 1990). In comparison to ordinary Gaussians, these modified functions include the addition of a power law index of  $n = -1$  to their energy dependence. Each MGM band is associated with three degrees of freedom (center, width, depth). The full model includes a continuum, which is typically linear

**Fig. 4.** Modified Gaussian model of asteroid (25143) Itokawa. From bottom to top: asteroid data with error bars (black), best-fit model (gray), model continuum (dashed), six Gaussian bands used in the model, and residuals from the model fit. The Gaussian band centered around 0.9  $\mu\text{m}$  (thick black line) is attributed to pyroxene (pyx), while the band around 1.2  $\mu\text{m}$  (thick gray line) is attributed to olivine (ol). The ratio of these bands' strengths provides a means for comparison to equivalent models of OC meteorite spectra. This comparison correctly predicts an LL-type composition for Itokawa (Binzel *et al.*, 2001).

in energy space and adds two free parameters for slope and offset. Initial values for all these parameters are specified at the onset of modeling and are iteratively adjusted until a best fit is determined by minimizing the RMS residuals of the difference between reflectance data and the model spectrum.

The MGM was originally employed to analyze laboratory spectra of terrestrial and meteorite samples (Sunshine *et al.*, 1990; Sunshine and Pieters, 1993) and has since been extensively applied to mafic silicate systems including the Moon (e.g., Isaacson *et al.*, 2011), Mars (e.g., Clenet *et al.*, 2013), and a variety of asteroid types. In its most basic implementation, the MGM can be used as a simple band analysis tool to measure band parameters, analogous to those discussed in section 3. Using the MGM to derive band parameters is beneficial because it can serve as a consistent analysis tool that does not vary from one implementation to the next. This is not necessarily the case with other band analysis techniques that may employ different methodologies (e.g., Cloutis *et al.*, 1986; Moskovitz *et al.*, 2010; Dunn *et al.*, 2013). Standardizing a tool like the MGM for measuring band parameters can facilitate comparisons across investigations, but does require that continua be modeled in a consistent manner.

The MGM has been employed as a band analysis tool in several studies of near-Earth asteroids. Rivkin *et al.* (2004) showed that the MGM could reliably recover Band I areas for S-type NEAs in cases where only near-IR spectra were available and the 1- $\mu\text{m}$  band was not fully resolved. These authors defined the MGM-derived ratio of band areas (RBA) parameter as an analog to BAR for spectra where visible

data were not available. Although not extensively tested, the RBA reasonably reproduces compositions for objects with well-constrained mineralogy like Itokawa and Eros. Vernazza *et al.* (2008) and Thomas and Binzel (2010) extended the use of the MGM as a band analysis tool to link H, L, and LL ordinary chondrites to their asteroidal counterparts in near-Earth space. The MGM has also been used to correlate the band parameters of V-type asteroids with subgroups of the HED meteorites (Mayne *et al.*, 2011).

In its full implementation the MGM is used to model specific mineral absorption bands. This can involve diagnosing the origin of unknown features (e.g., Hiroi *et al.*, 1996) or starting with *a priori* assumptions about composition to generate a mineralogical model (e.g., Mayne *et al.*, 2011). For example, the relative strengths of pyroxene and olivine bands in the vicinity of 1  $\mu\text{m}$  led Binzel *et al.* (2001) to correctly predict an LL-chondrite-like composition for (25143) Itokawa (Fig. 4). Analyses of other S-complex asteroids suggest that the MGM can constrain the relative abundance of high-Ca to low-Ca pyroxene. For example, Sunshine *et al.* (2004) found high-Ca pyroxene abundances >40% for the large main-belt asteroids (17) Thetis, (847) Agnia, and (808) Merxia, thus implying that these objects experienced high degrees of partial melting consistent with a history of igneous differentiation.

The three overlapping 1- $\mu\text{m}$  olivine bands, as seen in the spectra of A-type asteroids, are particularly well suited to MGM analysis, despite their sensitivity to space weathering (e.g., Brunetto *et al.*, 2007) and temperature (e.g., Lucey *et al.*, 1998). Using the MGM, Sunshine *et al.* (2007) showed that A-type asteroids segregate into two groups based on olivine composition. Those with magnesian (forsteritic) compositions suggest an igneous history involving the differentiation of ordinary chondrite precursors, whereas those with ferroan (fayalitic) compositions are more consistent with an origin tied to oxidized R-chondrite precursors. K-type asteroids in the Eos family have also been associated with an olivine-dominated composition (Mothé-Diniz *et al.*, 2008).

Due to their prominent 1- and 2- $\mu\text{m}$  absorption features, pyroxene-dominated V-type asteroids have been extensively modeled with the MGM. Traditional band analyses of these asteroids (section 3) have generally focused on deriving bulk pyroxene composition (e.g., Wo, Fs, and En numbers), whereas MGM analyses are typically used to measure the abundance ratio of high-Ca to low-Ca pyroxene. These different approaches can provide complementary insight when performed in tandem (e.g., Lim *et al.*, 2011). MGM analyses of V-type asteroids suggest that very roughly 25–40% of their total pyroxene is in the high-Ca phase (Duffard *et al.*, 2006; Mayne *et al.*, 2011), consistent with the pyroxene composition of the HED meteorites (Mittlefehldt *et al.*, 1998) and therefore supporting the generally accepted link between these asteroids and meteorites.

Like any compositional analysis tool the MGM has limitations. Perhaps its greatest weaknesses are the dependence on multiple free parameters in even relatively simple mineralogical models and the sensitivity of those parameters

to prescribed initial conditions. Without careful application these issues can produce nondiagnostic or degenerate fits.

## 5.2. Radiative Transfer Models

Models of radiative transfer on atmosphereless bodies generally involve computing reflectivity (i.e., scattering and phase-corrected single-scattering albedo) based on optical constants and particle sizes of specific mineral species. Reflectivity is computed as a function of assumed viewing geometry and is rooted in approximations of geometric optics. Radiative transfer models can provide insight into particle sizes, mineral compositions, and mineral abundances.

Various approaches have been developed to treat the presumably chaotic structure and mixture of mineral grains in planetary regoliths. The approximation of an areal or linear mixture involves computing the reflectance from mineral phases separately and then linearly combining those to represent the total reflectance. This “checkerboard” approach assumes the constituent minerals are optically separated so that multiple scattering does not occur between minerals. Intimate, nonlinear, or “salt-and-pepper” mixtures involve computing an average single-scattering albedo of the mineral constituents as input to the reflectivity calculation. The sizes of particles relative to the incident wavelength of light determine how the single-scattering albedo is calculated in such homogeneous mixtures (Shkuratov *et al.*, 1999; Poulet *et al.*, 2002).

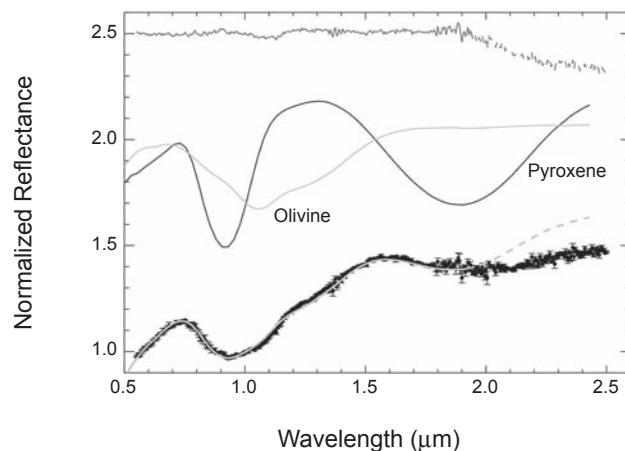

Radiative transfer models are some of the most widely used tools for compositional analyses of planetary bodies. The theory outlined by Hapke (1981) and since improved upon in a number of subsequent publications (Hapke, 1984, 1986, 2001, 2002, 2008) was one of the first to derive the single-scattering albedo for a grain with prescribed size and optical properties. Shkuratov *et al.* (1999) developed a similar but alternative model that employs a distinct treatment of particle scattering. A detailed review and comparison of these two implementations is presented in Poulet *et al.* (2002). More recently, Lawrence and Lucey (2007) expanded upon the Hapke formalism by incorporating the spectral effects of coarse-grained Fe-Ni metal to facilitate modeling of the metal-rich assemblages frequently encountered in small-body studies, thus enabling studies of the effects of space weathering on mafic silicate bodies like the Moon, basaltic achondrites, and ordinary chondrites. Finally, Lucey and Riner (2011) introduced a new treatment of large, opaque iron agglutinates as a way to model the optical effects of weathering via impact and shock-alteration processes.

Such radiative transfer models have been used for a variety of asteroid applications. Based on spectrophotometry from the Near Earth Asteroid Rendezvous (NEAR) mission, Clark *et al.* (2001, 2002) modeled near-IR spectra of the S-type NEA (433) Eros and were able to disentangle viewing geometry, grain size, composition, and surface weathering effects as causes of color and albedo variability across the asteroid’s surface. Clark *et al.* (2004) applied the same model to E-type asteroids and found that this single taxonomic class could actually be broken into three compositional groups:

objects like (44) Nysa with enstatite-like compositions that include a low-iron orthopyroxene component, objects like (64) Angelina composed of forsterite olivine and oldhamite, and objects like (434) Hungaria, which may be linked to the enstatite-rich aubrite meteorites.

Several variants of radiative transfer models have been used to address issues related to space weathering. Employing a variant of the Shkuratov model, Vernazza *et al.* (2008) showed that the majority of S-type NEAs, in spite of their weathered appearance, have compositions most similar to LL ordinary chondrites (Fig. 5). This is surprising in light of the fact that LL chondrites are rare among ordinary chondrite meteorite falls and may be a result of selection bias influencing the delivery of meteorites from the main belt to Earth. This same model was employed to argue that the timescale of space weathering is a rapid  $\sim 10^6$  yr (Brunetto *et al.*, 2006; Vernazza *et al.*, 2009a); however, this result remains somewhat controversial (Willman and Jedicke, 2011). As such, it is currently unclear how effective these models are in connecting the timescales of space weathering to observed spectral changes.

This particular implementation of the Shkuratov model (Vernazza *et al.*, 2008) does not attempt to fit data beyond  $\sim 2 \mu\text{m}$  due to ineffectiveness of the applied space-weathering model (Fig. 5). However, this implementation has been used exclusively to derive olivine to pyroxene abundance ratios, information that is entirely contained in the 0.6–1.6- $\mu\text{m}$  spectral range and therefore is not dependent on the properties of the 2- $\mu\text{m}$  band. As such, future work to derive silicate

**Fig. 5.** Shkuratov model of asteroid (25143) Itokawa. From bottom to top: asteroid data with error bars (black), best fit model (gray), spectra of mineral endmembers olivine (ol) and low-Ca pyroxene (pyx) used in the model, and residuals from the model fit. This model, based on Vernazza *et al.* (2008), assumes 50% porosity on the asteroid’s surface and only fits the data between 0.55 and 2  $\mu\text{m}$  due to inaccuracy in the treatment of space weathering at longer wavelengths (for details, see Brunetto *et al.*, 2006). This model suggests a composition of  $\text{ol}/(\text{ol} + \text{low-Ca pyx}) = 76\%$ , consistent with the known LL-chondrite composition of Itokawa.

abundances could benefit from exclusive focus on spectral information contained within the 1- $\mu\text{m}$  region.

Primitive compositions have also been modeled with radiative transfer techniques. The spectra of primitive asteroid types (e.g., C- and D-types) are generally red-sloped and largely devoid of prominent absorption features, particularly at visible and near-IR wavelengths. Thus, compositional models of these objects can be less specifically diagnostic, instead providing upper limits on mineral abundances. For example, *Cruikshank et al.* (2001) argued that the surface of the Trojan asteroid (624) Hektor contained <3 wt% water ice and <40% hydrated silicates. Their models further suggested that an unknown low-albedo, spectrally neutral material, potentially analogous to elemental carbon, is responsible for the red color and low albedo of D-type asteroids. *Emery and Brown* (2004) expanded upon this work by modeling the spectra of 17 Trojans. Their results are consistent with *Cruikshank et al.* (2001), suggesting that the Trojan's red spectral slopes are unlikely due to organics and that the Trojan's overall spectral properties may be attributed to a combination of anhydrous silicates and carbonaceous material. Based on data at thermal-IR wavelengths, *Emery et al.* (2006) modeled the emissivity spectra of several Trojans to argue for compositions due to fine-grained silicates embedded within an optically transparent matrix. *Yang and Jewitt* (2011) largely corroborated this result and suggested that Trojan silicates should be iron-poor to account for spectral data at both near-IR and thermal-IR wavelengths. Finally, *Yang et al.* (2013) modeled Trojan spectra to suggest a composition with small quantities of fine-grained silicates (1–5 wt%) and a low-albedo component (2–10 wt%) embedded within a matrix of salt deposits. In spite of these advances, full compositional characterization of Trojan asteroids remains an unsolved problem.

Perhaps the best examples of featureless spectra that evade compositional characterization are those belonging to the asteroid (21) Lutetia. Even though Lutetia was the target of a spacecraft flyby (see the chapter by Barrucci et al. in this volume), radiative transfer models suggest its composition consists of weathered goethite (*Rivkin et al.*, 2011), a hydrated iron-bearing mineral, whereas spectral matching to laboratory samples suggests a very different composition, more analogous to enstatite chondrites (*Vernazza et al.*, 2009b).

Spectral data at longer wavelengths (>3  $\mu\text{m}$ ) can better diagnose specific compositions on primitive asteroids. For example, radiative transfer models have provided specific insight into the presence of hydrated minerals on primitive asteroids (e.g., *Rivkin et al.*, 2006; *Rivkin and Emery*, 2010; *Campins et al.*, 2010). Compositional analysis at mid-IR wavelengths remains a major frontier of asteroid science (see the chapter by Rivkin et al. in this volume).

## 6. COMPOSITIONAL CONSTRAINTS FROM MID-INFRARED OBSERVATIONS

In the mid-IR wavelength region spectral bands are chiefly due to vibrational and lattice modes. The resulting reflectance and emission spectra in these wavelengths are

strongly dependent on surface parameters such as grain size (e.g., *Lyon*, 1964; *Hunt and Logan*, 1972; *Salisbury et al.*, 1991a; *Le Bras and Erard*, 2003) and porosity (*Aronson et al.*, 1966; *Logan et al.*, 1973; *Salisbury et al.*, 1991b), as well as environmental conditions such as ambient pressure (*Logan et al.*, 1973; *Salisbury and Walter*, 1989).

### 6.1. Diagnostic Spectral Features in the Mid-Infrared

Laboratory studies of powdered meteorites and silicate minerals display a variety of diagnostic spectral signatures: Christiansen features, Restrahlen bands, transparency features, and absorption bands. The Christiansen feature is a reflectance minimum (emissivity maximum) located ~7.5–10  $\mu\text{m}$  in most silicates. In this wavelength region the real part of the refractive index changes rapidly (dropping through unity) and therefore may approach the refractive index of the medium surrounding the mineral grains, resulting in minimal scattering. The location where the real refractive index equals unity is the Christiansen frequency (e.g., *Logan et al.*, 1973). For silicates, the Christiansen frequency occurs at a shorter wavelength than the Restrahlen band, where scattering is minimal and the absorption coefficient is small. The resulting reflectance minimum (the Christiansen feature) is often located at longer wavelengths than the Christiansen frequency. *Hapke* (1996) interpreted this feature as occurring due to a transition between the surface and volume scattering regimes. Past work (*Conel*, 1969; *Logan et al.*, 1973; *Salisbury and Walter*, 1989) has noted that the wavelength of the Christiansen feature is an indicator of mineral composition. The wavelength of the Christiansen feature for individual minerals depends on the polymerization of the mineral with the feature occurring at shorter wavelengths for feldspars and longer wavelengths for mafic minerals such as olivine and pyroxene (*Logan et al.*, 1973). For a given asteroid or meteorite, the Christiansen feature is the combination of the characteristic Christiansen features of all the constituent minerals. Often times the principal Christiansen feature corresponds to the strongest molecular vibration band. However, in the case of some meteorites, the individual Christiansen features are far enough apart that numerous local reflectance minima are seen.

Restrahlen bands are the result of strong fundamental molecular vibrations. For silicates they appear at ~8.5–12  $\mu\text{m}$  and are the product of Si-O asymmetric stretching (e.g., *Lyon*, 1964; *Hunt*, 1982; *Salisbury et al.*, 1991b). These bands appear as peaks in reflectance and troughs in transmittance (*Vincent and Hunt*, 1968) and are centered on the short wavelength side of the maximum of the imaginary index. In this wavelength region the absorption coefficient and specular reflectance are high (*Salisbury et al.*, 1987a), causing most incident radiation not to enter the sample and instead be reflected on the first surface. *Lyon* (1964) showed that Restrahlen bands are difficult to detect in the spectra of particulate minerals because of multiple occurring reflections, which increase the proportion of photons that enter the medium and are absorbed. Therefore, the height of Restrahlen

bands decreases with decreasing grain size (*Salisbury et al.*, 1987b; *Le Bras et al.*, 2003). A second group of less intense Restrahlen bands occurs between  $\sim 16.5$  and  $25\text{ }\mu\text{m}$  and is associated with Si-O-Si bending. Restrahlen features of silicates shift to longer wavelengths when heavier cations are in the lattice structure since they slow the frequency of the molecular vibrations. Meteorite spectra (*Salisbury et al.*, 1991a) show that the Restrahlen region is dominated by olivine and pyroxene. These spectra from *Salisbury et al.* (1991a) also demonstrate the slight shift to longer wavelengths with increasing iron content that can be seen in the ordinary chondrite's progression from more forsteritic olivine (H chondrites) to more fayalitic olivine (LL chondrites).

Between the two Restrahlen bands, the spectra of particulate silicates are dominated by a broad reflectance maximum (emissivity minimum) known as the transparency feature. The absorption coefficient is low enough in this region that silicate grains are optically thin and volume scattering dominates the scattering process. The feature is dependent on the presence of small particles ( $<75\text{ }\mu\text{m}$ ) and changing optical constants (*Salisbury et al.*, 1987b; *Salisbury and Walter*, 1989; *Mustard and Hays*, 1997). Laboratory spectra of silicate minerals demonstrate that the wavelengths of the transparency peaks and Christiansen features are diagnostic of composition and are correlated with each other (*Logan et al.*, 1973; *Salisbury et al.*, 1987b; *Salisbury and Walter*, 1989; *Hapke*, 2012).

Absorption features in the mid-IR are present at various wavelengths. For primitive carbonaceous chondrites, the most prominent absorption feature is the O-H stretching vibration feature near  $3.0\text{ }\mu\text{m}$  (*Salisbury and Hunt*, 1974; *Miyamoto*, 1988). This absorption feature tends to increase in spectral contrast as particle size is reduced below  $75\text{ }\mu\text{m}$  since the continuum reflectance rises with increasing scattering (*Salisbury and Walter*, 1989; *Salisbury et al.*, 1991b).

Crystalline olivines have strong diagnostic absorption features between  $9$  and  $12\text{ }\mu\text{m}$  (due to Si-O stretches) as well as several other minor bands at longer wavelengths. All olivine bands shift to shorter wavelengths with decreasing Fe/(Fe + Mg) content (*Koike et al.*, 2003) and decreasing temperature (*Koike et al.*, 2006). Crystalline pyroxenes have absorption features at similar but slightly shorter wavelengths than the olivines. Most of these features shift to shorter wavelengths with decreasing Fe/(Fe + Mg) content, except the  $10.5$ - and  $11.5\text{-}\mu\text{m}$  bands, which shift to longer wavelengths (*Chihara et al.*, 2002). Past spectral studies of crystalline olivine and pyroxene under a variety of laboratory conditions include *Mukai and Koike* (1990), *Koike et al.* (1993), *Jager et al.* (1998), *Henning and Mutschke* (1997), *Pitman et al.* (2010), and *Lane et al.* (2011). Amorphous olivines and pyroxenes have broad absorption features near  $10\text{ }\mu\text{m}$  with a weaker band near  $20\text{ }\mu\text{m}$ . Laboratory investigations of these amorphous silicates include *Day* (1981), *Koike and Hasegawa* (1987), *Scott and Duley* (1996), and *Brucato et al.* (1999).

Mid-infrared (or thermal) reflectance spectra ( $5$ – $25\text{ }\mu\text{m}$ ) of crystalline olivines and pyroxenes with various compositions and grain sizes are available at the ASTER spectral

library (<http://speclib.jpl.nasa.gov>) (*Baldridge et al.*, 2009). Additional data, including optical constants and references, are available at JPDOC (<http://www.astro.uni-jena.de/Laboratory/Database/jpdoc/f-dbase.html>) (*Henning et al.*, 1999).

## 6.2. Astronomical Observations in the Mid-Infrared

One key difference between mid-IR spectral laboratory data and mid-IR astronomical observations of asteroids is surface pressure. *Logan et al.* (1973) first demonstrated that decreasing the atmospheric pressure for a particulate sample results in an increase in spectral contrast, a shift to shorter wavelengths of the Christiansen feature, and potential loss of the transparency feature. These spectral changes are due to the fact that the space environment introduces thermal gradients in a particulate sample that alter the spectral features. At lower pressures a sharp thermal gradient occurs, as less or almost no interstitial gas is present to convectively transport heat. In a vacuum, the sample is heated by the absorption of radiation in visible wavelengths to a depth that is dependent on the absorption coefficient in visible wavelengths, and the sample emits to a cooler background in infrared wavelengths over a depth dependent on the absorption coefficient in infrared wavelengths. For silicates, the absorption coefficient for visible wavelengths is much smaller than the absorption coefficient in near-infrared wavelengths. This results in an emitting layer of particles that is shallower than the absorbing layer. Different wavelength regions in the spectrum are effectively sampling the two different temperatures, which increases the emissivity contrast.

In addition to surface pressure, grain size effects can also hinder mid-IR astronomical observations of asteroids. Various authors (e.g., *Lyon*, 1964; *Salisbury et al.*, 1987a; *Le Bras and Erard*, 2003) have demonstrated that the prominent Restrahlen features are difficult to detect for particulate surfaces and that the strength of the Restrahlen features varies inversely proportionally to particle size. Grain size effects can also impact attempts to apply spectral deconvolution techniques to mid-IR data. Past work has demonstrated that mid-IR spectra represent linear combinations of the abundances of the individual components (*Lyon*, 1964; *Thomson and Salisbury*, 1993; *Ramsey and Christensen*, 1998; *Hamilton and Christensen*, 2000). The effectiveness of linear spectral deconvolution techniques for asteroid surfaces is dependent on the particle size of the regolith. *Ramsey and Christensen* (1998) found that linear deconvolution fails for grain sizes below  $10\text{ }\mu\text{m}$  where nonlinear volume scattering dominates.

Finally, another important factor to consider when using astronomical observations of asteroids to determine silicate mineralogy is the presence of significant Si-O absorption features in the mid-IR spectra of observed standard stars. *Cohen et al.* (1992) identified the Si-O fundamental absorption in stellar spectra. Prior to that, early work to investigate asteroids using mid-IR spectroscopy was hindered by insufficient understanding of the nature of the standard stars (e.g., *Gillet and Merrill*, 1975; *Green et al.*, 1985).

The Kuiper Airborne Observatory (KAO) and the European Space Agency's Infrared Space Observatory (ISO) observed several large asteroids in the 1990s. KAO spectra (5–14  $\mu\text{m}$ ) of (1) Ceres showed three potential emission features, but no mineralogical match was identified (Cohen *et al.*, 1998). The ISO spectra (6–12  $\mu\text{m}$ ) showed evidence of silicates on the surface (Dotto *et al.*, 2000) and made connections between (10) Hygiea and (511) Davida and the CO and CM carbonaceous chondrites (Barucci *et al.*, 2002; Dotto *et al.*, 2002).

### 6.3. Recent Advances in Mid-Infrared Asteroid Spectroscopy

Since *Asteroids III*, there have been several notable works connecting mid-IR spectroscopy of asteroids to meteorites and silicate mineralogies. Much of the work in this area has focused on the 3- $\mu\text{m}$  region where hydrated silicates have a distinct absorption feature. This spectral feature was discussed in great detail in *Asteroids III* (Rivkin *et al.*, 2002). Recent work by Takir and Emery (2012) classified 3- $\mu\text{m}$  asteroid spectra into four distinct groups, demonstrating that there was thermal stratification of outer main-belt asteroids early in the history of the solar system. The asteroids that had experienced aqueous alteration (the “sharp” group) are located in the  $2.5 < a < 3.3 \text{ AU}$  region, while those that remained unaltered (the “rounded” group) are in the  $3.3 < a < 4.0 \text{ AU}$  region.

Lim *et al.* (2005) performed a survey of 29 asteroids using 8–13- $\mu\text{m}$  spectra. Their analysis identified emissivity features for (1) Ceres, which were similar to those seen by Cohen *et al.* (1998) with KAO and Dotto *et al.* (2000) with ISO. No definitive mineralogy was established. They also noted a marginal detection of features for (4) Vesta, which matched features found in HED meteorites (Salisbury *et al.*, 1991a). Work by Lim *et al.* (2011) attempted to establish a formalism for connecting features in the emissivity spectra of the V-type asteroid (956) Elisa to those seen in the spectra of HED meteorites.

Emery *et al.* (2006) presented mid-IR (5.2–38  $\mu\text{m}$ ) spectra of three Trojan asteroids: (624) Hektor, (911) Agamemnon, and (1172) Aneas. Using spectra of fine-grained silicates from the ASTER spectral library, they concluded that the spectra are characteristic of either small silicate grains imbedded in a relatively transparent matrix or small silicate grains in a very underdense (fairy castle) surface layer. Mid-infrared (8–33  $\mu\text{m}$ ) spectra of (617) Patroclus by Mueller *et al.* (2010) showed similar emissivity features, suggesting that the object has mineralogy much like that of the other observed Trojans.

The work of Vernazza *et al.* (2010) showed spectral variability between mid-IR spectra of eight S-type asteroids, which previous analyses using visible and near-infrared spectroscopic techniques had determined were of similar compositions. The analysis concluded that the variability was due to differences in the regolith particle size and space-weathering effects. The authors indicated that the asteroids are covered with a very-fine-grained regolith ( $< 5 \mu\text{m}$ ) that conceals some spectral features.

Vernazza *et al.* (2012) noted that while emission features on asteroids in the mid-IR spectral region were common, the asteroid spectra do not always match the laboratory spectra of minerals and meteorites. The authors demonstrated that by suspending the meteorite and mineral powders in potassium bromide powder, which is transparent in the infrared, and were able to recreate the spectra of main-belt asteroids with emissivity spectra. The work suggests that these asteroids have extremely porous regolith layers.

Irradiation experiments of the Tagish Lake meteorite demonstrated a small shift to longer wavelengths of the 10- $\mu\text{m}$  silicate emission feature that is likely caused by the amorphization of the silicates (Vernazza *et al.*, 2013). They used a combination of albedo with visible, near-IR, and mid-IR spectra to determine that Tagish Lake-like objects are a very small percentage of the main-belt population and that (368) Haidea is the best match to the meteorite's spectrum and albedo.

## 7. CONSTRAINTS FROM SPACECRAFT MISSIONS

Starting with the Galileo flyby of asteroids (951) Gaspra and (243) Ida, spacecraft investigations of asteroids have provided validation for groundbased spectroscopic studies. More recently, the Japanese Hayabusa and NASA's Dawn missions have completed detailed mineralogical studies of asteroids (25143) Itokawa and (4) Vesta, respectively, from orbit. The Hayabusa mission has also brought back microscopic samples of Itokawa that have helped immensely in the confirmation of precursor telescopic observations. Initially the surface composition of Eros was ambiguous, with derived compositions ranging from H-L-LL chondrites to primitive achondrites (McFadden *et al.*, 2001; Izenberg *et al.*, 2003; McCoy *et al.*, 2002). Further analysis of spectral observations of Eros by the Near-Infrared Spectrometer (NIS) and Multispectral Imager (MIS) on NEAR suggested a surface composition consistent with a space-weathered L6 ordinary chondrite (Nittler *et al.*, 2001; McCoy *et al.*, 2002; Izenberg *et al.*, 2003). McFadden *et al.* (2005) reported evidence for partial melting based on MGM analysis of Eros reflectance spectra. This debate between partial melt vs. space-weathered L6 chondrite was further fueled by the results from the NEAR X-Ray Spectrometer (XRS) experiment, which discovered strong sulfur depletion. Nittler *et al.* (2001) argued that the best explanation for the depletion is space weathering on an ordinary-chondrite-type object.

Similar to Eros, the surface composition of near-Earth asteroid (25143) Itokawa was the subject of much debate prior to the arrival of the Hayabusa spacecraft at the target object and subsequent return of the asteroid's samples to Earth. Binzel *et al.* (2001) interpreted the surface composition of Itokawa to be a space-weathered LL chondrite with 0.05% nanophase iron on the surface. In contrast, Abell *et al.* (2007) argued that the mean pyroxene chemistry of Itokawa ( $\sim\text{Fs}_{43\pm5}\text{Wo}_{14\pm5}$ ), estimated from its spectrum using calibrations from Gaffey *et al.* (2002), indicated a surface that

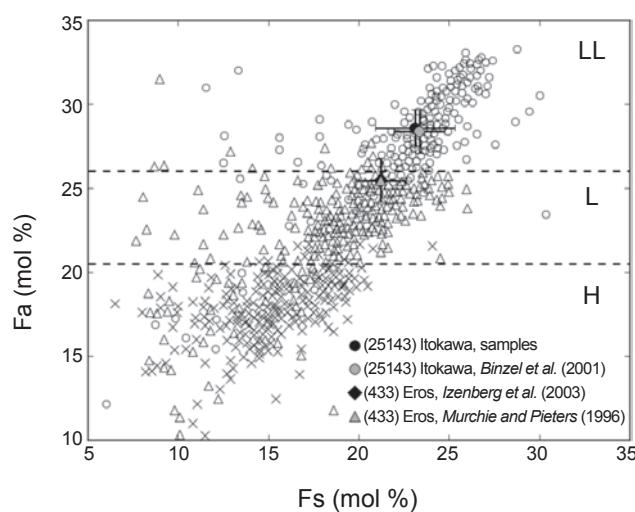

experienced partial melting. Analysis of samples returned by the Hayabusa spacecraft (Nakamura et al., 2011) has shown that Itokawa is indeed an LL chondrite as suggested by Binzel et al. (2001). Mineralogical analysis of the returned samples and the availability of newer spectral calibrations from Dunn et al. (2010b) provide us with an opportunity to validate groundbased spectral interpretive tools.

We used the spectral band parameters of Itokawa from the IRTF (Binzel et al., 2001; Abell et al., 2007) to calculate its olivine and pyroxene ratios and chemistries and to compare them with laboratory-measured values from samples returned by the Hayabusa spacecraft. Figure 6 (reproduced from Nakamura et al., 2011) shows olivine iron abundance (fayalite) on the Y-axis and pyroxene iron abundance (ferrosilite) on the X-axis from laboratory measurements of ordinary chondrites (H, L, and LL), Itokawa samples returned by the Hayabusa spacecraft (black circle), and those derived from the groundbased telescopic spectrum (gray circle) using the Dunn et al. (2010b) calibrations. The difference between laboratory measured values of Itokawa samples and those from groundbased spectral data is less than 1 mol%, confirming Itokawa as an LL chondrite and attesting to the

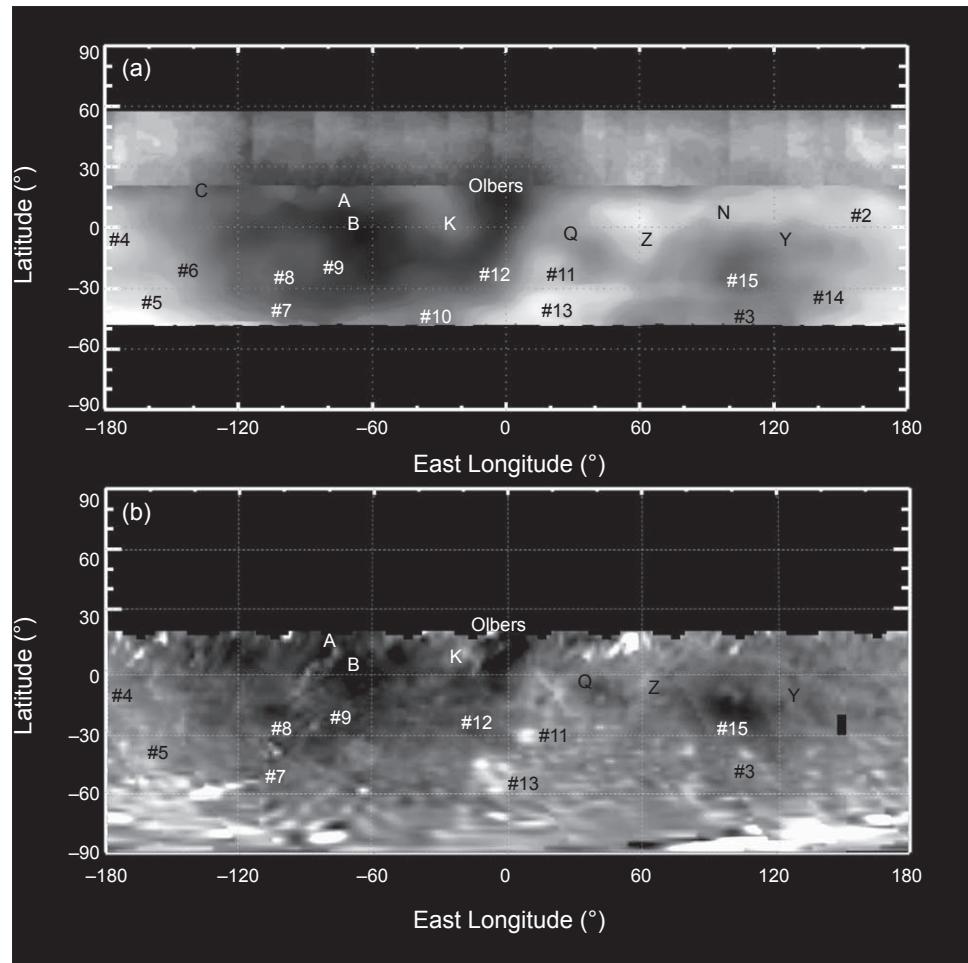

validity of the Dunn et al. (2010b) calibrations. Similarly, we used spectral band parameters for Eros from the NIS instrument on NEAR spacecraft (Izenberg et al., 2003) and groundbased spectral data (Murchie and Pieters, 1996) to calculate its olivine and pyroxene chemistries to (1) check for consistency between the two datasets, and (2) validate the L chondrite interpretation by Izenberg et al. (2003). Figure 6 also shows fayalite and ferrosilite values for Eros calculated from NEAR and groundbased spectral data. These results validate the Izenberg et al. (2003) interpretation that Eros' surface composition is similar to an L chondrite rather than a partial melt, as proposed by McFadden et al. (2005).

NASA's Dawn spacecraft completed a year-long mission to characterize asteroid (4) Vesta (Russell et al., 2012), mapping the surface with a multi-color Framing Camera (FC) (Reddy et al., 2012a; Jaumann et al., 2012), a VIS/NIR spectrometer (VIR) (De Sanctis et al., 2012a), and a gamma-ray and neutron detector (Prettyman et al., 2012). Prior to Dawn's arrival, Vesta had been the most studied asteroid in the asteroid belt (e.g., Gaffey, 1997; Reddy et al., 2010; Thomas et al., 1997a; Binzel et al., 1997; Li et al., 2010), with nearly 100 years of spectral observations dating back to the early part of the last century (Bobrovnikoff, 1929). Many groundbased and Hubble Space Telescope (HST) observations of the vestan surface were confirmed by the Dawn mission, such as the hemispherical albedo dichotomy between the eastern and western hemisphere (Reddy et al., 2013), which was proposed based on monomodal photometric lightcurve observations of Vesta (Li et al., 2010). Like many observations, this was confirmed by comparing groundbased and HST albedo and compositional maps of Vesta (Gaffey, 1997; Binzel et al., 1997; Li et al., 2010) to multi-color camera data from the Dawn mission (Reddy et al., 2010). Figure 7 shows albedo features identified first in HST images (Binzel et al., 1997; Li et al., 2010) and then by the Dawn spacecraft. Features are annotated to show positive identification of geological features on both datasets.

While groundbased and HST observations of Vesta matched those made by Dawn, the interpretation of certain features was enhanced due to better spatial resolution of the spacecraft data. Of particular interest to the groundbased spectroscopy community was the "olivine-rich" unit named "Leslie feature" in the Gaffey (1997) IRTF map of Vesta. Rotationally resolved spectra of Vesta showed a drop in BAR when this feature rotated into view. Le Corre et al. (2013) identified this as the Oppia crater and its surrounding ejecta blanket, but suggested that this drop in BAR was due to the presence of impact melt in the ejecta blanket rather than olivine. The rotational compositional variation between the northern and southern hemispheres, where the South Pole Rheasilvia basin excavated more diogenetic material (Reddy et al., 2010), was also confirmed by Dawn FC and VIR data (Reddy et al., 2012a; De Sanctis et al., 2012a). Dawn observations also confirmed the Hasegawa et al. (2003) hypothesis that the vestan surface was contaminated by carbonaceous chondrite impactors (Reddy et al., 2012b; McCord et al., 2012; De Sanctis et al., 2012b; Prettyman et al., 2012). This

**Fig. 6.** Plot showing olivine iron content (mol% fayalite) on the Y-axis and pyroxene iron content (mol% ferrosilite) on the X-axis from laboratory measurements of ordinary chondrites (H, L, and LL). Fayalite and ferrosilite values from Itokawa samples (Nakamura et al., 2011) and spectrally derived values using Binzel et al. (2001) IRTF telescopic spectra data are also shown. Spectrally derived values were calculated using equations from Dunn et al. (2010b). The difference between the olivine and pyroxene iron content between the two datasets is less than 1 mol% and plot in the LL chondrite zone as predicted by Binzel et al. (2001). Also shown, fayalite and ferrosilite values for (433) Eros from Murchie and Pieters (1996) (groundbased spectral data) and Izenberg et al. (2003) (NEAR NIS spectral data). The Fs and Fa values for Eros are identical and fall in the L-chondrite region of the plot. Figure adapted from Nakamura et al. (2011).

**Fig. 7.** (a) HST map of Vesta in 0.673- $\mu\text{m}$  filter projected in the Thomas *et al.* (1997a) coordinate system based on observations from 1994, 1996, and 2007 oppositions at a resolution of  $\sim$ 50 km/pixel. (b) Dawn FC map of Vesta in 0.75- $\mu\text{m}$  filter from Rotational Characterization 1 (RC1) phase at a resolution of 9.06 km/pixel with prime meridian similar to the Thomas *et al.* (1997a) coordinate system. The maps show corresponding bright features and dark features identified by Binzel *et al.* (1997) and Li *et al.* (2010). Figure reproduced from Reddy *et al.* (2013).

hypothesis was initially based on the groundbased identification of an OH absorption band at 2.8  $\mu\text{m}$ . Results from the Dawn mission have provided the groundbased spectroscopy community an opportunity to verify nearly a century of observations of Vesta.

## 8. ASTEROIDS WITH DERIVED MINERALOGIES

The challenges to link a meteorite with a particular parent body or source body are daunting. A parent body is the original body that the meteorite formed on, while the source body is a larger fragment of the original parent body that is the direct source of the meteorite. Lunar meteorites were easily identified (e.g., Marvin, 1983) due to their similarity in mineralogy and chemistry to returned Apollo samples. Martian meteorites were identified (e.g., Bogard and Johnson,

1983), in part, by the similarity of gas abundances found in meteoritic glasses and the composition of the martian atmosphere analyzed by the Viking spacecraft. The only instance in which a link between a meteorite and its asteroid source has been made with complete certainty is the Almahata Sitta meteorite and near-Earth asteroid 2008 TC<sub>3</sub>, which impacted the atmosphere in October 2008. Fragments of the asteroid “rained” down over the Sudan, then were collected and identified as a ureilites (Jenniskens *et al.*, 2009).

Apart from a compositional link, a dynamical pathway to deliver meteorites from an asteroid to Earth is needed. While challenges remain, we can now attempt to dynamically link an asteroid with a meteorite group, since the Yarkovsky effect (Bottke *et al.*, 2006) is known to be able to supply small fragments ( $<10$  km) to meteorite-supplying resonances across vast regions of the asteroid belt. Bottke *et al.* (2010) argues that the Yarkovsky effect allows asteroid families

far from meteorite-supplying resonances to dominate the meteorite flux. This allows all asteroids in the main belt to contribute meteorites to our terrestrial collection.

A few strong cases can be made for linkages between observed asteroids and meteorite types, such as those discussed in *Asteroids III*: (4) Vesta, (6) Hebe, and (3103) Eger. Asteroid (4) Vesta ( $a = 2.36$  AU) has been known since the 1970s to have visible (McCord et al., 1970) and near-IR (Larson and Fink, 1975) spectral properties similar to HEDs. This spectral similarity was confirmed by the Dawn mission and reinforced by bulk elemental composition of Vesta's surface, which are also similar to HEDs (Reddy et al., 2012a; De Sanctis et al., 2012a; Prettyman et al., 2012). Although Vesta's location in the asteroid belt makes it difficult to produce a significant flux of fragments to the 3:1 and  $v_6$  meteorite-supplying resonances (Wetherill, 1987), numerous V-type members of the Vesta family (called vestoids) populate the inner main belt between meteorite-supplying resonances ( $a = 2.22\text{--}2.49$  AU) (Binzel and Xu, 1993) and could serve as potential source bodies. Recently a number of V-types have also been identified in the outer asteroid belt (Lazarro et al., 2000; Hardersen et al., 2004). Although it is very difficult to dynamically move a body from the inner belt to the outer belt, the presence of a number of eucrites with distinctly different oxygen isotopic ratios than most HEDs implies that there could be multiple eucrite parent bodies (McSween et al., 2011), some of which could reside in the outer belt. The recovery of Bunburra Rockhole meteorite (anomalous eucrite) with an Aten-type orbit, delivered to Earth via  $v_6$  resonance from the inner main belt, serves as an additional evidence for multiple basaltic parent bodies (Bland et al., 2009).

S-type asteroid (6) Hebe ( $a = 2.43$  AU) was postulated as the parent body of the H chondrites and IIE iron meteorites based on its spectral parameters, large diameter ( $\sim 200$  km), and location near the 3:1 and  $v_6$  resonances (Gaffey and Gilbert, 1998). Recent modeling by Bottke et al. (2010) has confirmed that these resonances are probable source regions of the H chondrites. In addition, asteroid (695) Bella, located near the 3:1 resonance, has been interpreted as having a mineralogy similar to H chondrites (Fieber-Beyer et al., 2012).

E-type near-Earth asteroid (3103) Eger ( $a = 1.41$  AU) has been linked with the aubrite meteorites based on its high albedo, flat reflectance spectrum, and absorption feature at  $\sim 0.5 \mu\text{m}$  (Gaffey et al., 1992; Burbine et al., 2002). In the last decade a number of additional E-type asteroids have been observed to have spectral properties consistent with aubrites (Kelley and Gaffey, 2002; Clark et al., 2004; Fornasier et al., 2008). Many of these bodies, such as (434) Hungaria, are found among the Hungarias ( $a = 1.78\text{--}2.06$  AU) (McEarchen et al., 2010). The relatively old median cosmic-ray-exposure age of aubrites, compared to other meteorite groups, is consistent with being derived from bodies in the Hungaria region (Cuk et al., 2012). Spectra of E-type asteroid (2867) Šteins ( $a = 2.36$  AU), the target asteroid of the Rosetta mission, are also consistent with an aubrite composition (e.g., Markus et al., 2013).

Since the publication of *Asteroids III*, much of the focus on asteroid-meteorite connections has been on the L and LL chondrites. The (1272) Gefion family ( $a = 2.70\text{--}2.82$  AU) has been proposed by Bottke et al. (2005) and Nesvorný et al. (2009) to be the source of the L chondrites. The Gefion family is composed primarily of S-type objects (Bus, 1999) and has an estimated age that is consistent with the 470-Ma shock event (Korochantseva et al., 2007) found in L chondrites. Estimated cosmic-ray-exposure ages of fragments of the Gefion family, traveling through the 5:2 resonance, are consistent with L chondrites (Nesvorný et al., 2009). A few observed Gefion family members have interpreted mineralogies roughly consistent with L chondrites (Blagen, 2012; Roberts and Gaffey, 2014); however, this is not the case for all observed members (Roberts and Gaffey, 2014).

A relatively large percentage of observed near-Earth asteroids have spectral features and interpreted mineralogies similar to LL chondrites. In fact, approximately two-thirds of S- and Q-type NEAs studied by Vernazza et al. (2008) have olivine/(olivine + pyroxene) ratios similar to LL chondrites. The same is true for members of the (8) Flora family ( $a = 2.16\text{--}2.40$  AU), which is located near the  $v_6$  resonance. However, Gaffey (1984) argued that (8) Flora has a nonchondritic mineralogy due to interpreted mineralogical variations that are not consistent with an undifferentiated surface. The LL-chondrite mineralogy of at least one S-type asteroid, (25143) Itokawa, has been confirmed by the Hayabusa sample return mission (Nakamura et al., 2011). The Chelyabinsk, Russia, meteorite is also an LL chondrite, although the exact parent body is still debated. Reddy et al. (2014) suggested that it might be a fragment of the Flora asteroid family based on mineralogical analysis, while de la Fuente Marcos and de la Fuente Marcos (2013) suggested that the most likely source body was 2011 EO<sub>40</sub>, although its composition is unknown.

Another recent link has been made between the CM chondrites and Ch-type asteroids (13) Egeria ( $a = 2.58$  AU) and (19) Fortuna ( $a = 2.44$  AU) (Fornasier et al., 2014). Both objects have a distinctive spectral feature at  $0.7 \mu\text{m}$  that is only found in the spectra of CM meteorites. Vilas and Gaffey (1989) showed that spectra of dark asteroids showed diagnostic carbonaceous chondrite-like absorption bands. Burbine (1998) argued that the location of these bodies near meteorite-supplying resonances would be extremely favorable to supplying meteorites to Earth from these bodies, since the relatively fragile CM chondrites would not be expected to be able to survive long in space. However, a number of other asteroids have been classified as Ch-types (Bus and Binzel, 2002; DeMeo et al., 2009) and could also be potential CM chondrite parent bodies. Fieber-Beyer et al. (2012) identified (1358) Gaika, which is also located near the 3:1 resonance, as having an interpreted mineralogy similar to CM chondrites.

## 9. OUTSTANDING QUESTIONS AND FUTURE DIRECTIONS

Despite the advances in asteroid spectroscopy over the last decade, including our ability to constrain the mineralogies of

asteroids from which ~90% of meteorites in our terrestrial collection come, several challenges remain ahead, including our inability to identify parent bodies of iron meteorites.

1. With the addition of each new calibration for deriving asteroid mineralogy, our ability to characterize the mineralogies of asteroid surfaces improves significantly. However, because different formulas work better for different assemblages, caution must be used when applying these calibrations to any asteroid spectrum. Additional laboratory characterization of samples is necessary before a complete working inventory of calibrations for deriving mineralogies from VIS/NIR spectra can be developed.

2. Currently, we do not have a reliable method to constrain the mineralogy of most carbonaceous C-type asteroids, M-type asteroids, and primitive-achondrite-type asteroids. Our inability to treat complex mineralogies is the biggest challenge as we move ahead into the next decade of small-body characterization. Some recent advances have been made in showing that most carbonaceous chondrites (widely believed to derive from C-type asteroids) do exhibit absorption features that are diagnostic of their mafic silicates and calcium-aluminum-rich inclusions (*Cloutis et al.*, 2010, 2012).

3. Future work is needed to better establish relationships between MGM-derived bands and their corresponding mineralogical interpretations, particularly for compositions relevant to asteroids. Such calibrations exist for lunar and martian compositions, but are less common for asteroid studies.

4. Future work in radiative transfer modeling of regolith systems should continue to examine the importance of assumptions about particle sizes, shapes, compositions, and particle size distributions. For example, the treatment of complex particles such as agglutinates and impact glasses remains largely unexplored, but could be an important component of future modeling efforts. The planned sample return missions OSIRIS-REx and Hayabusa-2 will ultimately provide ground truth to improve upon the accuracy of radiative transfer models.

5. The availability (or lack) of optical constants for minerals relevant to asteroidal compositions can be a limitation of radiative transfer models. Radiative transfer methods are most effective at constraining compositions for S- and V-type asteroids (and their meteoritic counterparts) due to the wide availability of optical constants for Fe-bearing silicates (e.g., *Lucey et al.*, 1998; *Denevi et al.*, 2007; *Trang et al.*, 2013). These models are not as successful in treating Fe-poor systems such as Mercury (*Lucey and Riner*, 2011). Of potential importance to the compositional interpretation of asteroids such as M-types is the need for optical constants of opaque minerals beyond those measured for iron metal (*Cahill et al.*, 2012). There is also a need for improved optical constants at UV wavelengths (particularly for silicates), where little compositional modeling of asteroids has been conducted.

**Acknowledgments.** The authors are grateful for the comments of the editor (F. DeMeo) and two reviewers (P. S. Hardersen and E. A. Cloutis), whose comments helped to improve this chapter.

V.R. would like to thank J. A. Sanchez for valuable comments on the effects of temperature and phase angle on near-IR spectra and L. Le Corre for Vesta maps used in this chapter. N.A.M. is grateful to S. Lawrence for reviewing the Hapke modeling section. Support for V.R. to carry out this effort came from NASA Planetary Geology and Geophysics Grants NNX14AN35G (PI: Reddy) and NNX14AN05G (PI: Gaffey), as well as NASA Planetary Mission Data Analysis Program Grant NNX14AN16G (PI: Le Corre). V.R., C.A.T., N.A.M., and T.H.B. were visiting astronomers at the Infrared Telescope Facility, operated by the University of Hawai‘i under contract to the National Aeronautics and Space Administration.

We have long known that water and hydroxyl are important components in meteorites and asteroids. However, in the time since the publication of *Asteroids III*, evolution of astronomical instrumentation, laboratory capabilities, and theoretical models have led to great advances in our understanding of H<sub>2</sub>O/OH on small bodies, and spacecraft observations of the Moon and Vesta have important implications for our interpretations of the asteroidal population. We begin this chapter with the importance of water/OH in asteroids, after which we will discuss their spectral features throughout the visible and near-infrared (IR). We continue with an overview of the findings in meteorites and asteroids, closing with a discussion of future opportunities, the results from which we can anticipate reading in *Asteroids V*. Because this topic is of broad importance to asteroids, we also point to relevant in-depth discussions elsewhere in this volume.

## 1. WATER ICE SUBLIMATION AND PROCESSES THAT CREATE, INCORPORATE, OR DELIVER VOLATILES TO THE ASTEROID BELT

### 1.1. Accretion/Solar System Formation

The concept of the “snow line” (also known as the “water-frost line”) is often used in discussing the water inventory of small bodies in our solar system. The snow line is the heliocentric distance at which water ice is stable enough to be accreted into planetesimals. The placement of the snow line has varied in different models. A location just inside Jupiter helps explain the greater mass of the giant planets as they accrete a larger fraction of the mass in the solar nebula. Although the location of the snow line before and during planet formation

is uncertain, some studies show it may have fallen within the asteroid belt (*Lunine and Reid*, 2006). The location of the snow line in our solar system coinciding with the asteroid belt is consistent with observations of disks around other stars (e.g., *Su et al.*, 2013), where planetesimal rings tend to coincide with the snow line around those stars. However, it seems the relatively simple concept of a static snow line requires revisions in light of new results on several fronts. For instance, the snow line likely moved with time as the Sun’s luminosity changed early in solar system history (e.g., *Martin and Livio*, 2012). Even though there is no agreement on the details of planetesimal formation and growth, some models favor the growth of ~100-km-scale planetesimals directly from centimeter-scale pieces (*Morbidelli et al.*, 2009; *Cuzzi et al.*, 2010; for a dissenting view see *Weidenschilling*, 2011). Hence the timing of those assemblies as conditions change

could have a strong influence on the amount of radioactive elements present in a planetesimal's interior and on its rock-to-ice ratio, further complicating the concept of a snow line. Recent observations also point to a more complex picture. For example, the concept of an asteroid-comet continuum, where there is no clear boundary between primitive asteroids and cometary nuclei (e.g., *Gounelle*, 2011), is gaining support and is consistent with the intermittent cometary behavior of some main-belt and near-Earth asteroids (NEAs) (e.g., *Hsieh and Jewitt*, 2006; *Licandro et al.*, 2007, 2011b; *Jewitt et al.*, 2013; *Mommert et al.*, 2014), which will be discussed in more detail in section 1.3 below. The chapter by Johansen et al. in this volume summarizes the current state of thought about asteroid formation.

## 1.2. Grand Tack/Nice Model Delivery of Outer Solar System Material

One of the main motivations for studying the asteroid belt is to better understand the conditions in the solar nebula and the material that formed the terrestrial planets. The distribution of spectroscopic asteroid types is not randomly mixed, but instead follows a trend with heliocentric distance (*Chapman et al.*, 1975; *Gradie and Tedesco*, 1982), which has long been interpreted as a remnant property of the solar nebula. However, discoveries of extrasolar planets and other planetary systems have greatly broadened our notions of what is “normal” and “typical.” Also, increasing computational capabilities have allowed ever more realistic and detailed models of accretion, and are now challenging long-held ideas of what we thought we knew about solar system formation. The asteroid belt is an important key to constraining and testing these models.

Dynamical models suggest the asteroid belt of today may be very different from when it formed. *Bottke et al.* (2012) argue that the asteroid belt once extended significantly sunward compared with today, with the Hungaria region the eroded remnant of a once-larger population. Similarly, there are arguments that Vesta formed closer to the Sun and was later transported into the main asteroid belt (*Bottke et al.*, 2006). More importantly for the discussion here, the “Nice Model” (*Gomes et al.*, 2005; *Morbidelli et al.*, 2005; *Tsiganis et al.*, 2005), which has gained wide acceptance, predicts a large influx of volatile-rich objects from the outer solar system to the inner solar system and the insertion of primitive transneptunian objects (TNOs) into the outer belt (*Levison et al.*, 2009).

The related “Grand Tack” model (*Morbidelli et al.*, 2010; *Walsh et al.*, 2011) interprets the low-albedo asteroids as originating among the giant planets, with later delivery to their current positions in the main asteroid belt by the migration of Jupiter. *Walsh et al.* (2011) and references therein describe how the original material in the asteroid belt would be disturbed by inward migration of Jupiter, leaving only the inner asteroid belt intact, scattering some of these objects outward behind it as it moves. After Saturn moves into resonance with Jupiter, both begin to migrate

outward, and some of the previously scattered objects are scattered back into the asteroid belt region, along with other more volatile-rich objects (perhaps the antecedents of the C-complex asteroids) that may have formed closer to 5 AU.

This scenario solves the problem of having both high- and low-temperature materials side by side in the asteroid belt. However, it means that the compositional gradient with heliocentric distance is not primordial, and allows a larger amount of radial mixing than previously considered. The problem of linking meteorites to their asteroid parent bodies also becomes more complex, since the current position of the asteroids may be unrelated to where those bodies formed. However, asteroid families, collisional fragments of once intact parent bodies, are nearly all spectrally uniform, while many meteorites clearly show that differentiation has occurred. Differentiated objects can form closer to the Sun, and be emplaced in the asteroid belt by Jupiter during its migration. Undifferentiated objects form farther out, and are scattered inward by Jupiter. Both can now exist side by side, but neither is necessarily representative of material that condensed at 2–4 AU.

## 1.3. Hydroxyl/Water Creation Via Space Weathering

Although the term “space weathering” is usually associated with nanophase iron (or iron sulfide) embedded in glassy rims of silicate grains and the links between S-class asteroids and ordinary chondrites, the processes that form these rims (and npFe<sup>0</sup> particles) can also involve water and OH.

*Starukhina* (2001), modeling the interaction of solar wind protons with regolith, predicted that OH and its diagnostic 3-μm absorption band should always be present on airless bodies. While the quantitative results have not been borne out [for instance, Vesta has a 3-μm band depth ~2% at its deepest (*De Sanctis et al.*, 2012a), compared to the ~20–70% depth predicted by Starukhina], it was one of the first treatments attempting to predict the effects of space weathering in that spectral region. Thoughts on how the spectrum of airless bodies might change near 3 μm with exposure to typical regolith processes have varied from a prediction of dehydration (Pieters, personal communication) to the creation of bands (e.g., *Starukhina*, 2001) to no appreciable effect (*Rivkin et al.*, 2003).

The spectral models by Starukhina followed decades of lunar-centered work by other researchers. *Arnold* (1979) investigated ice survivability on the Moon, following up the work of *Watson et al.* (1961). Arnold proposed that solar wind reduction of iron in the lunar regolith, such as is now implicated in space weathering (*Noble et al.*, 2001), could create significant amounts of water, which could then potentially make its way to cold traps in permanently shadowed craters near the lunar poles. Lunar Prospector data shows a hydrogen enhancement near the lunar poles, interpreted as due to ice (*Feldman et al.*, 2001). The independent observation of 3-μm bands on the Moon by three spacecraft [Visible and Infrared Mapping Spectrometer (VIMS) on Cassini (*Clark*, 2009), High Resolution Instrument (HIR) on

the Deep Impact (DI) spacecraft (*Sunshine et al.*, 2009), the Moon Mineralogy Mapper (M<sup>3</sup>) on Chandrayaan-1 (*Pieters et al.*, 2009)] provided convincing evidence of OH on the Moon. While interpretations are continuing to evolve, the early consensus seems to be that the band is due, at least in part, to adsorbed water and OH likely created by the interaction of solar wind protons and silicates in the lunar regolith. The presence of ice at the lunar poles is consistent with formation of water in the regolith via solar wind interactions, but other potential water sources have been identified [such as retention and migration of cometary volatiles after impacts (e.g., *Stewart et al.* 2011)], and solar wind interaction is not the only possible origin for lunar water. The relative contribution and importance of any solar-wind-created water to any ice deposits is not yet fully understood.

The presence of water on the lunar surface potentially reopens interpretations of asteroidal (and other small body) surfaces. However, the small bodies also provide an opportunity to better understand the lunar results. If the 3-μm band seen on the Moon is due to the implantation of solar wind protons in the lunar regolith, this absorption band should also be present on other small body surfaces, with allowances made for the increased distance from the Sun and other factors. If independent of local composition, as suggested by the high-spatial-resolution M<sup>3</sup> data, most asteroids should have similar effects when under similar conditions. If temperature sensitive, as suggested by the DI data, differences may be seen with solar distance. If due to photometric effects but not temperature, a well-conceived program of NEA observations should be able to separate those effects. These are still active areas of research, with a better understanding of the relationship between regolith processes and hydroxyl/water content likely over the next decade.

In addition to the possibility of solar wind protons creating water or hydroxyl, space weathering processes may have additional effects on asteroidal surfaces. *Britt et al.* (2014) argued that the micrometeorite and ultraviolet (UV) processes that create nanophase iron in silicates would, given their different mineralogies, instead create amino acids on carbonaceous bodies like the C asteroids. They suggest that space weathering, when viewed from a thermodynamic standpoint, involves decomposition of rock-forming minerals with results depending on specific composition. In their view, this decomposition is only the first stage of space weathering, with a second stage using the results of that decomposition as catalysts. For the volatile-rich carbonaceous chondrites and their parent asteroids, not only silicates but water, carbon monoxide, and other volatiles can interact via Fischer-Tropsch reactions to create ever-longer carbon chains and kerogen-like insoluble organic matter, as is seen in carbonaceous chondrites. This line of research is still in its infancy, and the observational consequences and predictions are not yet fully understood, particularly in the context of water. Previous work on space weathering of carbonaceous chondrites and/or low-albedo asteroids has focused on changes in spectral slope rather than how it may alter absorptions associated with hydrated minerals.

#### 1.4. Delivery of Exogenic Hydrated Material

It has been proposed that dark material identified on the surface of asteroid (4) Vesta by NASA's Dawn spacecraft was delivered by low-velocity impacts with carbonaceous chondritic material (*Reddy et al.*, 2012). Several lines of evidence support this interpretation, including elemental composition (*Prettyman et al.*, 2012), near-infrared (IR) spectra (*McCord et al.*, 2012), geomorphology (*Denevi et al.*, 2012), and analogy with HED meteorites, especially howardites (*Reddy et al.*, 2012, and references therein). These findings confirm reports of a weak absorption near 3 μm in groundbased spectroscopy of Vesta by *Hasegawa et al.* (2003) and *Rivkin et al.* (2006), who suggested that impacts with carbonaceous objects could have added to the original igneous surface composition.

Visible images from the Dawn spacecraft place most of the dark material in the oldest regions of Vesta's surface. Initially two sources for this dark material were considered: ancient volcanic activity or exogenic material. However, convergence among the different observational constraints points to an exogenic origin for the dark material; further details appear in the chapter by Russell et al. in this volume.

The same exogenic source of hydrated carbonaceous chondritic material on Vesta is proposed by *Shepard et al.* (2015) to explain a 3-μm absorption feature, often attributed to the presence of hydrated minerals (*Rivkin et al.*, 2000), on a number of M-class asteroids with the high radar reflectivity suggestive of a high metal content. In a related result, *Landsman et al.* (2013) reported the detection of 3-μm absorption features on five M-class asteroids recently observed at these wavelengths. *Landsman et al.* (2013) also report considerable diversity in the shape of the hydrated mineral feature in their M-class asteroid sample. However, the M class in general contains a great deal of variety, and objects with low radar reflectivity and 3-μm bands also appear in this class. It seems likely that at least some M asteroids do not have high metal content. Further discussion of the M-class asteroids is found in section 3.3.4.

Interestingly, exogenic processes have also been invoked by *Bottke et al.* (2010, 2013), who argued that impact debris from the irregular satellites of the jovian planets should be driven onto the regular satellites of those systems, and could have accumulated to a depth of tens or even hundreds of meters on the Galilean satellites. The irregular satellites are further discussed below.

## 2. DISCUSSION OF SPECTRAL FEATURES ON ASTEROIDS AND METEORITES

While two sample returns to low-albedo asteroids are slated for the next decade (section 6.2), remote sensing will by necessity remain the primary method for detecting and characterizing the hydrated mineralogies of large numbers of small bodies. Three wavelength regions are primarily used for this purpose, each with their own strengths and limitations: the visible and near-IR spectral region (~0.4–0.8 μm),

the 3- $\mu\text{m}$  region, and the mid-IR (5–13  $\mu\text{m}$ ). An overview table of the most important absorption bands is presented in Table 1. Other wavelengths are used in cometary studies, for instance, but have not been used at asteroids due to an expectation of very low contrast and very meager gas production rates from asteroids. Other techniques, such as groundbased radar or submillimeter observations, may give indirect evidence for the presence of hydrated minerals (Hanson *et al.*, 2006), but our understanding of the relationship between radar albedo and hydrated minerals is incomplete. The meteorites have given us most of our information about the specific minerals present in the asteroids and the aqueous alteration processes that occurred early in solar system history. We discuss the spectral properties of the hydrated minerals and aqueous alteration products below, but details of the minerals in and processes experienced by the meteorites themselves, and the conditions under which they were created and operated, are discussed in detail in the chapter by Krot *et al.* in this volume.

We note that there are additional ways to detect water/OH and other volatiles, such as neutron spectrometers like the one carried by Dawn, or via sounding with radar instruments like the Shallow Radar (SHARAD) instrument on the Mars Reconnaissance Orbiter (MRO) (Seu *et al.*, 2004). These may be the only methods for directly detecting volatiles on some objects, particularly those for which surface volatiles are unstable. We acknowledge that such measurements are particularly valuable, but are out of the scope of discussion in a chapter devoted to “astronomical observations.”

## 2.1. Visible/Near-Infrared

An absorption band centered near 0.7  $\mu\text{m}$  is seen in asteroids as well as the CM meteorites. The absorption has classically been attributed to  $\text{Fe}^{2+}$ - $\text{Fe}^{3+}$  intervalence charge transfer, associated with phyllosilicates but not diagnostic of them (Vilas and Gaffey, 1989; Vilas, 1994; King and Clark, 1997). Cloutis *et al.* (2011a) attributes bands near 0.7  $\mu\text{m}$  to saponite group phyllosilicates (band centers 0.59–0.67  $\mu\text{m}$ ) and “mixed valence Fe-bearing serpentine group phyllosilicates” (band centers 0.70–0.75  $\mu\text{m}$ ). Unlike

the Ch asteroids, for which the 0.7- $\mu\text{m}$  band is a defining characteristic (section 3.3.1), some CM meteorites have no absorption band at these wavelengths. In addition, while a few thermally metamorphosed, non-CM meteorites also have the band (B-7904: C2-ung; Y-86029: CI1), such samples discussed in Cloutis *et al.* (2012) can be grouped with the CM meteorites for our purposes.

Combination bands involving the OH fundamental stretching mode appear in the 2.2–2.4  $\mu\text{m}$  region, generally in pairs (Hunt, 1977). These bands are commonly used to identify phyllosilicates on Earth and Mars, with the band positions providing the Al and/or Mg composition of the minerals. The presence of opaques strongly masks these bands (Clark, 1983), and there is only “occasional evidence” for them in spectra of CM chondrites (Cloutis *et al.*, 2011a) and they are only weakly found in “a few” CI chondrites (Cloutis *et al.*, 2011b). It is not surprising, then, that telescopic spectra of asteroids have not shown conclusive evidence of these bands. However, their presence in the meteorite data suggests that sufficiently high-quality data could be capable of capturing the bands, providing an additional way of measuring the composition of low-albedo asteroids.

Two additional near-IR bands of possible interest are at 1.4 and 1.9  $\mu\text{m}$ . These are overtones of longer-wavelength bands: the 1.4- $\mu\text{m}$  absorption is the first overtone of the OH band at ~2.7–2.8  $\mu\text{m}$  (see below), while the 1.9- $\mu\text{m}$  band is due to a combination of an  $\text{H}_2\text{O}$  bending mode and the OH stretching modes (Clark, 1999). As with the phyllosilicate bands above, these absorptions are of great use in terrestrial studies, but are much more difficult to use in asteroidal studies. In addition to their susceptibility to masking by opaque components, their association with water *per se* makes them difficult to observe through Earth’s atmosphere and in laboratory measurements at ambient conditions [see, e.g., Bishop and Pieters (1995) for spectral changes between Earth ambient and Mars ambient conditions]. Because of these limitations, the 1.4- and 1.9- $\mu\text{m}$  bands are unlikely to be utilized for observations of asteroidal volatiles in the near future.

There have also been investigations at wavelengths shorter than 0.5  $\mu\text{m}$ , most notably focusing on an absorption at 0.43  $\mu\text{m}$  that Vilas *et al.* (1993) attributed to ferric iron

TABLE 1. Characteristics of the main absorption bands discussed in this chapter.

Absorption Band	Composition	Notes
~0.6–0.67 $\mu\text{m}$	Saponite	Caused by $\text{Fe}^{3+}$ - $\text{Fe}^{2+}$ charge transfer
~0.7–0.75 $\mu\text{m}$	Serpentine	
~2.7–2.8 $\mu\text{m}$	Hydroxyl (OH)	Position can vary from 2.67 to 2.94 $\mu\text{m}$ in phyllosilicates
~2.95 $\mu\text{m}$	Water in minerals	Position can vary
~3.1–3.2 $\mu\text{m}$	Water ice	Positions vary depending on crystalline vs. amorphous nature, temperature
~10–12.5 $\mu\text{m}$	Aluminum, magnesium, iron hydroxides	$\text{Mg}_2\text{OH}$ center wavelengths 15–17 $\mu\text{m}$

Specific positions depend upon many factors, including temperature and specific mineral composition. Information taken from Clark *et al.* (1990), Cloutis *et al.* (2011a,b), and Dyar *et al.* (2010) and references therein.

in aqueously altered minerals and the U–B color index (an indication of oxidized iron), which *Feierberg et al.* (1985) suggested was correlated to 3-μm band depth in a sample of 14 low-albedo asteroids. *Vilas* (1995) found no correlation between U–B color and 3-μm absorption in higher-albedo objects, suggesting little oxidized iron on their surfaces. *Rivkin* (2012) found that the u'–g' color in the Sloan Digital Sky Survey (SDSS) did not differ between the C-complex asteroids with and without a 0.7-μm band, suggesting it was not diagnostic for hydrated minerals. While the rise of charge-coupled devices (CCDs) has led to relatively few UV observations of asteroids in the past decade, the UV capabilities of spacecraft like Rosetta (*Coradini et al.*, 1999; *Stern et al.*, 2011), New Horizons (*Stern et al.*, 2008), and Dawn (*De Sanctis et al.*, 2012b) may spur more small-bodies work in this wavelength region.

## 2.2. 3-μm Region

Water and hydroxyl both have strong absorptions in the 3-μm region. Hydroxyl has a band position that varies depending on specific composition but is generally expected in the 2.7–2.8-μm region (*Clark et al.*, 1990). However, the band's position can also vary with other factors: *Farmer* (1974) cites positions from 2.67 to 2.94 μm in layer silicates, and *Ryskin* (1974) finds a band position at wavelengths as long as 3.45 μm in some materials. The 3-μm region also hosts other volatile species: Methane and other organic materials have absorptions in the 3.3–3.4-μm region, and while ammonia is not expected on asteroidal surfaces, the ammonium ( $\text{NH}_4^+$ ) ion has a band center near 3.1 μm and was interpreted as present in Ceres' spectrum (*King et al.*, 1992). Several studies have established that the carbonaceous chondrite meteorites in our collections share particular band shapes (Fig. 1), with a strong absorption edge near 2.7 μm due to hydroxyl followed by a relatively linear return to continuum behavior as wavelengths increase. Earlier studies (*Hiroi et al.*, 1996; *Jones*, 1989) unavoidably retained some telluric water in their laboratory spectra, but similar spectral behavior is seen in samples in which telluric water has been removed (*Beck et al.*, 2010; *Takir et al.*, 2013) (see also section 3 below). However, in those cases where terrestrial adsorbed water is still present, the absorption band is deeper and wider. Studies have shown that the band minimum in the 2.7–2.8-μm region in carbonaceous chondrites is indicative of phyllosilicate composition and degree of aqueous alteration (*Sato et al.*, 1997; *Osawa et al.*, 2005; *Beck et al.*, 2010; *Takir et al.*, 2013).

The benefits derived from observing absorptions due to water and OH *per se* rather than indirectly via associated absorptions are partially offset due to the difficulties associated with observing at these wavelengths. Transmission through Earth's atmosphere is closely related to the spectrum of water vapor, and the wavelengths with the strongest absorptions in hydrated and hydroxylated minerals typically have low atmospheric transmission. Indeed, most researchers will simply omit data obtained in the 2.5–2.8-μm spectral region as compromised beyond recovery. Furthermore, detailed below,

laboratory measurements of materials are not immune to interference from terrestrial water. Early researchers found that atmospheric water quickly affected samples measured in ambient conditions, with atmospheric water readsorbing on samples between the time they were removed from a dry nitrogen atmosphere and the time they were measured in the spectrometer, and some adsorbed water remained even under a strong vacuum at room temperatures (*Clark et al.*, 1993).

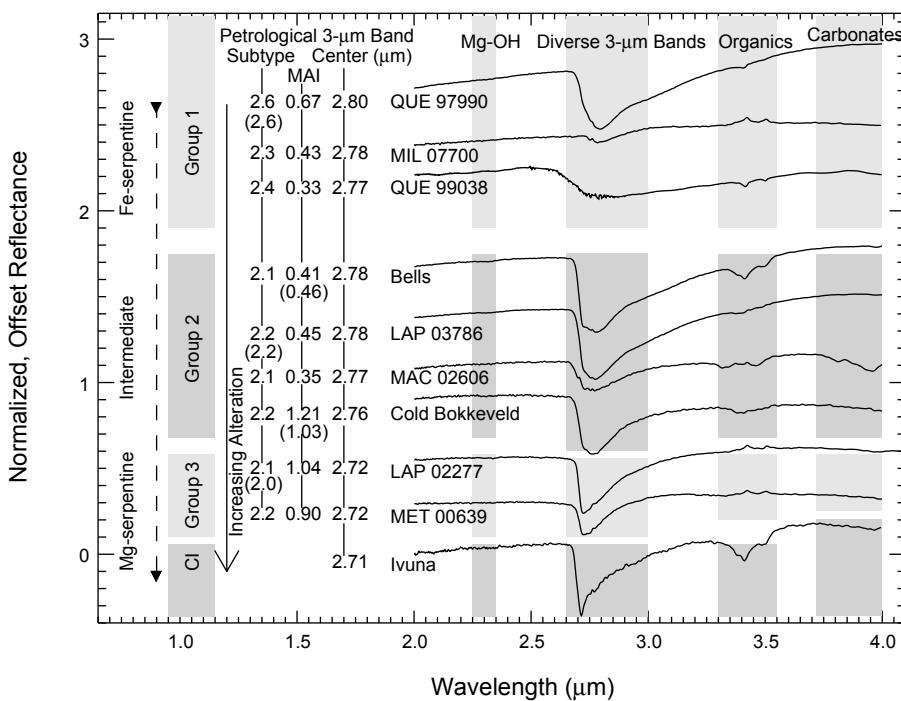

Comparing meteorite and asteroid reflectance spectra in the 3-μm region can therefore be challenging because meteorite spectra have usually been acquired under ambient terrestrial conditions where atmospheric water is dominant (see above), but advances in laboratory spectroscopy allow samples to be heated and/or put into vacuum to remove terrestrial water and spectra to be collected without exposing the sample to ambient conditions.

In addition to the measures to improve laboratory data, techniques for asteroid observations in this wavelength region have also been developed. The absorption bands seen in minerals in the 3-μm spectral region are broader than those seen in the atmosphere, and with care and effort the difficulties can be limited or minimized. The vast majority of observations in this wavelength region are obtained at Mauna Kea, with precipitable water vapor values commonly less than 10% of the mean U.S value of 20 mm (*Shands*, 1949), and reduction techniques have been developed to fit and remove atmospheric lines from object and standard spectra, minimizing the effects of airmass mismatch and increasing the number of calibration stars that can be fruitfully used for a given object (*Volquardsen et al.*, 2007).

Water *per se* has a different band shape and band position than hydroxyl. Water ice has three separate bands due to molecular vibrations in the 3-μm region, at ~3.2, ~3.1, and ~3.0 μm, with shifts in center depending on whether the ice is crystalline or amorphous, and as a function of temperature (*Mastrappa et al.*, 2009). The strength and proximity of these bands results in a broad “3-μm band” due to their overlap. The strength of the water band is such that thicknesses of more than ~100 nm result in band saturation. This is inevitably the case on icy satellites, but ices of this thickness or less have been reported on asteroids (*Rivkin and Emery*, 2010; *Campins et al.*, 2010).

In both the 3-μm region and the mid-IR (section 2.3), contributions by thermal emission from the asteroid to the measured spectrum can be important — indeed, by 4–5 μm thermal emission dominates over reflected light throughout the main asteroid belt. In order to make useful comparisons to laboratory data, this thermal flux must be modeled and removed. The techniques for doing so typically use the Standard Thermal Model (STM) or Near Earth Asteroid Thermal Model (NEATM). While beyond the scope of this chapter, details of these models can be found in *Lebofsky and Spencer* (1989) and *Harris and Lagerros* (2002), and in the chapter by Delbo et al. in this volume.

Thermal flux can also, in some circumstances, “fill in” an absorption band. Because these circumstances can arise in the 3-μm spectral region, of particular interest for hydrated

**Fig. 1.** Infrared reflectance spectra of CM and CI carbonaceous chondrites measured under dry and vacuum conditions. The MAI and the petrologic subtype were determined applying the alteration scales of Browning *et al.* (1996) and Rubin *et al.* (2007), respectively. Our spectral investigation revealed distinct groups among CM chondrites: group 1 (QUE 97990, QUE 99038, and MIL 07700), group 2 (Bells, LAP 03786, MAC 02606, and Cold Bokkeveld), and group 3 (LAP 02277 and MET 00639). Ivuna is the only CI chondrite analyzed. The 3- $\mu\text{m}$  band center decreases with increasing alteration. Adopted from Takir *et al.* (2013).

asteroid studies, here we discuss those circumstances and the consequences for astronomical observations following the logic presented by Rivkin *et al.* (2013a) and Clark (1979). In an absorption band, the emissivity increases relative to that outside the band because the reflectance decreases in the band. The increased emissivity leads to an increase in thermal flux inside the band, potentially enough to “fill in” the absorption at sufficiently high temperatures. It can easily be shown that halving the band depth (or doubling it) would similarly halve (or double) the change in emissivity, leading to the same level of fill-in at a given temperature regardless of band depth. Roughly speaking, to erase an absorption band, the thermal flux times the continuum reflectance at the wavelength of interest needs to be about the reflected flux. This condition does not occur in the 3- $\mu\text{m}$  region for main-belt asteroids, but can be reached by 3.5  $\mu\text{m}$  or shortward in near-Earth objects (NEOs) (Rivkin *et al.*, 2013b), and partial filling can occur at shorter wavelengths.

This treatment of thermal fill-in only formally holds in situations where Kirchhoff’s Law is valid. The bidirectional nature of the reflectance data collected for asteroids vs. the hemispherical-directional nature of the emission data collected means that Kirchhoff’s Law does not fully hold, and Hapke modeling of organic and carbon dioxide bands sug-

gests fill-in may occur for thermal fluxes ~30–50% of what the rule of thumb above would suggest. It is likely that the Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) mission will see band depths appear to change with time of day as surfaces on Bennu heat and cool, and it is possible that some observations of organic materials may be difficult or impossible at some times of day due to this effect. Such observations, however, will be useful for more rigorously understanding the conditions under which thermal fill-in is important.

### 2.3. Mid-Infrared Region

The mid-IR (5–50  $\mu\text{m}$ ) spectral region has not been widely used to measure asteroid mineralogy, including hydration state. The main reasons for this neglect are (1) spectral contrast is generally quite low and (2) the high flux and rapid variability of thermal emission from Earth’s atmosphere has made it difficult to obtain spectra of sufficient sensitivity. Nevertheless, several mid-IR spectral features offer the opportunity for evaluating hydration state, and space platforms and large groundbased telescopes have produced very-high-quality mid-IR data (see the chapter by Reddy *et al.* in this volume).

The primary feature for direct detection of hydration in the mid-IR is the H-O-H (or X-O-H) bending vibration near 6.25  $\mu\text{m}$ . For typical planetary materials, the strongest features in this wavelength range are the Si-O stretch and bend vibrational modes of silicates near 8–12  $\mu\text{m}$  and 15–25  $\mu\text{m}$ , respectively. Since bond strengths (and therefore vibrations) are sensitive to molecular structure, silicates express a rich diversity of mid-IR spectra that are diagnostic not only of silicate class, but also of compositions. Phyllosilicates, particularly those typically found in carbonaceous meteorites, tend to have a single-peaked absorption in the Si-O stretch region near 10  $\mu\text{m}$ . *Beck et al.* (2014), using transmission spectra, find a consistent anticorrelation between the location of this absorption and the presence of an olivine peak near 11.2  $\mu\text{m}$  for CI and CM meteorites, which they interpret as an indication of degree of hydration. The 6.25- $\mu\text{m}$  feature is not generally present in their spectra, but the transmission pathlengths may have been insufficient. It is not clear whether reflectance or emittance spectra would show such a trend, but mid-IR reflectance spectra of several CI and CM meteorites published by *Salisbury et al.* (1991) show indications of similar behavior. The reflectance spectra also contain a ~6.15- $\mu\text{m}$  feature, particularly in the more heavily hydrated meteorites, but the spectra were measured in air, so contamination by adsorbed  $\text{H}_2\text{O}$  is likely. Other phases associated with aqueous alteration (e.g., carbonates) also have spectral features in the mid-IR (e.g., *Clark et al.*, 2007).

Only a few applications of telescopic mid-IR data to identify hydration on asteroids have been published. *Milliken and Rivkin* (2009) show that a 6–14- $\mu\text{m}$  spectrum of Ceres obtained from the Kuiper Airborne Observatory by *Cohen et al.* (1998) is well-matched by linear-mixing models that were developed for the 2–4- $\mu\text{m}$  spectral region and that include brucite ( $\text{Mg}(\text{OH})_2$ ) and cronstedtite (Fe-rich serpentine). *Vernazza et al.* (2013) note that (368) Haidea is the only asteroid in the Spitzer Space Telescope (SST) spectral database (of 87 asteroids searched) that shows a single emissivity peak in the Si-O stretch region. The spectrum of Haidea is well-matched in the visible–near-IR and the mid-IR by the Tagish Lake meteorite, which is a heavily hydrated meteorite (*Zolensky et al.*, 2002), from which *Vernazza et al.* (2013) conclude that Haidea too is hydrated. SST spectra of other D-type asteroids (e.g., *Emery et al.*, 2006) show clear olivine peaks, quite distinct from Haidea and Tagish Lake, supporting the view that D-type asteroids are composed of anhydrous, primitive material and suggesting that both Tagish Lake and Haidea are somewhat anomalous. Using laboratory spectra of CM meteorites and SST spectra of three C-type asteroids, *McAdam et al.* (2013) suggest that some subfeatures at ~12–14  $\mu\text{m}$  in phyllosilicates may also be diagnostic of hydration. These are within the broader “transparency feature” found at those wavelengths, where the emissivity is at its lowest (see the Reddy et al. chapter in this volume for a fuller discussion of mid-IR spectral features).

With no active mid-IR space telescopes, with many of the mid-IR spectrometers on large groundbased telescopes not offered in recent calls, and with the future of the Stratospher-

ic Observatory for Infrared Astronomy (SOFIA) uncertain, the immediate future for exploring hydration in the mid-IR might seem challenging. However, CanariCam, a mid-IR camera/spectrometer on the recently built 10-m Gran Telescopio Canarias (GTC) is demonstrating that high-sensitivity mid-IR spectra of asteroids can be obtained from the ground (*Licandro et al.*, 2014). The James Webb Space Telescope (JWST), with spectral capability from 1 to 28  $\mu\text{m}$  (<http://jwst.nasa.gov/about.html>), should be an excellent facility for studying hydration on asteroids. And lastly, near- and mid-IR instrument payloads are becoming more common on proposed and in-development spacecraft missions, including the OSIRIS-REx Visible and IR Spectrometer (OVIRS) and OSIRIS-REx Thermal Emission Spectrometer (OTES) instruments, which will map the presumably hydrous (e.g., *Clark et al.*, 2011) asteroid Bennu from 0.4 to 50  $\mu\text{m}$  down to spatial scales of ~24 cm. These and other future opportunities are further discussed in section 6.

### 3. RESULTS AND INTERPRETATIONS FOR ASTEROIDS AND METEORITES

The spectral analysis of water and OH in meteorites has taken several large strides in the past decade. A series of papers by Cloutis et al. focused on the visible and near-IR spectra of carbonaceous chondrites. Increased laboratory capabilities, including the ability to drive off terrestrial water and take spectra without breaking vacuum, have led to a much better sense of the spectral properties of hydroxyl in carbonaceous chondrites (section 2.2 and below), and mapped out OH band centers with mineralogy. Work by *Milliken et al.* (2007) in the context of martian studies provides a potential way to remotely measure water in meteorites through calculation of spectral parameters such as band depth and integrated band depth, integrated band area, mean and normalized optical path length, and effective single-particle absorption thickness, although to this point these have not been applied to estimating hydroxyl amounts, nor have they been used on carbonaceous chondrites in the published literature.

CM (Mighei-like) and CI (Ivuna-like) carbonaceous chondrite meteorites are widely thought to be the possible analogs for dark and primitive asteroids [e.g., C-, D-, G-, K-, F-, and B-types in the Tholen taxonomy, C-complex in the Bus taxonomy (e.g., *Burbine et al.*, 2002)]. These meteorites experienced varying degrees of fluid-assisted alteration on their parent bodies (*McSween*, 1979). Spectroscopic, mineralogic, oxygen and hydrogen isotopic, and textural analyses of CM and CI carbonaceous chondrites have revealed that these meteorites contain aqueously altered materials (*Takir et al.*, 2013; *Hiroi et al.*, 1996; *Beck et al.*, 2010; *Zolensky et al.*, 1993; *Clayton and Mayeda*, 1999; *Lee*, 1993; and others). Laboratory analyses of carbonaceous chondrites combined with astronomical observations of hydrated asteroids can lead to important clues about abundance and distribution of  $\text{H}_2\text{O}$  in the early solar system.

*Takir et al.* (2013) measured meteorite spectra under dry (elevated temperatures) and vacuum ( $10^{-8}$ – $10^{-7}$  torr)

conditions to minimize the effect of adsorbed water and mimic the asteroid-like environment. *Beck et al.* (2010) previously measured carbonaceous chondrite transmission spectra; however, absorption features in transmission do not always have the same shape or position as they do when measured in reflectance, due to the scattering of reflected illumination by granular particles. *Takir et al.* (2013) also investigated the degree of hydration in CM and CI chondrites, using the previously defined alteration scales of *Browning et al.* (1996) (Mineralogical Alteration Index) and *Rubin et al.* (2007) (Petrological Subtype). *Takir et al.* (2013) identified three spectral groups of CM chondrites (plus the CI chondrite Ivuna), using the 3- $\mu\text{m}$  band center and shape of IR reflectance spectra (Fig. 1). The diversity in the 3- $\mu\text{m}$  band demonstrates that distinct parent body aqueous alteration environments experienced by carbonaceous chondrites can be distinguished using reflectance spectroscopy. The first group (Group 1) shows the lowest degree of aqueous alteration and is characterized by 3- $\mu\text{m}$  band centers at longer wavelengths than other groups. Group 1 is consistent with the occurrence of Fe-rich serpentine (cronstetite). Group 3, which exhibits the highest degree of aqueous alteration, is characterized by 3- $\mu\text{m}$  band centers at shorter wavelengths and is consistent with Mg-rich serpentine (antigorite). The third group, Group 2, is intermediate between Groups 1 and 3 and more likely includes both types of serpentine minerals.

Along with the advances in meteorite spectroscopy, observations of asteroids have flowered in the past decade. The majority of telescopic observations in the 3- $\mu\text{m}$  region have been obtained at the Infrared Telescope Facility (IRTF) using the SpeX instrument, but observations at other wavelengths have been made using other telescopes across the world, with orbiting telescopes, and *in situ* orbiting Vesta and flying past Lutetia. Asteroid researchers have also made use of datasets acquired for astrophysical projects such as the SDSS. The use

of all these observations has led to a fuller characterization of several individual objects and an understanding of the hydrated mineralogy present in the asteroid belt and beyond.

### 3.1. Correlation of 0.7- $\mu\text{m}$ Band and 3- $\mu\text{m}$ Band

A growing database of asteroidal spectra available at both 0.7 and 3  $\mu\text{m}$  has been accumulating in order to understand the relationship between these bands. *Vilas* (1994) showed that the 0.7- $\mu\text{m}$  band is present when the 3- $\mu\text{m}$  band is seen in ~85% of a sample of 31 CCD reflectance spectra and IR multicolor photometry observations of low-albedo asteroids, and applied this correlation to the larger Eight Color Asteroid Survey (ECAS) photometry database to identify potentially aqueously altered asteroids. While this is good evidence that the bands are related, it is also important to understand why the bands sometimes are not correlated. *Howell et al.* (2011) show that, upon closer examination using simultaneous observations, the 3- $\mu\text{m}$  band is often variable with rotation of an asteroid, and that whenever the 0.7- $\mu\text{m}$  band is present, the 3- $\mu\text{m}$  band is also seen. However, the 3- $\mu\text{m}$  band can be present without the 0.7- $\mu\text{m}$  band, and indeed is seen in about half the objects observed at 3- $\mu\text{m}$  for which the 0.7  $\mu\text{m}$  band is absent. This makes the 0.7- $\mu\text{m}$  absorption a reliable proxy for hydration, but the 0.7- $\mu\text{m}$  absorption is limited to only establishing a lower bound on the total number of hydrated objects. Table 2 shows the correlation of the 156 objects in the literature that have been observed at both wavelengths.

### 3.2. 3- $\mu\text{m}$ Band Shapes

Using high-quality near-IR (0.7–4.0  $\mu\text{m}$ ) spectra of 35 outer main-belt asteroids ( $2.5 < a < 4.0$  AU), *Takir and Emery* (2012) identified four 3- $\mu\text{m}$  spectral and orbital groups, each of which is presumably linked to distinct surface mineralogy (Figs. 2 and 3). Table 3 shows these groups, examples

TABLE 2. Correlation between the 0.7- and 3- $\mu\text{m}$  bands in the total sample of available main-belt asteroid spectra and the sample of C-complex asteroids.

		All Asteroids		C-Complex Asteroids	
		3- $\mu\text{m}$	3- $\mu\text{m}$	3- $\mu\text{m}$	3- $\mu\text{m}$
		Band	Band	Band	Band
		Absent	Present	Absent	Present
0.7- $\mu\text{m}$ band present	Number of objects	0	56	0	44
0.7- $\mu\text{m}$ band absent	Percent of objects	0%	35%	0%	63%
	Number of objects	57	47	9	17
	Percent of objects	37%	29%	13%	24%

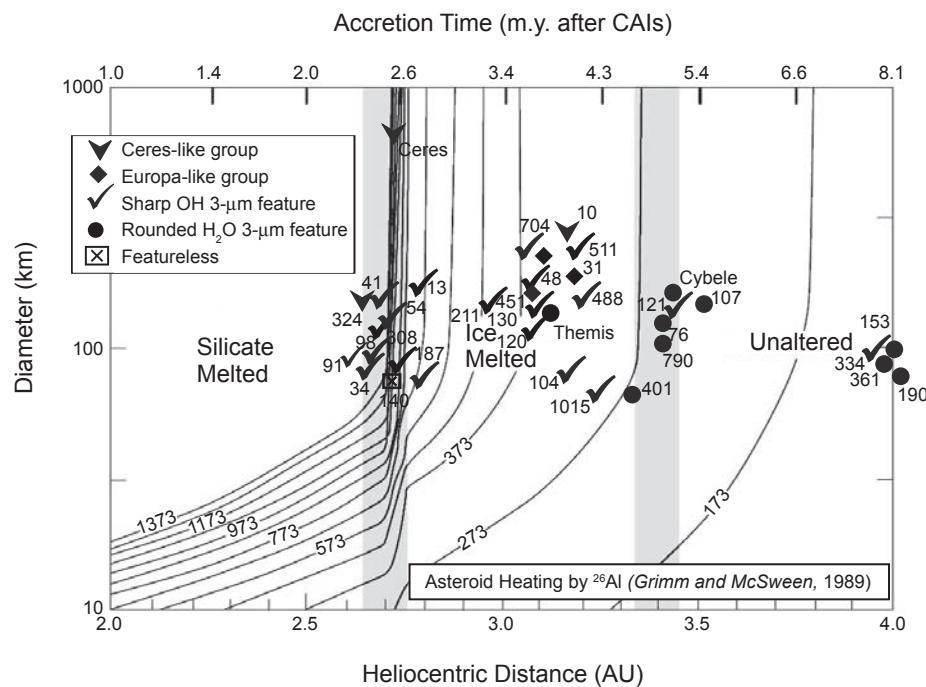

A total of 160 main-belt asteroids have been observed at both 0.7 and 3  $\mu\text{m}$  to investigate the hydration state. The bands are correlated for 113 objects, or 70% of the sample. The remaining objects have a 3- $\mu\text{m}$  band, but no 0.7- $\mu\text{m}$  band. No objects are found to have a 0.7- $\mu\text{m}$  band, and lacking a 3- $\mu\text{m}$  band, making the presence of the 0.7- $\mu\text{m}$  band a good proxy for hydration, but only a lower limit on the number of hydrated objects. The correlation for 70 C-complex objects is shown in the right two columns. In cases where insufficient data exists to determine the Bus-DeMeo taxonomic class, we include Tholen C, B, F, and G taxonomic classes as well as CP and PC, but not those classified as P. Data sources for this table are *Zellner et al.* (1985), *Lazzaro et al.* (2004), *Sawyer* (1991), *Vilas* (1994), *Lebofsky* (1980), *Lebofsky et al.* (1990), *Feierberg et al.* (1985), *Rivkin et al.* (2000, 2002b, 2012), *Fornasier et al.* (2011, 2014), and *Howell et al.* (2011).

of each, alternate names, and compositional interpretation. The sharp group (or Pallas types) exhibits a characteristically sharp 3- $\mu\text{m}$  feature, reflectance decreasing with decreasing wavelength into the 2.5–2.85- $\mu\text{m}$  spectral region, attributed to OH-stretching in hydrated minerals (e.g., phyllosilicates) (Rivkin et al., 2002b). The majority of asteroids in this group are concentrated in the  $2.5 < a < 3.3$ -AU region. The second group, the rounded group (or Themis types), exhibits a rounded 3- $\mu\text{m}$  band (reflectance increases with decreasing wavelength shortward of  $\sim 3.07$   $\mu\text{m}$ ), attributed to H<sub>2</sub>O ice (e.g., Rivkin and Emery, 2010). Asteroids in this group are located in  $3.4 < a < 4.0$ -AU region. The third group, the (1) Ceres-like group, is located in the 2.5–3.3-AU region and characterized by a narrow 3- $\mu\text{m}$  band center at  $\sim 3.05$   $\mu\text{m}$  superposed on a much wider absorption from 2.8 to 3.7  $\mu\text{m}$  that is consistent with brucite (Milliken and Rivkin, 2009). The fourth group, the 52 Europa-like group [grouped into

the Themis types by Rivkin et al. (2012)] exhibits a 3- $\mu\text{m}$  band centered around 3.15  $\mu\text{m}$  with longer wavelength band minimum and steeper rise on the long-wavelength edge of the absorption.

On the basis of the 3- $\mu\text{m}$  band shape and center, Takir et al. (2015) found that the sharp asteroids possibly have similar phyllosilicate mineralogy as CM Group 2 and Ivuna, suggesting that these asteroids and meteorites experienced similar aqueous alteration processes. These results suggest that CM and CI chondrites are possibly the meteorite analogs for the sharp group (Fig. 4). The authors found Ivuna to have a spectrum consistent with lizardite and chrysotile. No meteorite match was found either for the rounded group, Ceres-like group, or Europa-like group.

Differences within each of these groups are still to be fully understood. For instance, the relationship between the Europa, Ceres, and rounded groups is not entirely clear — the

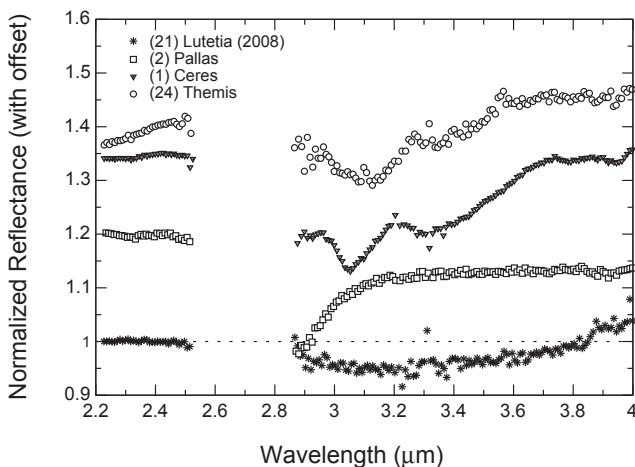

**Fig. 2.** Asteroids classified according to the Takir 3- $\mu\text{m}$  classes are plotted in the context of the thermal model of Grimm and McSween (1993). Adopted from Takir and Emery (2012).

TABLE 3. Potential major groupings for objects in the 3- $\mu\text{m}$  spectral region.

Example Body	Takir Class	Rivkin Class	Interpretation
511 Davida	Sharp	Pallas	CM-like phyllosilicates
24 Themis	Rounded	Themis	Water-ice frost, organics
52 Europa	Europa	Themis	Water-ice frost, organics
1 Ceres	Ceres	Ceres	Brucite, carbonates
21 Lutetia	—	Lutetia	Goethite?

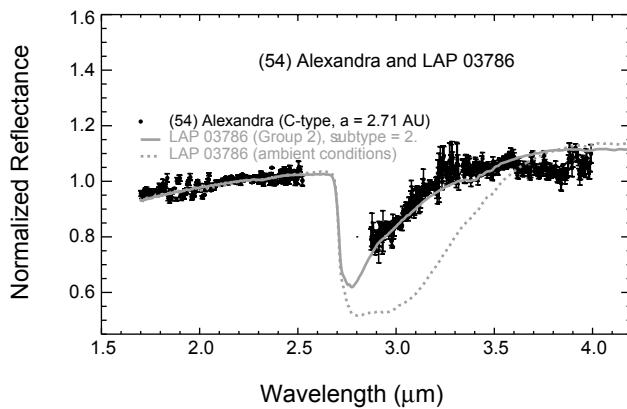

While a formal taxonomy has not yet been developed for objects in the 3- $\mu\text{m}$  spectral region, presented here are the potential classes as defined by Takir et al. (2012) and Rivkin et al. (2012), with type examples and possible compositions for each group (also from these cited works).

**Fig. 3.** The diversity of asteroids in the 3- $\mu\text{m}$  spectral region can be seen by comparing several of the largest objects. Each of these bodies shows evidence of different mineralogies, although the specific minerals in each case may still be under debate. Figure from Rivkin *et al.* (2011).

Ceres types are interpreted very differently from the rounded group, but there may be objects that appear spectrally intermediate between the groups. It is apparent that there is variation within the sharp group, with some structure visible within the main absorption on some objects. It is also not certain whether the same object can vary between different band shapes on its surface; for example, 704 Interamnia is classified differently in Takir and Emery (2012) and Rivkin *et al.* (2012). Further work is necessary to better establish the compositions found in these groups: Beck *et al.* (2010) proposed goethite as an alternate to ice frost in the Themis-type asteroids based in part on the thermodynamic difficulty of keeping frost on these asteroid surfaces. Nonetheless, while other closely related minerals have been found in both meteorite and asteroid spectra, extraterrestrial goethite has never been identified within the meteorite inventory. Jewitt (2012), considering ice vs. goethite, preferred ice as a simpler interpretation for this reason. Also, goethite is a poor match for the spectrum of (24) Themis at wavelengths shortward of 3  $\mu\text{m}$  (Pinilla-Alonso, 2011). The interpretation of brucite and carbonates on Ceres will be tested and honed by Dawn's visit to that object, with consequences for the interpretation of other Ceres types.

Additional groups beyond those identified in Takir *et al.* and mentioned above appear to be present. Rivkin *et al.* (2011) found the band shape on Lutetia to be unlike Pallas, Ceres, or Themis (Fig. 4) and proposed a fit to goethite, inspired by Beck *et al.* (2011). Yang *et al.* (2009) observed a flat-floored 3- $\mu\text{m}$  band on Comet Holmes due to ice grains, which may theoretically be present on portions of asteroid surfaces, although such a spectrum has not yet been found on asteroids. Finally, some objects appear to have no absorption band in the 3- $\mu\text{m}$  region. In some cases, like the Trojan asteroids, this may be because only relatively poor-quality data is available and significant absorptions may be hidden

**Fig. 4.** Meteorite LAP 03786 and (54) Alexandra, showing an example of the comparison between CM and CI chondrites and asteroids with the sharp/Pallas-type 3- $\mu\text{m}$  feature. While asteroid spectra have been poor matches for meteorite spectra taken in ambient conditions (dotted line), meteorite spectra with terrestrial water removed (solid line) are much better matches. Figure from Takir *et al.* (2015).

in the uncertainties. However, resolved observations of Comets 9P/Tempel 1 and 103P/Hartley 2 by Groussin *et al.* (2013) showed spectra were very well fit by a sum of reflected and thermally emitted flux, showing no 3- $\mu\text{m}$  absorption within ~2% (although H<sub>2</sub>O emission was seen in some cases).

Preliminary results from the LXD-mode Main belt and NEO Observing Program (LMNOP) (Rivkin *et al.*, 2012, 2014b) are consistent with Takir *et al.*, with some additional insights available from a larger sample size. The different 3- $\mu\text{m}$  types can be found in most of the C-complex component classes, other than the Ch class as discussed below. When the Ch class is excluded, Pallas/sharp types make up 44% of the 48 C-complex asteroids in the LMNOP for which band shapes can be assigned, while Themis types make up 42%. This is similar to the (smaller) X-complex sample of 13, including 7 Pallas types and 5 Themis types. The four Ceres types in the LMNOP sample are all found in the C complex.

The sample of low-albedo (but non-Ch) asteroids shows a correlation between 3- $\mu\text{m}$  band shape and size as well as with solar distance: Pallas types make up 27% of the H < 7 sample (corresponding roughly to D > 200 km), but 69% of the H < 8.5 sample (D < 100 km). The Themis types start at ~36% of the largest-sized sample, peaking at 55% of the 150–200-km sample before declining to 40% of the H < 8.5 group. The Ceres types are found only in the H < 7 group. Turning to solar distance (and again excluding the Ch asteroids) shows the inner belt (a < 2.82 AU) dominated by the Pallas types (63%), while in the outer belt (a > 2.82 AU) the Themis types are more numerous, outnumbering the Pallas types 48% to 33%.

The observation that Ch asteroids are overwhelmingly (perhaps unanimously) Pallas-type objects means that the former can be used as a proxy for the latter, even if only providing a lower limit on their numbers. The work of

Rivkin (2012) using the SDSS to study the 0.7- $\mu\text{m}$  band is consistent with the LMNOP findings and is discussed below.

### 3.3. Connections with Taxonomy

**3.3.1. C-complex asteroids.** The majority of work on hydrated asteroids has focused on the C-complex asteroids, a group that comprises the B, C, Cb, Cg, Ch, and Cgh classes in the Bus taxonomy (Bus and Binzel, 2002a). These asteroids, as described elsewhere in this volume, have low albedos and are generally associated with the carbonaceous chondrite meteorites. Most of the largest bodies in the asteroid belt are C-complex asteroids, including Ceres, Pallas, Hygiea, Interamnia, and Europa.

In the Bus asteroid taxonomy, the Cgh and Ch asteroid classes are defined as those with 0.7- $\mu\text{m}$  bands, with behavior shortward of 0.55  $\mu\text{m}$  discriminating between the Cgh and Ch classes. The extension of the Bus taxonomy to 2.5  $\mu\text{m}$  by DeMeo et al. (2009) maintained those two classes, with similar definitions. The Cgh class is relatively rare, with Ch asteroids in the Small Main-Belt Asteroid Spectroscopic Survey (SMASS) dataset outnumbering them 9:1. While the shared characteristic of these classes is the 0.7- $\mu\text{m}$  band, the exact band minimum varies from roughly 0.687–0.740  $\mu\text{m}$  in a sample of Ch asteroids studied by Rivkin et al. (2013b). Vilas (1994) noted the difference in 0.7- $\mu\text{m}$  band center between the C-class asteroids and the CM2 carbonaceous chondrites, where it is nearer to 0.72–0.73  $\mu\text{m}$ , and suggested that this difference could be due to a shift in temperature between asteroid surfaces and laboratory reflectance studies, but found no laboratory studies to confirm this. Vilas reported three main-belt asteroids, a Cybele, and a Hilda asteroid with absorption bands in the 0.6–0.65- $\mu\text{m}$  and 0.8–0.9- $\mu\text{m}$  ranges, which could be attributed to saponites (Cloutis et al., 2011a,b). Only one of these objects, (165) Loreley, was observed by the SMASS survey, where it was classified as a Cb and these features were not reported (Bus and Binzel, 2002a,b). None of the objects were observed by the Small Solar System Objects Spectroscopic Survey (S<sup>3</sup>OS<sup>2</sup>) survey (Lazzaro et al. 2004), and so confirmation awaits future studies.

The presence of a band near 0.7  $\mu\text{m}$  provides a partial link between the Ch asteroids and CM meteorites: They are the only asteroids and only meteorites that have identified absorption bands at those wavelengths. Carvano et al. (2003) performed least-squares comparisons of the asteroidal spectra in the S<sup>3</sup>OS<sup>2</sup> to laboratory spectra of meteorites and concluded that most asteroids with 0.7- $\mu\text{m}$  bands were “very likely” to be related to the CM2 meteorites. The connection between the Ch asteroids and the Pallas-type 3- $\mu\text{m}$  bands is discussed in section 3.2.

Fornasier et al. (2014) analyzed the visible–near-IR spectra of 600 low-albedo asteroids (C, G, B, F, P in the Tholen taxonomy), including 80 that were newly obtained. They found roughly 50% of the 454 C-class asteroids in their sample have the 0.7- $\mu\text{m}$  absorption, compared to only 10% of the 92 B-class asteroids they studied. The F, G, and

P asteroids have far fewer objects in their samples (13, 18, and 23, respectively) but all have strong tendencies to either lack the band (~8% of F asteroids and 4% of P asteroids) or have it (100% of G asteroids). They did not separate the P asteroids from the C-complex asteroids for most of their analysis, but the P asteroids are a small enough fraction of the overall sample that they should not skew the results. Fornasier et al. found that the fraction of hydrated asteroids decreased with decreasing size, although the decrease was not monotonic. They found no correlation between fraction of hydrated asteroids and geometric albedo. However, they concluded that the 0.7- $\mu\text{m}$  band centers for the meteorites are generally at longer wavelengths than for the asteroids, although no conclusion was reached as to why that is the case. They suggested that spectral differences may be attributed to different mineral abundances between CM chondrites and the asteroids, to possible effects due to grain size, or because the meteorite collection may not be fully representative of the aqueously altered asteroid population.

Rivkin (2012) used the SDSS to measure the fraction of objects with a 0.7- $\mu\text{m}$  band, first filtering the large set of objects in the *Third Release of the Moving Object Catalog* to include only those objects with C-like color indices, with a resulting sample size of 3724 observations of 3124 objects. He used two independent techniques, performing a best fit to the average of each C-complex component class convolved to SDSS resolution, as well as fitting the distribution of 0.7- $\mu\text{m}$  band depths to two Gaussians (one with zero band depth representing the C asteroids, one with a nonzero band depth representing the Ch asteroids). He estimated 30% of all C-complex asteroids have a band at 0.7  $\mu\text{m}$ , with some evidence of a higher fraction in the middle asteroid belt (2.50–2.82 AU) compared to the inner or outer belt. When including the SMASS and S<sup>3</sup>OS<sup>2</sup> datasets, it appears the Ch fraction of the C complex reaches an overall minimum near H  $\sim$  12–14. Fornasier et al. (2014) noted some of the differing conclusions between their work and that of Rivkin (2012), suggesting that some of the differences may be due to the non-optimal filter placement in the SDSS observations compared to the placement and width of the 0.7- $\mu\text{m}$  band.

All the 3- $\mu\text{m}$  band shapes discussed above are found in the C-complex population. Rivkin et al. (2013b) reports that all their samples of more than 30 Ch class asteroids have 3- $\mu\text{m}$  bands consistent with being all “sharp” (or “Pallas”) types, with the few possible exceptions attributable to low-quality data or misclassified asteroids. However, Pallas types are also present among other C-complex classes, as well as non-C classes.

The Japanese AKARI satellite conducted the first space-borne asteroid spectroscopic survey in the 3- $\mu\text{m}$  region, observing 33 low-albedo asteroids (Okamura et al., 2014a). Okamura et al. (2014b) performed principal component analysis (PCA) on these data as well as meteorite and mineral data. While some good matches were found, in general close matches between the AKARI observations and meteorite spectra were not found. However, the depth of the 2.7- $\mu\text{m}$  absorption was found to correlate with the

depth of the 0.7- $\mu\text{m}$  absorption, interpreted as meaning that the 2.7- $\mu\text{m}$  absorption is controlled by serpentine abundance.

Work at longer wavelengths has been more limited. However, *McAdam et al.* (2013) analyzed SST data for the 10–12- $\mu\text{m}$  feature discussed above, finding it in seven C-complex asteroids but absent from three D-class Trojan asteroids. *Licandro et al.* (2012) reported SST spectra covering the 5–14- $\mu\text{m}$  region for eight Themis family asteroids [including members of several classes in the C and X complexes (*Bus and Binzel*, 2002b; *Lazzaro et al.*, 2004)], finding broad emission features of  $\sim$ 2–4%. However, these were not interpreted in terms of phyllosilicate content. Spectroscopic observations of the OSIRIS-REx target asteroid (101955) Bennu from 5 to 38  $\mu\text{m}$  by *Emery et al.* (2014) showed no spectral features outside of observational uncertainties.

**3.3.2. B-class asteroids.** *Ali-Lagoa et al.* (2013) studied the physical properties of B-class asteroids, derived by fitting a thermal model to Wide-field Infrared Survey Explorer (WISE) observations, i.e., effective diameter, beaming parameter, and the albedo ratio  $p_{\text{IR}}/p_{\text{V}}$ , where  $p_{\text{IR}}$  is the albedo at 3.4  $\mu\text{m}$  as defined in *Mainzer et al.* (2011). *Ali-Lagoa et al.* (2013) include in their B-class sample all objects that have a published flat to slightly blue spectral slope in the visible range, i.e., any object that has ever been classified as B-class, including Tholen's F-types, and ambiguous designations, following *Clark et al.* (2010) and *de León et al.* (2012).

By combining the IR and visible albedos with 2.5- $\mu\text{m}$  reflectances from the literature (*Clark et al.*, 2010; *de León et al.*, 2012), *Ali-Lagoa et al.* (2013) obtained the ratio of reflectances at 3.4 and 2.5  $\mu\text{m}$ , from which they find statistically significant indications that the presence of a 3- $\mu\text{m}$  absorption band related to water may be commonplace among the B-types. Using Tholen's B-type ECAS classification, *Villas* (1994) concluded that 30% of those asteroids showed a 0.7- $\mu\text{m}$  absorption, which — using *Howell et al.*'s (2011) correlation — sets a significant lower limit on the presence of water in the B-types.

**3.3.3. P-class asteroids.** The X-complex asteroids span a range of albedos, as has been known since the 1980s when the Tholen taxonomy recognized that the E, M, and P classes were indistinguishable without albedo information and created the X class to hold such objects. The Bus taxonomy (and later Bus-DeMeo taxonomy) does not use albedo information, and has divided the X complex into several classes (Xe, Xk, Xc, X) based on spectral features alone, with imperfect correlations to the Tholen classes. While the Bus classes in the C complex are well suited to a discussion of hydrated minerals, the Tholen classes provide more convenient discussion of hydrated minerals in the X complex. Therefore, at the risk of some confusion, and understanding that several asteroids are classified in either the X or C complex depending on the specific spectrum analyzed, we use the E/M/P classes defined by Tholen in this section rather than the Bus classes.

The low-albedo X/P-class asteroids fit neatly into the discussion of the C-class asteroids above and, as noted, the work of *Fornasier et al.* (2014), following the work of

others, concluded that they belonged to the same alteration sequence as the C-complex asteroids. The largest P-class asteroid, (65) Cybele, has been found to have a Themis-like 3- $\mu\text{m}$  band, interpreted as due to surface ice frost (*Licandro et al.*, 2011a). The asteroid set analyzed by *Takir and Emery* (2012) included five P-class asteroids, including two in the Cybele region and two in the Hilda region. These four objects all have rounded 3- $\mu\text{m}$  bands, while the final P asteroid [(140) Siwa] did not show any absorption above the noise. The three Cybele/Hilda group C-class asteroids studied by Takir and Emery included both rounded and sharp members, providing further evidence that spectral slope and 3- $\mu\text{m}$  band shape are correlated, and perhaps connected.

**3.3.4. M-class asteroids.** Our understanding of M-class asteroids continues to evolve. While the presence of a 3- $\mu\text{m}$  band on several M asteroids (which led to their proposed reclassification as “W-class asteroids” by *Rivkin et al.*) was established late last century (*Jones et al.*, 1990; *Rivkin et al.*, 2000), no consensus on interpretations was reached. The discovery of objects with both a 3- $\mu\text{m}$  band and high radar albedo (*Shepard et al.*, 2015) has led to the consideration of impactor contamination as a cause of the 3- $\mu\text{m}$  band on these objects, as noted in section 1.4, but the band depths on some objects seem too deep to be caused by this process or are on objects with low radar albedo. While work is ongoing in general, we note that some objects have been reclassified into or out of the M-asteroid class based on additional spectra or new albedos [e.g., (785) Zwetana was classified as an M by *Zellner et al.* (1985), but as a Cb by *Bus and Binzel* (2002a)] and that the Lutetia-type 3- $\mu\text{m}$  band shape has only been seen in E- or M-class objects, suggesting that it is not simply caused by contamination by common carbonaceous material in all cases.

Several studies focused on the M-class asteroid (21) Lutetia, a Rosetta flyby target. *Rivkin et al.* (2011) compiled 3- $\mu\text{m}$  observations over several years to conclude Lutetia had a deeper 3- $\mu\text{m}$  band (3–5%) in its southern hemisphere than its northern hemisphere (<2%), and that goethite appeared to be a plausible surface constituent. The variation observed is consistent with the hemispheric-level variation seen at shorter wavelengths (*Nedelcu et al.*, 2007), where Lutetia's spectral slope varies from X-like to C-like. Two papers by *Birlan et al.* taken together also reported spectral variation on Lutetia consistent with what was seen by *Rivkin et al.* (2011), with *Birlan et al.* (2010) reporting an upper limit of 0.5% for any 3- $\mu\text{m}$  band depth from observations in 2010 compared to a band depth of several percent in 2003–2004 (*Birlan et al.*, 2006). The Rosetta flyby passed the northern hemisphere of Lutetia in July 2010, and found no absorption in the 3- $\mu\text{m}$  region, although instrumental artifacts make it difficult to judge the actual upper limit value. *Barucci et al.* (2012), considering all published data, concluded that Lutetia had a chondritic surface, possibly a mixture of enstatite and carbonaceous chondrite. The northern hemisphere of Lutetia stands as a cautionary tale about the difficulties of interpreting featureless spectra. Interestingly, the Alice instrument on Rosetta found a significantly lower UV albedo near

180 nm than 550 nm, and strong reflectance drop from 180 to 160 nm (Stern et al., 2011). The possible interpretations include water ice frost, although there are other possible interpretations, and the survival of frost on Lutetia's surface would be unexpected.

### 3.4. Near-Earth Asteroids

While the NEAs are derived from the main belt, we are aware that the populations are not exact mirrors of one another. The most important difference relevant to this chapter is the relative lack of Ch asteroids in the NEA population relative to their numbers in the main asteroid belt. As we have seen, estimates of the fraction of main-belt C-complex asteroids with 0.7-μm bands (i.e., the “Ch fraction”) range from ~30 to 45% (Rivkin, 2012; Fornasier et al., 2014). For comparison, Binzel et al. (2004) only found one Ch asteroid in their sample of 24 C-complex NEAs. Updated data from the Massachusetts Institute of Technology (MIT)-University of Hawaii (UH)-IRTF “Joint Campaign” finds 6 Ch or Cgh asteroids in a sample of 88 NEOs for which they have data covering the 0.7-μm region [(144901) 2004 WG<sub>1</sub>, (285263) 1998 QE<sub>2</sub>, (365246) 2009 NE, 2002 DH<sub>2</sub>, 2007 YB<sub>2</sub>, 2012 EG<sub>5</sub> (R. Binzel and F. DeMeo, personal communication)], a similar (if slightly larger) fraction as found in the 2004 work. This does not seem to be a size effect — the Mars-crossers in the Binzel et al. (2004) sample have a Ch fraction similar to the main-belt value (although the larger Joint Campaign dataset finds a much smaller Ch fraction), and Rivkin (2012) found a Ch fraction of 25–40% for the smallest size bin (H of 16–18) in the SDSS data, of similar size to the NEAs. Perhaps surprisingly, the small fraction of Ch-class NEAs is also inconsistent with the fraction of hydrated meteorites — while it is not obvious how best to compare numbers of meteorites in a consistent way, the fraction of carbonaceous chondrite meteorite falls of the CM group (in which the 0.7-μm band is prevalent; see section 3) is roughly 33%, again much higher than the 5% seen in the NEO population. A possible explanation for this can be found in the work of Marchi et al. (2009), who noted that the chaotic evolution of NEA orbits can lead to low-perihelion eras where surface temperatures exceed the stability temperatures of phyllosilicates. Given the factor of 4–8 difference between the Ch fraction of NEAs vs. main-belt asteroids and meteorites, Rivkin (2012) estimated ~75–88% of NEOs have experienced such eras, although this is perhaps a simplistic approach.

Observations of NEAs in the 3-μm region have been rare, with the vast majority of objects too faint to observe. However, absorptions have been found on two NEOs, 1992 UY<sub>4</sub> (Volquardsen et al., 2007) and 1996 FG<sub>3</sub> (Rivkin et al., 2013a). The band shapes for these objects are not as well-measured as those of brighter asteroids, but 1996 FG<sub>3</sub> appears to have a Pallas-type/sharp band. Volquardsen et al. (2007) interpreted the band shape of 1992 UY<sub>4</sub> as similar to that of (375) Ursula, which is a Ceres- or Themis-type, but the observational uncertainties do not rule out a Pallas-type spectrum at the 1σ level.

Absorptions in the 3-μm region have also been detected on the S-class asteroids (433) Eros and (1036) Ganymed (Rivkin et al., 2013c), with Wigton et al. (2014) also detecting a 3-μm band on (3122) Florence. At this writing, it is not yet clear whether these bands are caused by native material like the phyllosilicates found in the LL chondrite Semarkona; whether they are caused by solar wind interactions with regolith, like what is discussed in section 1.5 above; or whether they are due to some other process.

### 3.5. Main-Belt Comets (aka Active Asteroids) and Ceres

The discovery of “main-belt comets” (MBCs) (Hsieh and Jewitt, 2006; see also the chapter by Jewitt et al. in this volume), also known as “active asteroids,” suggests that ice persists near the surfaces of objects in the asteroid belt. Active asteroids are members of the NEA or main-belt asteroid populations that present comet-like tails, but have orbits that are unlikely to originate from the known comet reservoirs, e.g., the transneptunian belt and the Oort cloud, and are thought to have formed in the main belt instead. These objects eject dust, producing transient comet-like comae and tails. Several dust ejection mechanisms have been proposed: sublimation of ice, rotational fission, ejection by collisions, electrostatic repulsion, thermal fracture, dehydration stresses, and radiation pressure sweeping (e.g., Bertini, 2011; Jewitt, 2012; Jewitt et al., this volume), and at least some of the objects are best explained as experiencing processes unrelated to volatiles (e.g., Jewitt et al., 2015). Currently, 15 active asteroids are known, two of which are NEAs [(3200) Phaethon and (4015) Wilson-Harrington] while the other 13 are in the main belt.

The detection of repetitive dust ejection events in some MBCs [e.g., 133P/Elst-Pizarro and 238P/Read (see Hsieh et al., 2004; Jewitt et al., this volume, and references therein)] and the indication that in these and other MBCs [e.g., 238P, (300163) 2006 VW<sub>139</sub>, P/2010 R<sub>2</sub> (La Sagra), and P/2012 T<sub>1</sub> (PANSTARRS) (see Jewitt et al., this volume)] dust ejection lasted for several months strongly suggests that ice sublimation is their preferred ejection mechanism (Hsieh et al., 2004). Interestingly, three MBCs, 133P, 176P, and 238P, are members of the Themis dynamical family and share spectral properties with other asteroids in this family (see Licandro et al., 2011b, 2013; Hsieh et al., 2012), indicating they have a common origin. Furthermore, water ice was discovered on the surface of the largest member of this family, (24) Themis (Campins et al., 2010; Rivkin and Emery, 2010). Because the water ice on the surface of Themis is short-lived, it likely is resupplied from its interior, and this also supports the hypothesis that there is a water ice reservoir below the surface of some MBCs. Thermal models are consistent with the survival of very shallow subsurface water ice over the age of the solar system in main-belt asteroids (Schorghofer, 2008).

One interesting question regarding Themis family MBCs is, “Why are only some Themis family asteroids active?” If

activity in MBCs is indeed driven by ice sublimation, this ice may normally be protected from sunlight by a poorly conducting surface layer and activity could start with a collision penetrating this layer, exposing the ice to sunlight (*Hsieh and Jewitt*, 2006; *Schorghofer*, 2008; *Capria et al.*, 2012). Recent dynamical results are consistent with this proposed mechanism; more specifically, the discovery of a very young subfamily within the Themis family, called the Beagle family, and the fact that MBC 133P is also a member of the Beagle subfamily (*Nesvorný et al.*, 2008). The relatively recent formation event of the Beagle family may have produced fragments, such as 133P, with shallow ice that can be exposed by small (and thus more frequent) collisions. However, since the other MBC in the Themis family, 176P, is *not* a member of the Beagle family, multiple collisional events or perhaps surface disruption following YORP spin-up are needed to explain their activity (*Campins et al.*, 2012). Another factor that may help explain why only a few Themis family members show activity is a heterogeneous set of compositions among small Themis fragments. This issue can be addressed by focused spectroscopic studies of this family (section 4.7).

It is also suggestive that all the MBCs with known spectra are primitive asteroids. More specifically, 133P, 176P, 238P, (3200) Phaethon and (4015) Wilson-Harrington all belong to the C-complex population in the Tholen taxonomy (*Licandro et al.*, 2007, 2011b, 2013), and (596) Scheila [whose activity is attributed to an impulsive event like a collision (e.g., *Moreno et al.*, 2011)] is a D-type asteroid (*Licandro et al.*, 2011c).

A particularly interesting and related result is the detection by the Herschel Space Telescope of water vapor emission around asteroid (1) Ceres (*Kuipers et al.*, 2014). Models of Ceres' interior include a near-surface ice mantle above a rocky core (*Thomas et al.*, 2005; *McCord and Sotin*, 2005), with the ice separated from the vacuum of space by either a lag deposit similar to comets or a primordial crust. The water emission seen by Herschel is variable, suggesting a connection with surface features, and correlated with solar distance. While Ceres is not considered an MBC (no dust emission or tail has ever been seen), it is possible that MBCs and Themis originated in Ceres-like bodies that were catastrophically disrupted (*Castillo-Rogez and Schmidt*, 2010). Such a scenario could increase the ice fraction among some fragments and also maintain it near the surface in small objects like the MBCs, while still leaving it accessible for activation and sublimation via impacts.

### 3.6. Related Populations

The Trojan asteroids and satellites of Mars are discussed in detail in the chapters by Emery et al. and Murchie et al. in this volume. However, it is worth briefly discussing them again here, along with the irregular satellites of Jupiter, in the context of their hydrated or icy mineralogy. The Cybele and Hilda asteroids are considered in the context of the main-belt asteroids throughout this chapter, although dynamical studies

suggest their origins may lie outside the main belt and with the other objects discussed below.

The Trojan asteroids of Jupiter are dominated by members of the low-albedo P and D classes in the Tholen taxonomy: *DeMeo and Carry* (2013) estimate the Trojan population is two-thirds D-class asteroids by mass, with P-class asteroids making up the vast majority of the remainder. In a follow-up, *DeMeo and Carry* (2014) looked at the mass distribution with size, finding the D:P:C ratio varies wildly in the Trojan population, with Ds dominant in the 50–100-km size range but the D:P fraction more equal outside that range. Focused studies of Trojan asteroids by *Dotto et al.* (2006), *Fornasier et al.* (2007), and *De Luise et al.* (2010) found no objects with the 0.7-μm band seen in CM meteorites and Ch asteroids (section 2.1), even among objects with spectral slopes that place them in the C complex. *Emery and Brown* (2003) studied 20 Trojan asteroids in the 3-μm region, also finding them featureless. This is consistent with a lack of hydrated minerals, but the available spectra are necessarily of lower quality than main-belt objects of similar size. *Emery and Brown* (2004) find that the absence of absorptions in the 3-μm region limits the abundance of H<sub>2</sub>O ice to a few weight percent (at the surfaces), but up to 10–20 wt% hydrated minerals could be present and not seen in those data. *Cruikshank et al.* (2001) noted that 624 Hektor, the largest Trojan, could have 3 wt% ice or 40% hydrated minerals on its surface given observational uncertainties. If hydrated minerals are present on Trojan asteroids, their detection awaits observations from spacecraft visits or with larger or more capable telescopes than have been available to this point.

*Vilas et al.* (2006) compiled BVRI photometry, ECAS filter photometry, narrowband photometry, and CCD reflectance spectra of jovian irregular satellites, determining whether a 0.7-μm band was present. Of their sample of 16 targets, 11 tested positive for a 0.7-μm band. However, each of the groupings represented (Himalia prograde, Pasiphae retrograde, Carme retrograde) had members that tested both positive and negative. The sample also contained C types that tested both positive and negative and P/D types that tested both positive and negative. New CCD reflectance spectra (*Vilas*, 2010, 2013) confirm that the 0.7-μm feature is present in all Himalia group objects in their sample as well as some objects from the Pasiphae group.

Himalia, the largest of the jovian irregular satellites, has been observed from the ground and space. *Jarvis et al.* (2000) interpreted spectral and spectrophotometric data for Himalia to include a 0.7-μm band, although observational uncertainties were large. *Chamberlain and Brown* (2004) analyzed Cassini VIMS observations of Himalia, finding the “suggestion” of a 3-μm band, although large uncertainties frustrated a detailed spectral fit. More recently, *Brown and Rhoden* (2014) detected a 3-μm absorption on Himalia using the Keck telescope, finding a spectral shape that is a good match to the Themis/rounded type found in main-belt asteroids. While the *Vilas et al.* (2006) and *Jarvis et al.* (2000) findings of a 0.7-μm band would lead one to expect a 3-μm band on Himalia, a Pallas-type/sharp band

shape would be expected (see section 3.2). The finding of a Themis-type band shape led *Brown and Rhoden* (2014) to suggest additional observations of Himalia were needed to confirm the presence of a 0.7- $\mu\text{m}$  band. An additional possible explanation for the mismatch between the 3- $\mu\text{m}$  band shape seen on Himalia based on expectations from main-belt asteroids may be found in the work of *Clark et al.* (2012). They suggest that a band at 0.67  $\mu\text{m}$  seen on Iapetus by *Vilas et al.* (1996) may be due to nanophase hematite and/or iron. This may be a way of explaining a co-occurrence of the 0.7- $\mu\text{m}$  and non-Pallas-type 3- $\mu\text{m}$  bands, although obviously more work is needed.

Finally, *Fraeman et al.* (2014) used data from MRO's Compact Reconnaissance Imaging Spectrometer for Mars (CRISM) to detect absorptions centered near 0.65 and 2.8  $\mu\text{m}$  on Phobos and Deimos, the latter interpreted as due to hydrated minerals and with a band shape similar to the Pallas/sharp types. The band at 0.65  $\mu\text{m}$  was interpreted as either due to hydrated minerals (and the equivalent of the 0.7- $\mu\text{m}$  band discussed above) or, again, as due to nanophase materials. It is worth noting that while all of Deimos' surface and most of Phobos' surface had these absorptions, the areas of Phobos associated with Stickney and its ejecta have a more shallow spectral slope than the rest of Phobos and lack these absorptions, and are apparently anhydrous. Previous Earth- and spacebased observations of Phobos and Deimos did not find convincing evidence for hydrated minerals (*Murchie and Erard*, 1996; *Rivkin et al.*, 2002a; *Gendrin et al.*, 2005).

The Trojan asteroids, irregular satellites of the giant planets, and perhaps even Phobos and Deimos are thought to derive from the TNO population in Nice Model interpretations. Transneptunian objects are well known for having icy surfaces and a variety of spectral slopes similar to primitive asteroids. Other than Pluto, however, they are too faint to be observed in the 3- $\mu\text{m}$  region to study non-ice-hydrated minerals. Aqueous alteration products have been reported in the 0.7- $\mu\text{m}$  region on some TNOs and the related Centaur population (*De Bergh et al.*, 2004), although these interpretations have not been confirmed (*Fornasier et al.*, 2009) and band centers are different from what is seen on Ch asteroids (perhaps they are due to nanophase materials rather than phyllosilicates, as suggested above for Himalia). *Barucci et al.* (2008) reviews the evidence for TNO aqueous alteration from visible spectra.

### 3.7. Rotational Variation

To investigate the correlation of the 0.7- and 3- $\mu\text{m}$  absorption bands, *Howell et al.* (2005) reported rotationally resolved spectra of several asteroids to test whether variability with rotation could explain previous inconsistent observations. When simultaneous observations were not possible, full rotational coverage was obtained to explore whether spectral variation was present. The sample was not unbiased, since objects with inconsistent spectral observations were specifically targeted, so the rate of variability seen may not be typical. However, band depth variations ranging from 1% to 5% were found

in most of the objects studied, suggesting that variation is common, if not ubiquitous. Variation in band depth is now thought to explain all the cases where an asteroid with a 0.7- $\mu\text{m}$  band was not seen to have a corresponding 3- $\mu\text{m}$  band. For instance, *Lebofsky* (1980) found that the Ch asteroid (554) Peraga did not have a 3- $\mu\text{m}$  absorption, but due to the wavelength he used as the continuum to define the band, and the low spectral resolution of their photometry, those observations did not have the precision required to detect the band that is now seen.

*Rivkin and Volquardsen* (2010) observed Ceres over its entire rotation, finding band depths to be shallower at the longitudes associated with bright regions in the Hubble Space Telescope (HST) maps. This could be due to a smaller concentration of brucite and carbonates, or plausibly consistent with a variation in particle size. The variation seen and the precision of the data led to an estimate that brucite-free areas 200 km in diameter (at the equator) or larger would have been detected, and that if the ~3% variation in band depth were entirely due to the bright regions, those bright regions would have band depths of ~15–17% compared to the ~20–21% global average band depth.

Improved instrumentation has greatly expanded the number of asteroids observable at 3  $\mu\text{m}$ , and the sensitivity of the band depth that is detectable. However, the interpretation of the Vesta low-albedo surface material as impactor ejecta (section 1.6) might lead one to think that contamination may be a common occurrence and explains most if not all observations of variation. The nature and depth of the 3- $\mu\text{m}$  band that is observed suggests that this is not the case. Groundbased observations of Vesta show a much weaker band than the 10–20% band seen on most Ch asteroids. While other bright S-type objects (and members of other taxonomic classes not expected to have abundant hydrated surface materials) may show possible bands of a few percent, none show the deep, obvious bands of the Ch or even many of the W-class objects. More work certainly needs to be done to clarify this issue, but the current evidence suggests that there are asteroids composed of abundant hydrated silicates, formed in place, parents of CM and CI chondrites, among others. There may also be traces of impactor material detectable on asteroids without native hydrated silicates in their interiors, but careful groundbased spectroscopy can often distinguish them from each other. Improving these methods and finding robust tests of hydrated composition will certainly be a high priority in the future and an important goal of future missions.

### 3.8. Family Studies

Members of asteroid families are the fragments of larger, collisionally disrupted or cratered parent bodies; spectroscopic studies of family members provide information about the interior of the parent body. Three chapters in this volume (by Nesvorný et al., Masiero et al., and Michel et al.) address various aspects of asteroid family studies. Observations of the Themis family serve to illustrate the benefits of characterizing

hydration and other properties of family members. The Themis family is one of the most numerous and statistically reliable in the asteroid belt. It is approximately 3.2 AU from the Sun in low-inclination orbits and, as discussed in section 3.5, contains three MBCs. Spectroscopic studies of this family reveal an interesting picture. *Florczak et al.* (1999) obtained visible spectra (0.49–0.92 μm) of 36 members of this family, and found that about 50% of their sample showed evidence of aqueous alteration, indicating that the parent body was sufficiently warm to mobilize water. Their results also suggest that the percentage of asteroids showing aqueous alteration may decrease with the diameter of the objects; however, this needs confirmation as it could be due to observational biases, including the difficulty of detecting the 0.7-μm band in the fainter targets. In addition, *Campins* (2014) pointed out that Themis family fragments show clear spectral diversity in the near-IR (1–2.5 μm), with individual objects falling in four of the five groups of B-type near-IR spectra identified by *de León et al.* (2012). Wide variety in spectral slopes was also seen in the Themis family by *Fornasier et al.* (2014). Moreover, the 3-μm band on (24) Themis itself is indicative of water ice as opposed to hydrated minerals, as noted. The above results support at least some compositional diversity in the parent body of the Themis family and the distribution of compositions could be attributed to fragments coming from different depths in the original parent body. This tantalizing result and other aspects of family structure and composition can be addressed by new spectroscopic surveys, such as the European Space Agency's Gaia mission (*Campins et al.*, 2012) and targeted ground- and spacebased studies.

Family studies will also be important for understanding the nature of the different 3-μm types. While families are known to be relatively homogeneous in terms of their Tholen or Bus-DeMeo classifications, it is not yet clear how homogeneous they will be in terms of their hydrated mineralogies. The Hygiea family in particular should provide an interesting test: *Rivkin et al.* (2014a) argued that the lack of a Ceres family is supporting evidence that it has an icy shell covered by a lag deposit so that any collisional debris would quickly sublime away. It is tempting to assign a similar interior structure to Hygiea given its surface similarity to Ceres, but the existence of a Hygiea collisional family is at odds with the Ceres family scenario. Observations to determine whether Hygiea family members share a similar 3-μm band shape or not will be critical in interpreting whether Hygiea is an interloper in its own family.

#### 4. DISCUSSION

While much work is still to be done, and some key datasets are not yet in the literature or in some cases even yet obtained, the outlines of an overall scenario can be discerned. The strong correlation between the 0.7-μm band and the Sharp/Pallas-type 3-μm band shape suggests that the process creating the minerals responsible for the former also creates minerals responsible for the latter. However, because some Pallas types can be found without a 0.7-μm

band, the situation is likely not as simple as one mineral being responsible for both bands in all cases. Similarly, the presence of Themis-type band shapes in members of the C, P, and B classes suggests that whatever is causing the different spectral slopes of these objects is independent of the hydrated mineral composition, and the apparent concentration of the Ceres-type bands in large asteroids, if not related to poorer-quality data for smaller (and on average fainter) objects, is suggestive of similar histories for those objects (although see section 3.8). Furthermore, the fact that only Pallas-type bands are found in the meteorite collection is also likely an important clue.

The process or processes that changed aggregations of pebbles and dust (with or without ice) into solid rock is not well understood (*Consolmagno et al.*, 2003; H. Connolly, personal communication). Indeed, the process by which planetesimals are assembled has been a subject of much recent interest, with recent evidence suggesting that 100-km-scale objects are created directly from centimeter-sized building blocks, without intermediate stages (*Morbidelli et al.*, 2009).

One can imagine scenarios that, while at this point provisional, account for all of these factors: Carbonaceous/low-albedo 100-km-scale objects form as dust/pebble/ice aggregates into objects we would now call Themis types. The objects that have internal heat sufficient to melt ice undergo aqueous alteration, which can include exothermic reactions that lead to a self-perpetuating process. The aqueous alteration process lithifies bodies, and creates the minerals that exhibit Pallas-type bands. Objects that are sufficiently large and/or contain sufficient heat can differentiate with an icy crust/mantle over a rocky core. The alteration processes associated with this pathway may create the brucite and carbonates seen on the Ceres types. The Themis types remain as they were at formation, unlithified and therefore unable to generate meteorites. The Ceres types may not create meteorites because they have near-surface ice, and large impacts may only create icy families that are short-lived against sublimation instead of the rocky families created by other parent bodies (see *Rivkin et al.*, 2014a). In this scenario, only the Pallas types, lithified by aqueous alteration, can generate low-albedo, carbonaceous material strong enough to survive passage through Earth's atmosphere to be collected as meteorites.

This scenario has potential inconsistencies — for instance, it's not clear if dynamical families can be created in situations where meteorites are not predicted (for instance, with the Themis family), and it's not obvious that Hygiea and Ceres, both of which have very similar spectra in the 3-μm region, will necessarily have had similar histories and have similar interiors. Nevertheless, the ongoing work in understanding the hydrated mineralogies of the asteroids seem likely lead to paradigms at least broadly similar to what is outlined above.

#### 5. FUTURE WORK

We have spent the previous pages discussing the current state of affairs with regard to water/hydroxyl in the

asteroid and meteorite populations. The upcoming decade promises further progress on many fronts, from Earth-based observations using new capabilities and facilities to *in situ* observations by spacecraft and sample returns.

### 5.1. Observing from the Stratosphere and Above

As noted above, Earth's atmosphere places limitations on groundbased studies of asteroidal water/OH, making some wavelengths basically unobservable. The capability to observe from above Earth's atmosphere would revolutionize the work presented here, allowing OH band depths and band centers to be directly measured instead of inferred or modeled. The spaceborne telescopes of the late twentieth and early twenty-first century generally did not cover the 3- $\mu\text{m}$  region, or had broadband filters that only allowed indirect measurements, but the next generation of facilities should provide improved coverage.

**5.1.1. Stratospheric Observatory for Infrared Astronomy.** The SOFIA project has been fully commissioned, with the First Light Infrared TEst CAMera (FLITECAM) instrument providing spectroscopic data with spectral resolution ( $\lambda/\Delta\lambda$ ) of 1300 from wavelengths 1.14–4.07  $\mu\text{m}$ , with some gaps in coverage. Its typical flight altitude of 11–14 km puts it above 99% of Earth's water vapor, making it well suited to observations in the 3- $\mu\text{m}$  region. However, it is unclear how many asteroids will be observable due to proposal pressure over SOFIA's planned lifetime, and budget pressures threaten to shorten the mission lifetime to a much shorter one than originally expected.

**5.1.2. Balloon-borne observations and suborbital flights.** New efforts to use balloon-borne telescopes to study small bodies began with the effort mounted to observe Comet ISON in 2013 ("BRRISON"). Very high-altitude balloons show the promise of providing a long-term platform to study astronomical phenomena above much of Earth's atmosphere, thus reducing, if not quite fully eliminating, the effects of Earth's atmosphere on IR observations (Young *et al.*, 2013), although pointing stability of the balloons remains an ongoing concern. The BRRISON and BOPPS missions included asteroids in their observing plans, and Ceres was observed with UV/visible and IR instruments during the BOPPS flight, which occurred as this was being written.

Concurrently, telescopes are being developed for commercial suborbital spacecraft that will operate above Earth's atmosphere. These should be capable of making rapid timescale observations, and can sample UV through the NIR spectral region (Vilas *et al.*, 2013), eliminating atmospheric contamination effects, but are more limited in observational duration. These techniques also hold the promise of expanding observations of water-bearing asteroids while minimizing atmospheric contamination.

**5.1.3. James Webb Space Telescope.** The James Webb Space Telescope (JWST) has similar potential to revolutionize asteroidal studies. Its Near-Infrared Spectrograph (NIRSPEC) instrument has spectroscopic capabilities in the 1–5- $\mu\text{m}$  spectral region, and the Mid-Infrared Instrument

(MIRI) provides low-resolution spectroscopy ( $\lambda/\Delta\lambda \sim 100$ ) from 5 to 14  $\mu\text{m}$  and medium-resolution spectroscopy ( $\lambda/\Delta\lambda \sim 2200$ –3500) and imaging in nine bands from 5 to 28  $\mu\text{m}$ . The anticipated sensitivity for JWST should allow high-quality ( $S/N > 30$  in 10<sup>4</sup> s) measurements in the 3- $\mu\text{m}$  region to be made for low-albedo main-belt asteroids of ~3 km diameter, with the size rising to ~10 km in the Trojan clouds (or for the irregular satellites of Jupiter). Unfortunately, the current capabilities planned for JWST do not include the ability to track objects moving faster than Mars, which precludes observations of NEOs at arbitrary times (for instance, near perihelion and/or away from quadrature). It is possible, however, that certain NEOs of interest can be observed at specific times when their apparent rates of motion are slower (if such times exist). As with SOFIA, proposal pressure for JWST may be the greatest impediment to asteroidal studies.

### 5.2. Spacecraft Visits to Asteroids

In addition to spacecraft telescopically observing asteroids, at least three spacecraft will be visiting asteroids and making close-up observations. Dawn, mentioned above in the context of Vesta, will be visiting Ceres by the time this book is published. We expect it to make great progress toward answering several of the questions posed here. The other two spacecraft, Hayabusa-2 and OSIRIS-REx, are intended as sample return missions to primitive asteroids. However, both missions also carry IR spectrometers that will allow observations in the wavelength regions discussed above to provide context for the samples.

**5.2.1. Dawn at Ceres.** The Dawn mission team has contrasted the water-rich nature of Ceres to the water-poor nature of Vesta, and several of the mission goals at Ceres relate to water, including mapping hydrogen abundance using the neutron spectrometer. More pertinent to this chapter, the VIR visible and near-IR spectrometer covers the 0.25–5- $\mu\text{m}$  spectral range, including both the 0.7- $\mu\text{m}$  and 3- $\mu\text{m}$  region. The mission plan includes obtaining half of the VIR frames with a spatial resolution of 400 m or better, with the remainder at a spatial resolution of 1.6 km or better. While Earth-based observations have not detected ice on Ceres' surface, the higher spatial resolution available in the Dawn data will be able to detect much smaller amounts of surface ice (stable at very high latitudes) or place much stronger upper limits on ice abundance than are currently available. It will also provide context for the Herschel observations of water sublimation from Ceres (Kippers *et al.*, 2014), perhaps by identifying surface features related to sublimation.

**5.2.2. Hayabusa-2.** The Hayabusa-2 mission was launched in 2015 by the Japanese space agency JAXA, targeting the low-albedo asteroid 1999 JU<sub>3</sub> for a sample return mission. Observations of 1999 JU<sub>3</sub> place it in the C class (Pinilla-Alonso *et al.*, 2013). Besides the returned sample, Hayabusa-2 carries two instruments that will be able to detect and characterize hydrated minerals on the asteroidal surface: a multiband imager (ONC-T), which would allow measurement of the 0.7- $\mu\text{m}$  band if present at

spatial resolution of 2 m/pixel, and a near-IR spectrometer (NIRS3), which covers a wavelength range of 1.8–3.2 μm. The goal of NIRS3 is to allow hydrated mineral quantities to be estimated to ~1–2% (Iwata *et al.*, 2013), and the spatial sampling is ~40 m/spectrum at the 20-km “home position” altitude, improving to 2 m/spectrum during one low-altitude mission phase.

**5.2.3. Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer.** As noted above, NASA’s OSIRIS-REx mission will return samples to Earth from the NEA 101955 Bennu (Lauretta *et al.*, 2015). The OSIRIS-REx spacecraft will be well instrumented to carry out a year-long campaign to characterize Bennu and select a sampling site. OVIRS will map the spectrum of the asteroid from 0.4 to 4.2 μm. These data will be well suited for direct searches for the 0.7- and 3-μm hydration features. OTES will similarly map Bennu from 6 to 50 μm, providing complementary spectral information in the mid-IR for mineralogical characterization. Thermal mapping at different times of day and points in the orbit around the Sun will enable monitoring of temperatures and derivation of spatially resolved thermal inertias, which can both be used to understand the stability of water (in its various forms) on and below Bennu’s surface as well as measure mid-IR bands associated with phyllosilicates (section 2.3). The imagers will be used for sensitive searches for extended emission and/or plumes, which, if present, could suggest either thermal fatigue- or volatile-related release of dust. Most importantly, the samples returned to Earth will be analyzed in detail, providing a window into the make-up of primitive solar system material and excellent ground truth for the interpretation of remote observations.

### 5.3. Large Groundbased Telescopes

The prospects for larger groundbased telescopes provide additional opportunities for observing smaller and more distant asteroids in the future. Planned telescopes in the 20-m and larger class like the Giant Magellan Telescope (GMT) (25 m), Thirty Meter Telescope (TMT) (30 m), and European Extremely Large Telescope (E-ELT) (39 m) will begin operation late this decade and early next decade. Instrumentation on the TMT and GMT, expected to be the first ones completed, will not cover the 3-μm region at first and will only cover the 0.7-μm region at very high spectral resolution (<http://tmt.org/sites/default/files/TMT-Instrumentation-and-Performance-Handbook.pdf>, <http://www.eso.org/sci/meetings/2013/EELT2013/talks/Jacoby.pdf>). Instrumentation at the E-ELT is yet to be finalized. Despite this, we expect members of the community to make use of these facilities in ways that are not necessarily obvious at the moment.

## 6. OPEN QUESTIONS

1. *Can the different 3-μm types be found on a single body?* Did the aqueous alteration process create spectrally distinct minerals at different times? Were some minerals more

commonly created with depth? Is the 3-μm type a function of starting material?

2. *To what extent is impactor contamination important on small bodies?* If contamination by carbonaceous impactors has caused the 3-μm band on Vesta, is it also potentially important on large (or small) S-class asteroids? What does the existence of different 3-μm types and the correlation of the 0.7-μm band and the Pallas-type 3-μm band tell us about how widespread impactor contamination may be? Can we identify this process on low-albedo objects as well, and should contamination by ordinary chondrite impactors also be expected?

3. *How do the outer solar system small-body populations (Trojans, irregular satellites, comets) fit into the overall picture?* At the time of *Asteroids III*, it was thought that asteroids and comets were disjunct sets and the Hilda and Trojan asteroids were in effect an outward extension of the asteroid belt. At this writing, there appear to be ample objects with physical natures that are partially cometary and partially asteroidal. Do the Trojans and irregular satellites represent material that is distinct from both asteroids and comets, or are they simply typical comets that experienced transport early in solar system history?

4. *Does the solar wind create appreciable amounts of OH on small-body surfaces?* The water brought to Earth by asteroidal impacts may not only have come on carbonaceous bodies — if significant amounts of OH can be created by the solar wind, most asteroidal impactors regardless of composition will have brought in some water, if only a trace. In addition, while the timescale for mining water from asteroids commercially is likely decades away, the techniques needed to identify good targets will be critically dependent upon knowing whether any OH detected is on the very surface or likely to be representative of the interior.

5. *What is responsible for the varying appearance of the 0.7-μm band in asteroids/meteorites that otherwise appear similar at 3 μm?* The frequent presence of 0.7-μm bands in CM meteorite spectra leads to a reasonable linkage between that meteorite group and the Ch asteroids, as discussed several times above. However, there is a significant fraction of C-complex asteroids without the 0.7-μm band but with a Pallas-type 3-μm band. What is their association with the Ch asteroids?

6. *What variation in band shape is present in each of the 3-μm types, and what is causing that variability?* Are the differences in band position in the Themis types, or the presence/absence of shoulders in Pallas-type bands, indicative of important compositional differences?

7. *How can we best account for volatiles hidden from the surface?* The MBCs offer examples of the importance of indirect measurements of water ice when targets are faint. Similarly, the lack of any water or hydroxyl absorption in Rosetta measurements of Comet 67P (Capaccioni *et al.*, 2015) indicates that spectral evidence for volatiles may be absent even if high-spatial-resolution and high-quality data are available. It is possible that many (most?) undifferentiated low-albedo objects in the outer asteroid and beyond

have much more ice than their surface spectra betray, and depending on surface conditions any ice table may be deeper than even neutron spectroscopy can reach.

## 7. CONCLUSIONS

Since the publication of *Asteroids III*, the water content of small bodies has been recognized as of great importance to their study, with robotic and human exploration of water-rich asteroids assigned high priority by the international planetary science community. New instruments and capabilities in laboratories and at telescopes have allowed better data to be obtained and the interfering effects of Earth's water to be minimized. The discovery of the “activated asteroids” and of ice at asteroidal surfaces has demonstrated that free water is still present today in significant amounts. Work by many authors has linked the Ch asteroid class to the CM meteorite group sufficiently firmly that the type of statistical and mineralogical analysis that has been commonplace for ordinary chondrite and basaltic achondrite analogs can now begin for the carbonaceous chondrites. Variety in the hydrated mineralogy of asteroids has been seen, and we are starting to associate that variety with particular asteroid sizes and locations, with an apparent path toward divining their histories. Toward this effort, the groundbased remote sensing that we have historically used to study asteroids will be augmented in the near future with observations by airborne and spaceborne platforms, visits to hydrated asteroids, and ground truth via sample return. By the time *Asteroids V* is released, presumably sometime in the 2020s or early 2030s, it seems likely that the state of knowledge of the hydrated minerals on asteroids will not be containable in a single chapter.

---

Large-area surveys operating at mid-infrared wavelengths have proven to be a valuable means of discovering and characterizing minor planets. Through the use of radiometric models, it is possible to derive physical properties such as diameters, albedos, and thermal inertia for large numbers of objects. Modern detector array technology has resulted in a significant improvement in spatial resolution and sensitivity compared with previous generations of spacebased infrared telescopes, giving rise to a commensurate increase in the number of objects that have been observed at these wavelengths. Spacebased infrared surveys of asteroids therefore offer an effective method of rapidly gathering information about the orbital and physical properties of small-body populations. The AKARI, Wide-field Infrared Survey Explorer (WISE)/ Near-Earth Object Wide-field Infrared Survey Explorer (NEOWISE), Spitzer Space Telescope, and Herschel Space Observatory missions have significantly increased the number of minor planets with well-determined diameters and albedos.

## 1. INTRODUCTION

A variety of remote-sensing techniques have given rise to much of our understanding of the small-body populations in our solar system. Groundbased surveys operating at visible wavelengths have discovered most of the minor planets that are known today. At present, roughly 700,000 asteroids have been discovered in the main belt between Mars and Jupiter, ~13,000 near-Earth objects (NEOs) are known at all sizes, and some 5000 jovian Trojans have been found. While these numbers are thought to represent only a tiny fraction of the small bodies believed to exist in our solar system, much can be learned about these populations by studying the physical and dynamical properties of representative samples (e.g., Bottke et al., 2005; Mainzer et al., 2011b; Grav et al., 2011a; see also the chapter by Jedicke et al. in this volume). Moreover, information about the probable composition and mineralogy of asteroids can be learned from visible and near-infrared (VNIR) spectroscopy and spectrophotometry. Such studies have been carried out for ~2500 asteroids [e.g., the Massachusetts Institute of Technology (MIT)-University of Hawaii (UH)-Infrared Telescope Facility (IRTF) Joint Campaign for NEO Spectral Reconnaissance (*Tholen and Barucci*, 1989; *Xu* et al., 1995; *Bus and Binzel*, 2002; *DeMeo* et al., 2009; *Reddy*, 2010; *Kuroda* et al., 2014; and many others)]. Compared to broadband imaging, spectrally resolved observations require brighter sources for the same signal-to-

noise ratio, which limits the number of targets observable. The fourth release of the Sloan Digital Sky Survey (SDSS) Moving Object Catalog (*Stoughton* et al., 2002; *Abazajian* et al., 2003) provided ~100,000 observations in u, g, r, i, and z filters, leading to taxonomic classifications for ~64,000 asteroids (*Carvano* et al., 2010).

Asteroid lightcurves, sometimes combined with stellar occultation data, have been inverted to obtain models of shapes and rotational states for hundreds of objects (*Kaasalainen* et al., 2001; *Durech* et al., 2010; see also the chapter by Durech et al. in this volume). Radar observations can produce the most detailed information about shape, size, orbit, and spin state short of visiting a body with spacecraft (e.g., *Ostro* et al., 2002; see the chapter by Benner et al. in this volume). Since radar echoes must be sent to and received from a body, sensitivity drops as distance to the fourth power, so objects must make fairly close approaches in order to be detected. Approximately 600 asteroids have been observed with radar to date (<http://echo.jpl.nasa.gov/asteroids/index.html>). Polarimetry offers a means of studying asteroid surface properties, but since only a small fraction of the total luminosity is polarized, this technique has been applied to ~300 asteroids thus far (*Lupishko and Vasilyev*, 2012; *Gil-Hutton and Canada-Assani*, 2012).

While powerful, these techniques have only been employed on a small fraction of asteroids. Until recently, for the vast majority of asteroids, nothing was known except

for absolute visible magnitudes (denoted H) and orbital parameters. Observing small bodies at thermal infrared (IR) wavelengths with space telescopes complements other techniques such as visible-light groundbased surveys, VNIR spectroscopy and spectrophotometry, radar studies, and *in situ* spacecraft visits. If a telescope can be cryogenically cooled such that its sensitivity is limited by the natural backgrounds in space, rather than by self-emission, it is possible to obtain measurements of physical properties such as diameters and albedos very rapidly for a large number of asteroids. Advances in IR detector technology have made it possible to achieve diffraction-limited imaging and orders-of-magnitude improvement in sensitivity compared to previous generations of IR space telescopes such as the Infrared Astronomical Satellite (IRAS) (Neugebauer *et al.*, 1984; Tedesco *et al.*, 2002b), the Mid-Course Space Experiment (MSX) (Mill *et al.*, 1994; Price *et al.*, 2001; Tedesco *et al.*, 2002a), and the Infrared Space Observatory (ISO) (Kessler *et al.*, 1996). More recent surveys have now observed a substantial fraction of the known asteroids at thermal-IR wavelengths, allowing for robust determinations of their diameters and (where corresponding visible light observations are available) albedos. These measurements in turn inform the understanding of the dynamical and collisional history of the asteroids, their probable compositions and structure, and the impact hazard they pose to Earth.

Groundbased thermal-IR observations began to play an important role in the physical characterization of the largest asteroids beginning in the 1970s with the advent of IR detectors (e.g., Allen, 1970, 1971; Matson, 1971). These observations require the largest groundbased telescopes due to the enormous thermal background from Earth's atmosphere and the telescope itself (backgrounds  $\sim 10^6$  lower between  $\sim 4$  and  $200\text{ }\mu\text{m}$  are achievable with a spacebased cooled telescope). Moreover, Earth's atmospheric opacity restricts groundbased observations to selected wavelengths. Some mid-IR instruments are available on groundbased telescopes, especially at high-altitude observatories in Hawaii and Chile, leading to observations of several hundred objects to date (e.g., Hansen, 1976; Cruikshank, 1977; Lebofsky *et al.*, 1978; Morrison and Lebofsky, 1979; Delbó *et al.*, 2003, 2011; Matter *et al.*, 2011; Müller *et al.*, 2012, 2013; Wolters *et al.*, 2005, 2008).

Thermal IR fluxes can be used to derive physical properties such as effective spherical diameter (defined as the diameter of a spherical thermal model asteroid emitting the same IR flux as that observed) through the use of radiometric models. Section 3 below and the chapter by Delbó *et al.* in this volume give a more detailed description of common thermal models (see also Harris and Lagerros, 2002). Small-body spectral energy distributions consist of the sum of blackbody curves produced by reflected sunlight, centered at visible wavelengths, and blackbody curves generated by thermal emission from areas at different temperatures. The central wavelength of the thermal peak depends on an object's heliocentric distance and thermal properties but usually lies somewhere between 5 and  $20\text{ }\mu\text{m}$  for most aster-

oids interior to Saturn's orbit. Hence, by combining orbital information with thermal-IR observations that bracket an object's rotational lightcurve, it is possible to constrain the total energy being emitted by an asteroid and convert this into an effective spherical diameter. With only a single IR measurement, it is possible to compute a projected size, but this does not necessarily correspond to the effective spherical diameter if the object is elongated. Diameters derived from good-quality thermal-IR measurements are considerably more accurate than those estimated from visible-light observations alone, since an asteroid's visible flux depends strongly on its albedo. With multiple thermally dominated IR bands that adequately sample rotational phase, effective spherical diameters can be determined to within  $\pm 10\%$  (Mainzer *et al.*, 2011c) (see section 3 for a more detailed discussion). However, since asteroid albedos range from a few percent to  $\sim 50\%$  (e.g., Binzel *et al.*, 2004; Mainzer *et al.*, 2011b), effective spherical diameters derived from only visible light measurements are typically uncertain by factors of 2–3. If both IR and visible observations are available, it is possible to solve for albedo as well.

Spacebased thermal-IR surveys therefore offer a number of advantages for understanding small-body populations. Since an asteroid's visible flux is a strong function of its albedo, visible-light surveys are preferentially biased against low-albedo objects, which are intrinsically dimmer than higher-albedo asteroids. By contrast, surveys that independently detect asteroids (whether previously known or new) based solely on their thermal-IR flux are approximately equally sensitive to low- and high-albedo asteroids. Infrared-selected samples directly measure diameter and are insensitive to albedo, allowing for direct determination of a population's size-frequency distribution rather than its H-magnitude distribution. An IR-selected sample can therefore be readily extrapolated to determine the orbital and physical properties of the underlying population.

In addition, albedos derived from the combination of visible and IR observations offer clues to an object's probable composition. Accurate measurements of asteroid diameters are needed to constrain the impact energy of potentially hazardous objects and inform mitigation strategies. Spacebased telescopes can, depending on their design, observe regions of sky that are inaccessible to groundbased observers. All-sky surveys offer the additional benefit of sampling the population of objects with high inclinations more thoroughly. Thermal-IR observations can be used to determine thermal inertia, a key parameter for understanding the nature of asteroid regoliths (see the chapter by Delbó *et al.* in this volume). Depending on wavelength and spectral resolution, spacebased IR instruments can allow for measurement of emission and absorption features that are difficult or impossible to access from groundbased facilities.

## 2. THE MISSIONS

The IRAS space telescope was the first space mission to survey the minor planets at thermal-IR wavelengths in 1983,

followed by MSX and ISO in 1995–1998 and 1996–1997, respectively. With 62 pixels and a 60-cm telescope, the IRAS mission observed ~2200 asteroids (Matson et al., 1989; Veecher et al., 1989; Tedesco et al., 2002b). ISO observed ~40 different asteroids in targeted mode (Dotto et al., 2002), and MSX observed an additional ~30 objects not detected by IRAS (Tedesco et al., 2002a). IRAS was not diffraction limited due to the large physical size of its pixels; its minimum spatial resolution was ~30 arcsec. IRAS discovered six asteroids, including (3200) Phaethon, the parent body of the Geminid meteor stream (Whipple, 1983; Green et al., 1985), and five comets.

As larger-format IR arrays with smaller pixels and lower noise became available, they were incorporated into next-generation observatories such as the Spitzer Space Telescope (hereafter Spitzer) (Werner et al., 2004), the AKARI mission (Murakami et al., 2007), WISE (Wright et al., 2010), and the Herschel Space Observatory (hereafter Herschel) (Pilbratt et al., 2010). These new arrays allowed for Nyquist-sampled images (i.e. the pixel width is less than half the size of the point spread function produced by the telescope), improving spatial resolution and sensitivity by orders of magnitude over IRAS and MSX.

The advances in microelectronics, visible-light camera chips, and tactical sensors are directly responsible for the vast improvement in sensitivity and miniaturization from the IRAS mission to today. The 62 IRAS detectors were individually manufactured and hand-assembled; each pixel was ~1–2 mm across (Young, 1993). Major developments since IRAS include the advent of monolithically fabricated arrays of pixels and the ability to produce semiconductor material with extremely low levels of impurities. The result is the development of megapixel IR arrays capable of achieving low read noise and dark currents well below the natural zodiacal background at thermal-IR wavelengths. For example, the WISE mission included four 1024<sup>2</sup> detector arrays, each with 18-μm pixels (Mainzer et al., 2005). Recent developments include the fabrication of megapixel mid-IR detectors capable of operating at higher temperatures, which will ease the burden on cryogenic systems for future missions (McMurtry et al., 2013).

Spitzer, AKARI, WISE, and Herschel were cryogenically cooled during their prime mission phases, and all but Herschel continued to operate using the wavelengths that remained available following depletion of their liquid or solid cryogens. Table 1 summarizes the key technical and operational differences between them. Spitzer and Herschel functioned as general-purpose observatories, with a wide range of observing modes employed during their fully cryogenic missions. Both performed targeted observations of previously known objects; neither mission has been widely used for asteroid discovery. WISE operated in a single-survey mode, covering the entire sky in six months. Modifications to its science data processing pipeline allowed new discoveries of minor planets to be made. The primary objective of the AKARI mission was to carry out an all-sky survey; AKARI also had the capability of performing targeted spectroscopic

and imaging observations. After the liquid cryogen boiled off, only near-IR observations in a targeted mode were carried out. AKARI did not discover new asteroids; the all-sky observing cadence did not support the multiple observations needed to discover new moving objects.

In this chapter, we review only spacebased asteroid studies from remote telescopic observations. For a detailed discussion of the results from mid-IR observations of small bodies carried out by *in situ* missions such as Dawn and Rosetta, the reader is referred to the chapters by Barucci et al. and Russell et al. in this volume. These missions gathered thermal-IR maps of bodies such as (2867) Šteins (Leyrat et al., 2011), (21) Lutetia, and (4) Vesta (Keihm et al., 2012; Tosi et al., 2014; Capria et al., 2014).

## 2.1. Spitzer Space Telescope

Spitzer was launched on August 25, 2003, into an Earth-trailing orbit (Werner et al., 2004). As a NASA “Great Observatory,” it was designed to function as a facility observatory for the astrophysics and planetary communities. The 85-cm telescope was launched warm, sitting atop a ~350-L superfluid helium cryostat that enclosed the instruments and fine guidance sensor. During its 5.5-year fully cryogenic mission, three instruments were available: the Infrared Array Camera (IRAC), an imager operating at 3.6, 4.5, 5.8, and 8 μm (Fazio et al., 2004); the Multiband Imaging Photometer for Spitzer (MIPS), which provided imaging and spectroscopy covering the wavelength range 24–160 μm (Rieke et al., 2004); and the Infrared Spectrograph (IRS), which provided low- and medium-resolution spectroscopy between 5 and 35 μm and imaging at 16 and 22 μm (Houck et al., 2004). The IRAC instrument observed the 3.4- and 5.8-μm channels simultaneously, and the 4.5- and 8-μm channels simultaneously. During the fully cryogenic portion of the Spitzer mission, the telescope temperature was maintained below 8 K using vapor escaping from the superfluid helium cryostat; focal planes were maintained at 1.4 K to support operation of the longest wavelengths.

In 2008, the liquid helium was depleted; at this point, the focal planes and telescope reached an equilibrium temperature near 29 K. The 3.6- and 4.5-μm channels of IRAC continued to operate via passive cooling in an extended “warm mission” phase (Storrie-Lombardi and Dodd, 2012). Asteroids throughout the solar system were targeted using all three Spitzer instruments during the fully cryogenic and warm mission phases (e.g., Emery et al., 2006, 2014; Trilling et al., 2010; Licandro et al., 2012; Bhattacharya et al., 2010; Mommert et al., 2015; Ryan et al., 2015).

Data from Spitzer can be accessed through the Spitzer Heritage Archive (<http://sha.ipac.caltech.edu>). In general, proprietary periods are one year for Guest Observer programs.

## 2.2. AKARI

Consisting of a 68.5-cm telescope, the AKARI satellite (meaning “light” as opposed to representing an acronym)

TABLE 1. Summary of recent spacebased IR telescope capabilities (as of March 2015).

Mission	Date	Wavelengths	Field of View (arcmin)	Observing Modes
Spitzer	2003–2008	IRAC: Imaging 3.6, 4.5, 5.8, 8 $\mu\text{m}$ IRS: Spectroscopy 5–35 $\mu\text{m}$ IRS: Imaging 16, 22 $\mu\text{m}$ MIPS: Imaging 24, 70, 160 $\mu\text{m}$ MIPS: Spectroscopy 55–95 $\mu\text{m}$	IRAC: 5 $\times$ 5 IRS: $\sim$ 0.9 $\times$ 1.35 MIPS: 5 $\times$ 5	Targeted

launched on February 21, 2006, into a Sun-synchronous polar orbit at 700 km altitude (*Murakami et al.*, 2007). AKARI carried two instruments, the InfraRed Camera (IRC) (*Onaka et al.*, 2007) and the Far-Infrared Surveyor (FIS) (*Kawada et al.*, 2007), covering the spectral ranges of 2–26  $\mu\text{m}$  and 50–180  $\mu\text{m}$ , respectively. The whole telescope and instruments were cooled down to  $\sim$ 6 K using 180 L of superfluid helium and two sets of two-stage Stirling cycle mechanical coolers (*Nakagawa et al.*, 2007). AKARI’s liquid helium supply lasted until August 26, 2007, and enabled 550 days of fully cryogenic operations (the AKARI “cold mission”).

During the cold mission phase, AKARI completed an all-sky survey at six bands: 9, 18, 65, 90, 140, and 160  $\mu\text{m}$  (*Ishihara et al.*, 2010; *Yamamura et al.*, 2010). The mid-IR part of the all-sky survey was conducted at two broadbands centered at 9 and 18  $\mu\text{m}$  with the IRC. More than 90% of the sky was observed with both bands, and a large portion of the sky was observed more than three times. The point source catalog of  $\sim$ 877,000 objects was produced from the mid-IR images of the all-sky survey data (*Ishihara et al.*, 2010). An asteroid catalog was also constructed from the mid-IR survey data (*Usui et al.*, 2011). The 16-month cold mission allowed the inner edge of the main belt to be observed at least once (*Usui et al.*, 2013). AKARI detected point sources by identifying objects that were detected at least twice at the same fixed point on the sky, leaving transient sources to

be identified with the list of solar system bodies known at the time of data processing. Most asteroids in the AKARI catalog were detected fewer than five times, with  $\sim$ 25% having one detection (*Usui et al.*, 2011). The two mid-IR bands observed different regions of the sky, separated by  $\sim$ 25' in the cross-scan direction; thus solar system objects were not observed simultaneously in both bands. In total, 5120 known asteroids were identified with AKARI detections. The list of derived sizes and albedos, known as the Asteroid Catalog Using AKARI (AcuA), is publicly available (<http://darts.isas.jaxa.jp/ir/akari/catalogue/AcuA.html>). The IR fluxes of individual asteroids observed with AKARI will also be released in the near future.

The instruments onboard AKARI performed both deep imaging and spectroscopy in the targeted observation mode, occasionally inserted into a continuous survey operation. The targeted observations were planned in advance to maximize the all-sky survey coverage and efficiency. A number of observations for a wide variety of astrophysical targets ranging from solar system objects to galaxies at cosmological distances were carried out in the targeted mode. During the cold mission, AKARI made more than 5000 targeted observations, including a small serendipitous survey of asteroids (*Hasegawa et al.*, 2013), thermal-IR photometric observations of (25143) Itokawa (*Müller et al.*, 2014b) and (162173) 1999 JU<sub>3</sub> (*Hasegawa et al.*, 2008), the targets of

the Japan Aerospace Exploration Agency (JAXA) Hayabusa and Hayabusa-2 sample return missions (see the chapter by Yoshikawa et al. in this volume).

After the exhaustion of AKARI's liquid helium, the telescope and instruments remained at sufficiently low temperatures (below 50 K) owing to the mechanical cooler. Targeted near-IR observations with the IRC were therefore able to be carried out in the AKARI "warm mission" phase. Low-resolution spectroscopy was performed using the near-IR channel of the IRC from 2–5  $\mu\text{m}$ . The AKARI warm mission's science observations began in June 2008 and continued until May 2011. The IRC carried out more than 12,000 targeted observations during the warm mission, including spectroscopy of 70 asteroids. The AKARI data are available from the Institute of Space and Astronautical Science (ISAS)/JAXA (<http://www.ir.isas.jaxa.jp/AKARI/Observation/>).

### 2.3. Wide-Field Infrared Survey Explorer/Near-Earth Object Wide-Field Infrared Survey Explorer

Launched on December 14, 2009, into a 525-km Sun-synchronous orbit, the WISE mission surveyed the entire sky at four infrared wavelengths (3.4, 4.6, 12 and 22  $\mu\text{m}$ ; denoted W1, W2, W3, and W4 respectively) using a 40-cm telescope (Wright et al., 2010). The survey's scientific objectives were to find the cool stars and luminous galaxies using a single operational mode. The survey strategy was designed for rapid sky coverage, resulting in observations of the entire sky with an average depth of  $\sim$ 10 exposures on the ecliptic plane (rising to thousands at the ecliptic poles) after six months. All four wavelengths were imaged simultaneously using beam splitters. Augmentations to the WISE science data processing pipeline allowed for archiving of the individual single-frame exposures as well as mining of moving objects from the images in real time (Mainzer et al., 2011a). The fully cryogenic baseline mission was completed in July 2010, and the solid hydrogen cryogen used to cool the W3 and W4 detectors was partially exhausted on August 5, 2010, resulting in the loss of the W4 channel. Operations continued using the W1, W2, and W3 arrays until the cryogen was fully exhausted on September 30, 2010. The mission continued in a post-cryogenic phase with the goal of observing NEOs (asteroids and comets with perihelia  $<1.3$  AU) until February 1, 2011, using the passively cooled W1 and W2 channels. After this, it was placed into hibernation for 32 months. During all phases of the prime mission,  $>158,000$  asteroids were detected, including  $\sim$ 34,000 new discoveries.

The spacecraft was reawakened in August 2013 to begin an extended mission, known as NEOWISE, to discover and characterize the NEO population using the 3.4- and 4.6- $\mu\text{m}$  channels, which remain operational via passive cooling to  $\sim$ 75 K. Survey operations resumed on December 21, 2013, and are expected to continue until early 2017. To date, the spacecraft has observed  $\sim$ 15,600 minor planets, including 391 NEOs, a rate of  $\sim$ 0.7–0.8 NEOs per day (Mainzer et al., 2014b; Nugent et al., 2015).

The WISE observational strategy typically resulted in  $\sim$ 10–12 observations of most asteroids spaced over  $\sim$ 36 hours. However, the short length of the observational arc means that groundbased follow-up is necessary to secure orbits for new discoveries. The worldwide community of professional and amateur observers has contributed to follow-up for NEOWISE NEO candidate discoveries, which are typically found with  $R \sim 22$  mag. As an all-sky survey, NEOWISE candidates are frequently found at high declinations, regardless of weather or lunar phase, posing unique challenges for follow-up observers.

All data from the WISE prime mission and the first year of the NEOWISE reactivation have been publicly released and are available through NASA's Infrared Science Archive (IRSA) (<http://irsa.ipac.caltech.edu/Missions/wise.html>). Derived physical properties for minor planets are being prepared for submission to NASA's Planetary Data System; until then, they are available through the individual NEOWISE team publications, i.e., Mainzer et al. (2011b, 2012a, 2014a,b) for the NEOs; Masiero et al. (2011, 2012a, 2014) for the main-belt asteroids (MBAs); Grav et al. (2011b, 2012a,b) for the Hilda group and jovian Trojans; and Bauer et al. (2013) for the scattered-disk objects and Centaur populations.

### 2.4. Herschel Space Observatory

Herschel launched on May 14, 2009, carrying a 3.5-m telescope into orbit around the Earth-Sun L<sub>2</sub> Lagrange point (Pilbratt et al., 2010). Herschel's telescope was passively cooled, and a Dewar containing  $\sim$ 2370 L of superfluid liquid helium was used to cool its far-IR instruments, the Photodetector Array Camera and Spectrometer (PACS) (Poglitsch et al., 2010), the Spectral and Photometric Imaging REceiver (SPIRE) (Griffin et al., 2010), and the Heterodyne Instrument for the Far Infrared (HIFI) (de Graauw et al., 2010). Owing to its longer wavelengths, spanning 55–671  $\mu\text{m}$ , Herschel was primarily used to observe the more distant minor planets (which are cooler and therefore emit strongly at far-IR) such as transneptunian and Kuiper belt objects by the open-time key program entitled "TNOs are cool: A survey of the transneptunian region" (Müller et al., 2010). However, MBAs were used as calibration sources (Müller et al., 2014a), and measurements of individual targets of interest were made for  $\sim$ 10 asteroids (e.g., Leyrat et al., 2012; O'Rourke et al., 2012; Müller et al., 2013, 2014b,c).

Herschel data may be accessed through the Herschel Science Archive (HSA) maintained by the European Space Agency (ESA) (<http://www.cosmos.esa.int/web/herschel/science-archive>). It is also possible to query the HSA through NASA's Herschel Science Center (<http://irsa.ipac.caltech.edu/applications/Herschel/>).

## 3. THERMAL MODELING

Thermal models range in sophistication and complexity; different models are used depending on data quality,

computing resources, and the availability of ancillary data such as shape models and rotational states. All models begin by solving the energy balance between incident solar radiation, reflected sunlight, and thermal emission (e.g., *Lebofsky et al.*, 1986). For a spherical, airless body, this is given by

$$A_p S = L_r + L_e \quad (1)$$

where  $A_p$  is the object's projected area,  $S$  is the solar flux at the distance of the asteroid, and  $L_r$  and  $L_e$  are the reflected and emitted radiation, respectively, and  $L_r/L_e = A/(1-A)$ , where  $A$  is the bolometric Bond albedo. In essence, the purpose of thermal modeling is to determine  $L_e$  from the observed flux in one direction (or a few directions for objects observed at multiple viewing geometries), and one or a few thermally dominated bandpasses. The extrapolation to all directions and the bolometric emitted radiation are what the model provides. The total thermal emission is given by

$$L_e = \varepsilon \eta \sigma R^2 \int_{-\pi}^{\pi} \int_{-\pi/2}^{\pi/2} T^4(\theta, \phi) \cos(\phi) d\phi d\theta \quad (2)$$

where  $\varepsilon$  is the emissivity as a function of wavelength,  $\eta$  is the so-called beaming parameter (described in more detail below),  $\sigma$  is the Stefan-Boltzmann constant,  $R$  is the object's radius, and  $T$  is the object's temperature distribution as a function of longitude ( $\theta$ ) and latitude ( $\phi$ ), measured from the subsolar point.

The standard thermal model (STM) (*Lebofsky et al.*, 1986, and references therein) and the popular near-Earth asteroid thermal model (NEATM) (*Harris*, 1998) adopt the following temperature distribution across the asteroid's surface

$$T(\theta, \phi) = \begin{cases} T_{ss} \cos^{1/4} \zeta & \text{if } \zeta < \pi/2 \\ 0 & \text{if } \zeta \geq \pi/2 \end{cases} \quad (3)$$

where the angular distance from the subsolar point is  $\zeta$  and the temperature at the subsolar point ( $T_{ss}$ ) is

$$T_{ss} = \left[ \frac{S(1-A)}{\eta \varepsilon \sigma} \right]^{1/4} \quad (4)$$

Since the peak of the Sun's spectral energy distribution occurs at visible wavelengths, the Bond albedo is customarily assumed to be equal to the total Bond albedo at V band ( $\sim 0.56 \mu\text{m}$ ),  $A_v$ . In the system of *Bowell et al.* (1989), the Bond albedo is related to the more readily measured visible geometric albedo  $p_V$  by

$$A \sim A_v = p_V q = p_V (0.29 + 0.684G) \quad (5)$$

where  $G$  is the so-called phase slope parameter that ranges from  $\sim -0.1$  to  $0.4$  (*Bowell et al.*, 1989; *Harris et al.*, 1989).

Since  $p_V$  is generally  $< 1$ ,  $A$  is usually  $\ll 1$ . We therefore have a direct relationship between the asteroid's thermal flux

and its diameter  $D$ :  $L_e \propto D^2(1-A) \rightarrow D^2$ . However, since the asteroid's reflected sunlight goes as  $L_r = A_p AS \propto AD^2$ , diameter and albedo cannot be easily disentangled if only  $L_r$  is measured. This results in a much larger uncertainty in the derived diameter unless  $p_V$  is already known, given the large range of asteroid albedos ( $\sim 0.02$  to  $> 0.5$ ) (*Binzel et al.*, 2004; *Mainzer et al.*, 2011b; *Masiero et al.*, 2011).

If only the absolute visible magnitude  $H$  of the asteroid is available, corresponding to its V-band magnitude measured or extrapolated at  $\alpha = 0^\circ$  and object-to-observer and heliocentric distances of 1 AU, a frequently used empirical relationship for diameter is given by

$$D = \frac{1329}{\sqrt{p_V}} 10^{-H/5} \quad (6)$$

where  $D$  is the diameter in kilometers (*Bowell et al.*, 1989; *Harris and Lagerros* 2002). This relationship also demonstrates that diameter derived from visible-light observations alone is a sensitive function of an asteroid's albedo, underscoring the value of obtaining diameters obtained radiometrically.

Thermal models offer the possibility of deriving physical properties for large numbers of asteroids, with increasingly sophisticated models and better data allowing for more and improved constraints on parameters such as diameter, geometric visible albedo ( $p_V$ ), infrared albedo ( $p_{IR}$ ), emissivity, shape, rotational state, and thermal inertia. The STM corresponds to the case of a nonrotating spherical body, or one with zero thermal inertia and no nightside emission, observed at  $0^\circ$  solar phase angle. The beaming parameter  $\eta$ , which takes into account surface roughness and the "beaming" of thermal emission in the direction of the Sun, is often set to 0.756 in the STM based on empirical fits to the diameters of (1) Ceres and (2) Pallas derived from stellar occultations. The fast rotating model (FRM) (*Lebofsky et al.*, 1978; *Veeder et al.*, 1989; *Lebofsky and Spencer*, 1989), by contrast, is more appropriate for an object that rotates rapidly or has high thermal inertia/high thermal conductivity; effectively,  $\eta$  is set to  $\pi$ , and the nightside emits flux and does not follow equation (3). The NEATM assumes a hybrid approach that still assumes zero contribution from the nightside, but allows  $\eta$  to be fit as a free parameter if observations from more than one thermal-IR band are available.

NEATM-derived diameters generally reproduce measurements from radar, stellar occultations, and *in situ* spacecraft visits to within  $\pm 10\%$ , given multiple thermally dominated IR measurements that adequately sample an asteroid's rotational light curve with good signal-to-noise ratio (SNR) and an accurate determination of distance from knowledge of its orbit (*Mainzer et al.*, 2011c). It is worth noting that the accuracy of the diameters of objects used to confirm the performance of radiometric thermal models (such as radar or stellar occultations) is typically  $\sim 10\%$ . With these caveats, albedos can be determined to within  $\pm 25\%$  of their value (i.e.,  $p_V = 0.04 \pm 0.01$ ) if good-quality visible-light observations are available. The accuracy of the derived albedo

depends critically on the accuracy of H (see below). If only observations at a single band centered near 4.6  $\mu\text{m}$  are available (as is the case for some WISE/NEOWISE and Spitzer targets), diameter errors typically degrade to  $\pm 20\text{--}25\%$ , and albedos can only be known to within  $\pm 40\text{--}50\%$  of their value (Mueller et al., 2007; Harris et al., 2011; Mainzer et al., 2012a; Masiero et al., 2012a).

While diameter determinations from thermal-IR observations are relatively insensitive to visible light measurements, the latter are required to determine  $p_V$ . Obtaining good-quality H and G measurements (Bowell et al., 1989) is a persistent difficulty. Most of the time, visible observations collected simultaneously with IR fluxes are not available, so the absolute magnitude H and phase curve slope parameter G must be used to extrapolate the apparent visible magnitude at the time the IR observations were taken. Most asteroid observations come from the visible-light surveys that discover them, such as the Catalina Sky Survey, Lincoln Near Earth Asteroid Research (LINEAR), and Panoramic Survey Telescope and Rapid Response System (PanSTARRS). Typically, discovery observations are made with broadband V + R band filters to maximize sensitivity to NEOs, and while astrometric calibrations can be very accurate, photometric measurements can be considerably more variable. Moreover, G is known to vary with asteroid taxonomic type (e.g., Harris and Young, 1989). Williams (2012) recomputed H and G values for the entire Minor Planet Center catalog on a survey-by-survey basis and found that H offsets peak at +0.4 mag in the range H = 14.2–14.5 mag, but decrease to +0.1 mag for H > 20 mag, significantly expanding on the work of Pravec et al. (2012), who measured H values for 583 minor planets. Williams (2012) recomputed photometric magnitudes to account for the various surveys' filters. NEOWISE thermal model fits were performed assuming large ( $\pm 0.3$  mag or more) errors for H if no direct measurements of these parameters were available (e.g., from Warner et al., 2009; Pravec et al., 2012) at the time of publication. Future work will incorporate the Williams (2012) H and G values into thermal models from NEOWISE. If H values are well known, albedo can be determined to within 25%, but if H is poorly known, then the accuracy of the albedo degrades accordingly.

In bands where reflected sunlight contributes a non-negligible fraction of the total flux, the albedo at that wavelength ( $p_{\text{IR}}$ ) must also be treated as a free parameter in thermal models. For NEOs with subsolar temperatures

close to  $\sim 300$  K, peak thermal emission occurs near  $\sim 10 \mu\text{m}$ . Wavelengths longer than  $\sim 4 \mu\text{m}$  are typically thermally dominated for asteroids at heliocentric distances less than  $\sim 4$  AU; shorter wavelengths are a mix of reflected sunlight and thermal emission.

The infrared albedo at  $\sim 3 \mu\text{m}$  is not necessarily equal to the visible albedo, and it is correlated with taxonomic type. The trends for each taxonomic type are (Mainzer et al., 2011d, 2012c)  $p_{\text{IR}}/p_V \sim 1$  for C-complex asteroids (except for D-types),  $p_{\text{IR}}/p_V \sim 1.7$  for S-complex asteroids,  $p_{\text{IR}}/p_V \sim 2.2$  for D-types, and  $p_{\text{IR}}/p_V \lesssim 1$  for B-types. The differences between  $p_{\text{IR}}/p_V$  for all of these taxonomic types is likely due to the fact that their VNIR slopes are either blue (as is the case for the B-types), flat (C-complex), red (S-complex), or very red (D-types), and the trend of these slopes continues out to  $\sim 3 \mu\text{m}$ . Consequently, if  $p_{\text{IR}}$  can be determined, it can be used as a proxy for distinguishing between taxonomic types that otherwise have nearly identical visible albedos (Grav et al., 2012a,b, 2015; Alí-Lagoa et al., 2013; Masiero et al., 2014).

While STM, FRM, and NEATM are useful tools for rapidly determining effective spherical diameter,  $p_V$ , and  $p_{\text{IR}}$  for large numbers of asteroids, they are of limited use for determining additional parameters such as emissivity and thermal inertia. To extract these parameters, *thermophysical* models are needed; see the chapter by Delbó et al. in this volume for a detailed discussion of their theory and application.

## 4. RESULTS

Table 2 summarizes the numbers of asteroids that are known to have been observed to date by Spitzer, WISE/NEOWISE, AKARI, and Herschel for NEOs, MBAs, jovian Trojans, and Centaurs. Given the capabilities of each mission's survey data and selection methods, much can be learned about the properties of the various asteroid populations.

### 4.1. Infrared-Selected and Optically Selected Population Studies

Samples of asteroids imaged by spacebased IR telescopes can be selected in two ways. In an independent survey, all small-body candidates are treated identically regardless of whether they are previously known or might be new discoveries (assuming the survey's cadence allows for an

TABLE 2. Summary of recent spacebased asteroid observations and discoveries.

Mission	NEOs	MBAs	Cybeles	Hildas	Jovian Trojans	Centaurs	Asteroid Discoveries
Spitzer	<10	~2000	1	62	~70	42	0
Spitzer Warm Mission	~600	0	0	0	0	28	0
AKARI	90	4806	106	86	110	7	0
WISE	~700	~158,000	1342	1023	~2000	52	~34,000
NEOWISE	391	~15,600	100	50	50	1	215
Herschel	~7	~8	1	0	0	18	0

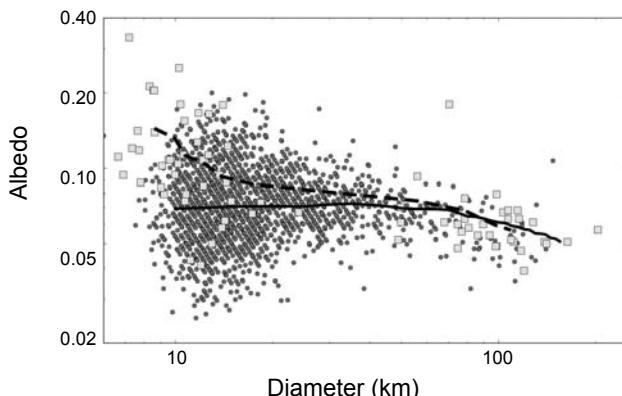

observational arc sufficient to enable the discovery of new moving objects). In a targeted sample, the telescope observes previously known asteroids and cannot independently discover new ones.

In an independent survey, asteroids are selected based on their IR fluxes, whereas in a targeted survey, asteroids are drawn from the catalog of objects discovered by other observers, almost all of whom operate at visible wavelengths. Understanding the selection biases of the sample is critical when probing population properties below the size regime for which the sample is observationally complete.

Since IR flux is insensitive to albedo, IR surveys are less biased against low-albedo objects than surveys that select targets based on their visible flux alone. Visible-light surveys are less likely to discover low-albedo objects, particularly at smaller sizes, due to their intrinsic faintness. Moreover, since diameter is determined directly from IR fluxes, no conversion between H and diameter is needed, eliminating the uncertainty associated with the large range of possible asteroid albedos. Infrared-selected samples can be extrapolated to determine the size-frequency distribution of the underlying population they represent, since the sample selection method is insensitive to albedo.

The NEOWISE project operated as an independent survey, using data processing methods to select moving object objects based on their IR fluxes. Known and new candidates were treated identically by the WISE Moving Object Processing System (WMOPS), which required all moving object candidates to be detected a minimum of 5 times over  $\sim 15$  hours (Mainzer et al., 2011a; Cutri et al., 2012). A detailed description of WMOPS can be found in the WISE Explanatory Supplement, section IV.5. Most objects were observed an average of  $\sim 12$  times over  $\sim 36$  hours. Over the course of the year-long prime mission,  $\sim 158,000$  asteroids were detected, including  $\sim 34,000$  new discoveries. During the 8.5-month fully cryogenic portion of the mission, asteroids were selected by WMOPS based on their 12- $\mu\text{m}$  flux; after the cryogen depleted, the primary band for asteroid selection became the 4.6- $\mu\text{m}$  channel.

One of the main results of the WMOPS-selected sample was the discovery that asteroid albedo distributions appear to remain constant over a wide range of diameters. An example of this can be seen in Fig. 1, which compares the albedo-size relationship for a sample of 44 optically selected jovian Trojans observed with Spitzer (Fernández et al., 2009) to a sample of 1739 Trojans found using WMOPS (Grav et al., 2011a). While the optically selected sample shows a strong trend of increasing albedo with decreasing size, no strong trend is apparent in the IR-selected, albedo-insensitive sample. A similar effect is observed when the diameter-albedo relationship for NEO samples is examined (Fig. 2) (Delbó et al., 2003; Binzel et al., 2004; Trilling et al., 2010). For the small NEOs, a real increase in albedo with decreasing diameter cannot be ruled out, but because the sample was selected on the basis of its visible flux, any real trend is entangled with the optical surveys' bias against discovery of small, dark NEOs (Mainzer et al., 2014a). The

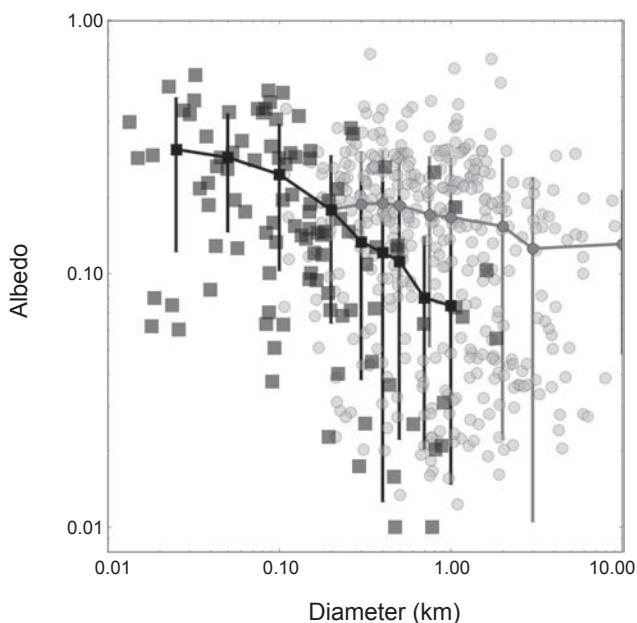

**Fig. 1.** Comparison of the IR-selected NEOWISE sample of 1739 jovian Trojans (filled gray circles) (Grav et al., 2011a, 2012b) to the optically selected sample observed by Spitzer (light gray squares) (Fernández et al., 2009); the solid and dashed lines give the running medians for the NEOWISE and Spitzer samples, respectively.

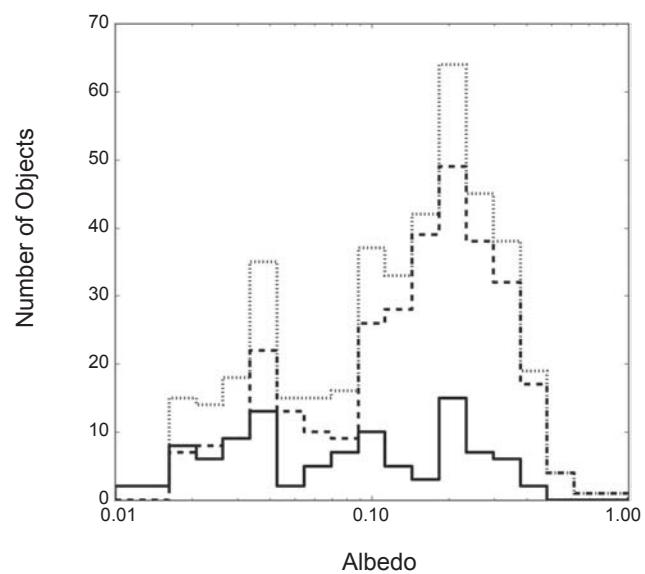

NEOWISE-discovered NEOs have lower albedos than those discovered by optical surveys (Fig. 3).

Using the IR-selected sample from NEOWISE, survey biases were estimated in order to determine the orbital properties, numbers, and physical properties of various asteroid populations. Survey biases were computed as a function of orbital and physical properties using the complete survey pointing list and the sensitivity in each wavelength, which derives from observations of asteroids with well-determined orbits [see Mainzer et al. (2011b) and Grav et al. (2011a) for an expanded description of the debiasing methodology as applied to WISE data]. The process of removing the survey bias signatures from the observed sample is known as debiasing (cf. Bottke et al., 2002; Jedicke and Metcalfe, 1998; Spahr, 1998).

Mainzer et al. (2011b) found that there are  $\sim 20,500 \pm 3000$  near-Earth asteroids larger than 100 m in diameter, of which  $\sim 25\%$  had been discovered as of 2011. That work verified that  $>90\%$  of NEAs larger than 1 km had been discovered, fulfilling the 1998 “Spaceguard” goal given to NASA. The subpopulations of the NEAs, including potentially hazardous asteroids (PHAs) (asteroids whose minimum orbit intersection distances are  $<0.05$  AU and  $H < 22$  mag) were studied by Mainzer et al. (2012b). However, since WISE measures diameter, rather than H, the authors recommended a change to a diameter-based definition for PHAs and concluded that there are  $\sim 4700 \pm 1500$  PHAs larger than  $\sim 100$  m (Mainzer et al., 2012b). Matches to the orbital-element models of Bottke et al. (2002) and Greenstreet and Gladman (2013) are generally in good agreement. Approximately twice as many PHAs were found occupying orbits with the lowest inclinations as compared with the model of Bottke et al. (2002); however, by recomputing the evolutionary models of NEOs with a finer orbital-element grid, Greenstreet and Gladman (2013) found similar results for the lowest-inclination bins. NEOWISE did not effectively probe the NEA population below 100 m,

**Fig. 2.** The IR-selected sample of NEOs from NEOWISE (gray points; running median shown as gray line) shows little change in albedo with diameter, whereas a sample of asteroids selected based on their visible magnitudes (black points and line) shows an increase in albedo with decreasing diameter (Mainzer *et al.*, 2014a).

**Fig. 3.** The albedo distribution of the NEOs discovered by WISE during its prime mission (black) has relatively more low-albedo NEOs than the objects discovered by visible light surveys (dot-dashed line). The albedo distribution for the entire NEO sample from the WISE prime mission is shown as a finely dashed line; 36% of NEOs have albedos <0.1 (Mainzer et al., 2011b).

with the exception of the optically selected sample shown in Fig. 3. Debiasing for this sample requires accounting for the optical survey selection effects in addition to the NEOWISE sample biases, a more complicated undertaking.

*Grav et al.* (2011b) and *Grav et al.* (2012a) debiased the NEOWISE jovian Trojan and Hilda samples, respectively, facilitating comparison between the leading and trailing Trojan clouds and leading to estimates of their numbers, size, and albedo distributions. Infrared observations have revealed key attributes of the jovian Trojans, Hildas, and Cybele asteroids. These results indicate that Trojans in the leading and trailing clouds are extremely similar in terms of albedos, taxonomic types, and size distributions; the major difference is that Trojans in the leading ( $L_4$ ) cloud outnumber the trailing ( $L_5$ ) by a factor of  $1.4 \pm 0.2$  (*Grav et al.*, 2011a). Theories of early giant planet migration must account for these observational constraints. *Marsset et al.* (2014) obtained visible and near-IR spectra of eight jovian Trojans found by WISE and Spitzer to have relatively high albedos and found that these objects had taxonomic types consistent with other primitive, low-albedo Trojans. One likely explanation is that when determining albedos for thousands of objects, normal statistical fluctuations will scatter a small fraction of the observations in favor of brighter albedos. See the chapter by Emery et al. in this volume for a more comprehensive discussion of the jovian Trojans.

Spitzer observed an optically selected sample of ~600 NEOs during its warm mission at 3.6 and 4.5  $\mu\text{m}$  (*Trilling et al., 2010; Mueller et al., 2011*). Improved diameter con-

straints assist with assessments of impact hazard. Targets of interest, such as (101955) Bennu, the target of the upcoming Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) mission, have also been observed with Spitzer and Herschel to determine size, albedo, and thermal inertia (*Emery et al.*, 2014; *Yu et al.*, 2014; *Mommert et al.*, 2014a,b; see also the chapter by Delb o et al. in this volume). The target of the Hayabusa-2 mission, (162173) 1999 JU<sub>3</sub>, has been intensively observed with AKARI, Spitzer, and Herschel, as well as groundbased facilities such as Subaru (*Hasegawa et al.*, 2008; *Mueller et al.*, 2011). WISE, Spitzer, and Herschel have been used to study Centaurs, a transitional population between transneptunian objects and Jupiter-family comets (*Bauer et al.*, 2013; *Duffard et al.*, 2014). Measurements from IRAS, AKARI, and WISE have been used to identify NEOs likely to be of cometary origin by performing follow-up observations of objects with low albedos and comet-like orbits (*Kim et al.*, 2014). This work builds on the work of *DeMeo and Binzel* (2008) and *Fern ndez et al.* (2005), who estimated the fraction of NEOs likely to be of cometary origins as 8% and 4%, respectively. *Mommert et al.* (2015) debiased the sample of large NEOs detected during the fully cryogenic portion of the WISE mission and found that 9% are likely to be dormant short-period comets.

The albedo-insensitive sample from *Mainzer et al.* (2012c) suggests a paucity of NEOs with low albedos at low perihelion distances, although the sample size is small. *Delb  * et al. (2014) posit that thermal cracking plays a key role in

regolith production, with an erosion and destruction process that preferentially affects more fragile, low-albedo, carbonaceous objects as they approach the Sun; see also Čapek and Vokrouhlický (2010, 2012).

#### 4.2. Main-Belt Asteroid Studies

The MBAs have now been extensively studied at thermal-IR wavelengths, with >155,000 having been observed by WISE and 4806 objects by AKARI (Masiero et al., 2011, 2012a; Usui et al., 2011; Hasegawa et al., 2013). Usui et al. (2014) shows the comparison of diameters and albedos derived for the ~1900 MBAs observed in common between AKARI and WISE. Diameters between the two datasets match to within  $\pm 10\%$ , and albedos to within  $\pm 22\%$ ; these results are in good agreement with the error bars described above. Figure 4 shows that, as found by IRAS, the asteroids within the main belt become darker with increasing heliocentric distance (Masiero et al., 2011).

Radiometrically derived diameters and albedos are valuable for improving determinations of asteroid collisional family ages and membership; in most cases, calculations prior to the recent IR missions described here have relied on sizes estimated from H and an assumed albedo (cf. Marzari et al., 1995). By combining albedos and colors with orbital information, it is possible to identify probable family members at velocity limits that would otherwise be indistinguishable from background objects, assuming that collisional family members have similar albedos and colors. Furthermore, families that overlap in velocity space can be disentangled on the basis of their albedos and colors (Masiero et al., 2013; Walsh et al., 2013; Carruba et al., 2013;

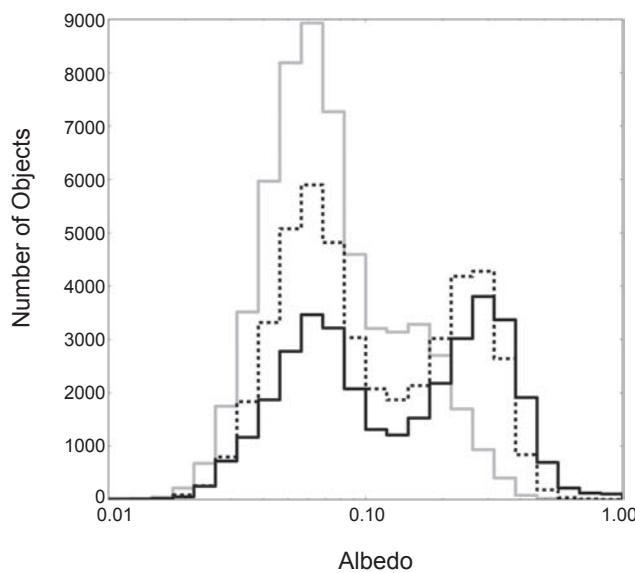

Milani et al., 2014). With improved and expanded family membership lists down to smaller sizes, the timing of collisions can be determined with greater precision, since the age-determination technique relies upon the strength of non-gravitational forces such as the Yarkovsky and Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) effects, which in turn depends on the size and mass of an object (Masiero et al., 2012b). Asteroid collisional families are discussed in greater depth in the chapters by Nesvorný et al., Michel et al., and Masiero et al. in this volume.

Diameters and albedos play a role in understanding which source reservoirs among the MBAs and comets are most likely to have produced NEOs. While it is difficult to associate the origins of an individual asteroid with a specific source region, associations can sometimes be inferred by comparing source region albedos to the object of interest and by using diameters to constrain migration timescales due to nongravitational forces (e.g., Campins et al., 2013; Masiero et al., 2015). Gathering measurements of albedos and diameters for larger numbers of asteroids down to smaller sizes will facilitate improved understanding of NEO origins and subsequent evolution, since nongravitational forces depend strongly on asteroid sizes (see the chapter by Vokrouhlický et al. in this volume).

#### 4.3. Taxonomy, Albedo, and Beaming

Albedos and diameters derived from IR observations have proven useful for studies of the compositional diversity of asteroids throughout the main belt. Previous measurements of the asteroids in the main belt suggested a uniform, smooth change in composition from more highly reflective, stony asteroids closer to the Sun to dark, carbon-rich objects that were barely altered by solar heating in its more distant regions. However, data from the WISE mission and the SDSS have shown that while there is an overall gradient, the true picture is much more jumbled, with a wide range of different compositions scattered throughout the belt. Asteroids rich in minerals that require high temperatures to form have been found in the outer belt, while primitive objects are found close to its inner edge. These results suggest that the early migration of the giant planets may have turbulently scrambled the asteroids and show at the very least that the early solar system was more dynamic than previously believed (DeMeo and Carry, 2013, 2014); see also the chapter by DeMeo et al. in this volume.

Comparisons between albedos derived from infrared data and taxonomic classifications derived from VNIR spectroscopy and spectrophotometry indicate a strong but not universal correlation between taxonomic types and albedos (Mainzer et al., 2011a,b; Thomas et al., 2011). Asteroids with neutral or blue spectra at VNIR wavelengths tend to have low visible albedos, and most red objects are associated with higher visible albedos (with the exception of classes such as D-types, which despite their red VNIR spectra have low albedos). However, as described above, even though average  $p_V$  values may be nearly identical for some taxonomic types such as

**Fig. 4.** The albedo distribution for asteroids in the inner (solid line; defined as semimajor axes between 1.8 and 2.5 AU), middle (dashed line; 2.5–2.82 AU), and outer (dotted line;  $2.82 < 3.6$  AU) regions of the main belt from Masiero et al. (2011).

C-, P-, and D-types, their 3  $\mu\text{m}$  albedos ( $p_{\text{IR}}$ ) are distinctly different. Therefore,  $p_{\text{IR}}$  can be used to distinguish between C/P-types and D-types (Grav et al., 2012b) when VNIR spectra are unavailable. Albedos have been used to identify candidate V-type asteroids throughout the main belt that have been subsequently observed spectroscopically to confirm their taxonomic type (Hardersen et al., 2014). Moreover, objects with extremely low albedos ( $p_V \sim 0.02$ ) in the main belt have been identified as the possible progenitors of the Tagish Lake meteorite, one of the darkest and most primitive carbonaceous chondrites ever found (Vernazza et al., 2013).

The beaming parameter  $\eta$  has also been shown to correlate with thermal inertia and rotation rate (Harris, 1998; Spencer et al., 1989; Delbó, 2004; Delbó et al., 2007). However, caution must be used in the interpretation of beaming values, since  $\eta$  also correlates with the phase angle at which an object is observed (Delbó et al., 2003, 2007; Wolters et al., 2008; Mainzer et al., 2011b). The NEATM assumes a temperature distribution that drops to zero at the terminator. For rotating bodies with anything other than low thermal inertias, the temperature distribution is likely to be nonzero past the terminator; when these bodies are observed at high phase angle, some portion of the nightside flux is seen, resulting in changes to  $\eta$  to conserve energy. Moreover, increased surface roughness can increase the sunward beaming of radiation, and  $\eta$  also depends on the spin axis orientation with respect to the Sun.

With these caveats, objects with extremely high values of  $\eta$  are good candidates for high thermal inertias or rapid rotation rates. Harris and Drube (2014) found 18 NEOs with high  $\eta$  values ( $>2$ ) and albedos that may indicate a metallic composition consistent with the fragmented cores of differentiated bodies. Since high radar albedos can correspond to high metal content, follow-up radar observations are desirable to confirm their nature. NEOs tend to have higher  $\eta$  values than MBAs and jovian Trojans; this may indicate higher thermal inertia, although they are often observed at higher phase angles than MBAs (Delbó et al., 2007; Mainzer et al., 2011b; Masiero et al., 2011; Grav et al., 2011b). Bauer et al. (2013) used WISE to perform thermal modeling on 52 Centaurs and scattered disk objects, finding that most  $\eta$  values were low and similar to those of bare cometary nuclei, suggesting a common origin. Observations of 85 transneptunian objects by Lellouch et al. (2013) showed that high  $\eta$  values were rare at low heliocentric distances, which they interpret as evidence of decreasing thermal inertia. The advent of new mid-IR data from WISE, Spitzer, AKARI, and Herschel promises to shed further light on thermal inertia trends as thermophysical models are applied to many more objects (see recent results from, e.g., Hanus et al., 2015; Koren et al., 2015; and the chapter by Delbó et al. in this volume).

#### 4.4. Activated Asteroids and Comets

The boundary between asteroids and comets is now considerably more permeable than previously suspected. Objects with low albedos and cometary orbits (often telltale

signatures of comets) have stubbornly resisted attempts to find evidence of cometary activity such as comae or tails, and asteroids are sometimes revealed upon further inspection to have become active. Thermal IR imaging surveys have been used to constrain cometary nucleus sizes during periods of inactivity when dust and gas do not obscure them, allowing for determinations of comet size frequency distributions (e.g., Bauer et al., 2011; Fernández et al., 2013). Thermal-IR imaging can also discover cometary activity around objects previously thought to be asteroidal. For example, WISE observed extended emission around three asteroids during its prime mission, which were subsequently redesignated as comets (237/P LINEAR, 233/P La Sagra, and P/2009 WX51 Catalina), and Spitzer found evidence for activity on (3552) Don Quixote (Mommert et al., 2014c). Since dust emits strongly at thermal-IR wavelengths when comets reach the inner solar system, IR surveys can be used to discover new comets. IRAS discovered five comets, and NEOWISE has discovered 24 to date.

Although a detailed discussion of comets is outside the scope of this book, thermal-IR data can also constrain the sizes and quantities of the dust particles produced by comets (Bauer et al., 2012a). The slope of the particle size distributions in turn can be used to determine whether the dust was produced by a collision between two asteroids or driven off the surface by volatiles such as CO and CO<sub>2</sub>, a key signature of cometary activity. This technique is useful for understanding the nature of activity observed in some MBAs (Bauer et al., 2012b; Stevenson et al., 2012); see the chapter by Jewitt et al. in this volume for a detailed discussion of these objects.

#### 4.5. Mid-Infrared Spectroscopy of Asteroids

A number of key spectral features that vary depending on a surface's composition, grain size, and porosity can be observed at mid-IR wavelengths. Laboratory studies of meteorites indicate the presence of absorption and emission features caused by vibrational and lattice modes; for example, crystalline and amorphous silicates show broad absorption features near  $\sim 10 \mu\text{m}$ .

AKARI, Spitzer, and Herschel all carried spectrographs operating at mid-IR wavelengths during their fully cryogenic mission phases. Spectra have been collected for  $\sim 87$  asteroids using the Spitzer IRS and MIPS instruments (e.g., Cruikshank et al., 2006; Campins et al., 2009a,b; Lim et al., 2011; Marchis et al., 2012). Spitzer IRS spectra covering 5–38  $\mu\text{m}$  revealed broad emission features near 10 and 20  $\mu\text{m}$  on three jovian Trojans, consistent with the presence of fine-grained silicates (Emery et al., 2006; Cruikshank, 2005). Similar but smaller emission plateaus were observed between 9 and 12  $\mu\text{m}$  on eight Themis-family asteroids and (65) Cybele, indicating that these bodies may also be covered with small silicate grains (Licandro et al., 2011, 2012); see also the chapters by Delbó et al. and Emery et al. in this volume. Moreover, Vernazza et al. (2012) showed that mid-IR spectra meteorite samples diluted with IR-transparent KBr powder matched observed emissivity features in MBAs, suggesting

that surface porosity can also be constrained. *Marchis et al.* (2012) used Spitzer IRS spectroscopy of binary asteroids to constrain their bulk densities, thermal inertia, and surface grain properties. The chapter by Reddy et al. in this volume provides a more comprehensive discussion of mid-IR spectroscopy, including theory and observations.

Mid-IR spectra have also proven useful for constraining the abundance of volatiles on small bodies; for example, many species such as CO and CO<sub>2</sub> have been identified on comets photometrically through excess flux above their thermal emission (e.g., *Bauer et al.*, 2011; *Reach et al.*, 2013). Recently, Herschel heterodyne spectroscopy of the largest object in the main belt, (1) Ceres, has revealed the presence of water vapor as the dwarf planet approached perihelion (*Küppers et al.*, 2014). The water vapor line was detected at three separate epochs at 557 GHz ( $\lambda = 540\mu\text{m}$ ), further illustrating that the distinction between dark asteroids and comets is sometimes blurred (*Briani et al.*, 2011). See the chapter by Rivkin et al. in this volume for a discussion of the implications of this result.

#### 4.6. Earth Co-Orbitals

Among the near-Earth objects discovered by NEOWISE during its post-cryogenic mission is the first known Earth Trojan, 2010 TK<sub>7</sub>, and an object in a so-called “horseshoe” orbit co-orbital with Earth, 2010 SO<sub>16</sub> (*Connors et al.*, 2011; *Christou and Asher*, 2011; *Mainzer et al.*, 2012a). 2010 TK<sub>7</sub> was discovered by NEOWISE because its  $\sim$ 395-year libration period caused it to move to the region near 90° solar elongation where the satellite continually observes. Because Earth Trojans are thought to be dynamically constrained to remain more than  $\sim$ 24° away from Earth in mean anomaly (*Tabachnik and Evans*, 2000), they spend most of their time in regions of the sky that are difficult or impossible for groundbased telescopes to observe. Infrared measurements from NEOWISE have provided preliminary estimates of diameters and albedos (*Mainzer et al.*, 2012a). 2010 TK<sub>7</sub> is thought to be temporarily captured by Earth, with a dynamical stability timescale of  $\sim$ 7000 years (*Connors et al.*, 2011; *Marzari and Scholl*, 2013). By contrast, 2010 SO<sub>16</sub> librates across the L<sub>3</sub> Earth-Sun Lagrange point in a horseshoe pattern that has the longest known stability of any Earth co-orbital, several hundred thousand years (*Christou and Asher*, 2011).

Although approximately half a dozen horseshoe and quasisatellite co-orbitals are known at present, 2010 TK<sub>7</sub> remains the sole Earth Trojan found to date. These objects may represent a much larger population that remains undiscovered because they spend the majority of their time in the daytime sky on Earth. Future surveys designed to survey at low solar elongations may be able to find more of these unusual objects.

### 5. CONCLUSIONS

Spacebased infrared studies of asteroids offer a valuable means of rapidly determining the physical and orbital proper-

ties of large numbers of objects. Modern detector arrays have allowed recent space missions to reach background-limited sensitivities that are improved by orders of magnitude compared to prior generations of IR telescopes. These capabilities have opened a new window into the nature of our solar system’s small bodies. Future generations of spacebased IR telescopes using new large-format detectors (e.g., *McMurtry et al.*, 2013) will further improve our understanding.

**Acknowledgments.** This study is based on observations with AKARI, a JAXA project with the participation of ESA. This work is based in part on observations made with the Spitzer Space Telescope, which is operated by the Jet Propulsion Laboratory/California Institute of Technology under a contract with NASA. This publication makes use of data products from NEOWISE, which is a project of the Jet Propulsion Laboratory/California Institute of Technology funded by the National Aeronautics and Space Administration. This publication makes use of data products from the Wide-field Infrared Survey Explorer, which is a joint project of the University of California, Los Angeles, and the Jet Propulsion Laboratory/California Institute of Technology, funded by the National Aeronautics and Space Administration. Herschel is an ESA space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from NASA. The field of asteroid thermophysical modeling has experienced an extraordinary growth in the last 10 years, as new thermal-infrared data became available for hundreds of thousands of asteroids. The infrared emission of asteroids depends on the body's size, shape, albedo, thermal inertia, roughness, and rotational properties. These parameters can therefore be derived by thermophysical modeling of infrared data. Thermophysical modeling led to asteroid size estimates that were confirmed at the few-percent level by later spacecraft visits. We discuss how instrumentation advances now allow mid-infrared interferometric observations as well as high-accuracy spectrophotometry, posing their own set of thermal-modeling challenges. We present major breakthroughs achieved in studies of the thermal inertia, a sensitive indicator for the nature of asteroids soils, allowing us to, e.g., determine the grain size of asteroidal regoliths. Thermal inertia also governs nongravitational effects on asteroid orbits, requiring thermophysical modeling for precise asteroid dynamical studies. The radiative heating of asteroids, meteoroids, and comets from the Sun also governs the thermal stress in surface material; only recently has it been recognized as a significant weathering process. Asteroid space missions with thermal-infrared instruments are currently undergoing study at all major space agencies. This will require a high level of sophistication of thermophysical models in order to analyze high-quality spacecraft data.

## 1. INTRODUCTION

Asteroid thermophysical modeling is about calculating the temperature of asteroids' surface and immediate subsurface, which depend on absorption of sunlight, multiple scattering of reflected and thermally emitted photons, and heat conduction. Physical parameters such as albedo (or reflectivity), thermal conductivity, heat capacity, emissivity, density and roughness, along with the shape (e.g., elevation model) of the body, its orientation in space, and its previous thermal history are taken into account. From the synthetic surface temperatures, thermally emitted fluxes (typically in the infrared) can be calculated. Physical properties are constrained by fitting model fluxes to observational data.

It is important to differentiate between sophisticated *thermophysical models* (TPMs) (Lebofsky and Spencer, 1989; Spencer, 1990; Spencer et al., 1989; Lagerros, 1997, 1996a, 1998; Delbo, 2004; Mueller, 2007; Rozitis and Green, 2011) and *simple thermal models*, which typically assume spherical

shape, neglect heat conduction (or simplify its treatment), and do not treat surface roughness (for reviews, see Harris and Lagerros, 2002; Delbo and Harris, 2002). In the past, the use of TPMs was reserved to the few exceptional asteroids for which detailed shape models and high-quality thermal-infrared data existed (Harris and Lagerros, 2002). In the last 10 years, however, TPMs became significantly more applicable (see section 6), thanks both to new spaceborne infrared telescopes [the Spitzer Space Telescope (Spitzer), Wide-field Infrared Survey Explorer (WISE), and AKARI] (see the chapter by Mainzer et al. in this volume) and to the availability of an ever-growing number of asteroid shape models (see the chapter by Durech et al. in this volume).

After introducing the motivations and the different contexts for calculating asteroid temperatures (section 2), we provide an overview of simple thermal models (section 3) and of TPMs (section 4). We describe data analysis techniques based on TPMs (section 5), then we present the latest results and implications on the physics of asteroids (section 6). In

section 7, we discuss temperature-induced surface changes on asteroids (see also the chapter by Murdoch et al. in this volume). All symbols used in this chapter are detailed in Table 1.

Note that we do not discuss here the so-called asteroid thermal evolution models that are generally used to compute

the temperature throughout the body as a function of time, typically taking into account internal heat sources such as the decay of radiogenic  $^{26}\text{Al}$ . Such models allow estimates of the degree of metamorphism, aqueous alteration, melting, and differentiation that asteroids experienced during the early phases of the solar system formation (for a review, see McSween et al., 2002).

## 2. MOTIVATIONS AND APPLICATIONS OF THERMOPHYSICAL MODELS

Thermophysical modeling of observations of asteroids in the thermal infrared ( $\lambda \geq 4 \mu\text{m}$ ) is a powerful technique to determine the values of physical parameters of asteroids, such as their sizes (e.g., Müller et al., 2014a), thermal inertia, and roughness of their soils (e.g., Müller and Lagerros, 1998; Mueller, 2007; Delbo and Tanga, 2009; Matter et al., 2011; Rozitis and Green, 2014; Capria et al., 2014), and in certain cases their bulk density and bulk porosity as well (Rozitis et al., 2013, 2014; Emery et al., 2014; Chesley et al., 2014).

Knowledge of physical properties is crucial to understand asteroids. For example, size information is fundamental to constrain the asteroid size frequency distribution, which informs us about the collisional evolution of these bodies (Bottke et al., 2005), and is of paramount importance for the study of asteroid families, Earth-impact risk assessment of near-Earth asteroids (NEAs) (for a review, see the chapter by Harris et al. in this volume), and development of asteroid space mission scenarios (section 5.7). Accurate sizes are also a prerequisite for calculating the volumes of asteroids for which we know the mass, allowing us to derive the bulk density, which informs us about the internal structure of these bodies (e.g., Carry, 2012).

Thermal inertia, the resistance of a material to temperature change (section 5.2), is a sensitive indicator for the properties of the grainy soil (regolith) (see the chapter by Murdoch et al. in this volume) on asteroids; e.g., the typical grain size (Gundlach and Blum, 2013) and degree of cementation (Piqueux and Christensen, 2009a,b) can be inferred from thermal-inertia measurements. In general, the regolith is what we study by means of remote-sensing observations. Understanding the regolith is therefore crucial to infer the nature of the underlying body. Regolith informs us about the geological processes occurring on asteroids (see the chapter by Murdoch et al. in this volume), such as impacts, micrometeoroid bombardment (Hörz and Cintala, 1997), and thermal cracking (Delbo et al., 2014). Regolith contains records of elements implanted by the solar wind and cosmic radiation, and therefore informs us about the sources of those materials (Lucey, 2006). Regolith porosity can shed light on the role of electrostatic and van der Waals forces acting on the surface of these bodies (e.g., Rozitis et al., 2014; Vernazza et al., 2012).

Knowledge of surface temperatures is also essential for the design of the instruments and for the near-surface operation of space missions, as in the case of the sample return missions Hayabusa-2 [Japan Aerospace Exploration Agency (JAXA)] and Origins, Spectral Interpretation, Resource Identification,

TABLE 1. Nomenclature.

Symbol	Quantity	Unit
T	Temperature	K
$T_{\text{SS}}$	Subsolar temperature	K
$\sigma$	Stefan-Boltzmann constant	(5.67051 $10^{-8}$ ) $\text{W m}^{-2} \text{K}^{-4}$
$S_{\odot}$	Solar constant at $r = 1 \text{ AU}$	(1329) $\text{W m}^{-1}$
r	Distance to the Sun	AU
$\vec{r}$	Vector to the Sun	m
$\Delta$	Distance to the observer	AU
$\epsilon$	Emissivity	—
$\eta$	Beaming parameter	—
$\kappa$	Thermal conductivity	$\text{W m}^{-1} \text{K}^{-1}$
C	Heat capacity	$\text{J kg}^{-1} \text{K}^{-1}$
$\Gamma$	Thermal inertia	$\text{J m}^{-2} \text{s}^{-1/2} \text{K}^{-1}$
$\Theta$	Thermal parameter	—
$\rho$	Material density	$\text{kg m}^{-3}$
H	Absolute magnitude of the H,G system	
G	Slope parameter of the H,G system	
V	Actual magnitude in the V-band	
D	Diameter	m (or km)
A	Bolometric Bond albedo	—
$p_V$	Geometric visible albedo	—
z	Depth in the subsoil	m
t	Time	s
$r_p$	Pore radius of regolith	m
$\bar{\theta}$	Mean surface slope	deg
$l_s$	Thermal skin depth	m
P	Rotation period	s
$\omega$	$= 2\pi/P$	$\text{s}^{-1}$
$\lambda_p$	ecliptic longitude of the pole	deg
$\beta_p$	ecliptic latitude of the pole	deg
$\phi_0$	Initial rotational phase at epoch	deg
$\alpha$	(Phase) angle between asteroid-Sun-observer	deg
a	Area of a facet	$\text{m}^2$
S	Shadowing function	
$F_{\vec{i},\vec{j}}$	View factor	
$J_V(j)$	Visible radiosity	
$J_{IR}(j)$	Infrared radiosity	
$\hat{n}$	Local normal	m
$\vec{i}$	Vector to the local facet	m
$\vec{j}$	Vector to the remote facet	m
$\gamma_c$	Crater opening angle	deg
$\rho_c$ or $f$	Area density of craters	
$\phi$	Emission angle	rad
$f_{\lambda}(\tau)$	Infrared flux	$\text{W m}^{-2} \mu\text{m}^{-1}$
$\lambda$	Wavelength	$\mu\text{m}$

Security, Regolith Explorer (OSIRIS-REx) (NASA). In the future, knowledge of asteroid temperatures will be crucial for planning human interaction with asteroids.

Another reason to model asteroid surface temperatures is that they affect the orbital and spin-state evolution via the Yarkovsky and Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) effects, respectively (see section 5.8 and the chapter by Vokrouhlický et al. in this volume). In particular, thermal inertia dictates the strength of the asteroid Yarkovsky effect. This influences the dispersion of members of asteroid families, the orbital evolution of potentially hazardous asteroids, and the delivery of  $D \leq 40$  km asteroids and meteoroids from the main belt into dynamical resonance zones capable of transporting them to Earth-crossing orbits (see chapter by Vokrouhlický et al. in this volume and references therein).

The YORP effect is believed to be shaping the distribution of rotation rates (Bottke et al., 2006) and spin-vector orientation (Vokrouhlický et al., 2003; Hanuš et al., 2011, 2013); small gravitationally bound aggregates could be spun up so fast (Vokrouhlický et al., this volume; Bottke et al., 2006, and references therein) that they are forced to change shape and/or undergo mass shedding (Holsapple, 2010). Approximately 15% of NEAs are observed to be binaries (Pravec et al., 2006), and YORP spinup is proposed as a viable formation mechanism (Walsh et al., 2008; Scheeres, 2007; Jacobson and Scheeres, 2011).

A further motivation to apply TPM techniques is to constrain the spin-axis orientation and the sense of rotation of asteroids [examples are 101955 Bennu and 2005 YU<sub>55</sub> (Müller et al., 2012, 2013)]. The chapter by Durech et al. in this volume describes how to use optical and thermal-infrared data simultaneously to derive more reliable asteroid shapes and spin properties.

The temperature and its evolution through the entire life of an asteroid can alter its surface composition and nature of the regolith (section 7). For example, when the temperature rises above a certain threshold for a sustained period, certain volatiles can be lost via sublimation (Schorghofer, 2008; Capria et al., 2012), dehydration (Marchi et al., 2009), or desiccation (Delbo and Michel, 2011; chapter by Jewitt et al. in this volume, and references therein).

There can be pronounced and fast temperature variations between day and night. Modeling these temperature variations is fundamental to studying the effect of thermal cracking of asteroid surface material (section 7.1), which was found to be an important source of fresh regolith production (Delbo et al., 2014).

### 3. SIMPLE THERMAL MODELS

We start by introducing the Near-Earth Asteroid Thermal Model (NEATM) (Harris, 1998), which is typically used where the data quality and/or the available knowledge about asteroid shape and spin preclude the usage of TPMs. Typically, the NEATM allows a robust estimation of asteroid diameter and albedo, but does not provide any direct information on thermal inertia or surface roughness

(for a review, see Harris and Lagerros, 2002). The recent large-scale thermal-emission surveys of asteroids and trans-neptunian objects (TNOs) (see Mainzer et al., this volume; Lellouch et al., 2013, and references therein) typically use the NEATM in their data analysis, thereby establishing it as the de facto default among the simple thermal models. The typical NEATM accuracy is 15% in diameter and roughly 30% in albedo (Harris, 2006). Other simple thermal models are the standard thermal model (STM) (Lebofsky et al., 1986), isothermal latitude model (ILM) [also known as the fast rotating model (FRM)] (Lebofsky and Spencer, 1989), and the night emission simulated thermal model (NESTM) (Wolters and Green, 2009). The STM and the ILM [reviewed by, e.g., Harris and Lagerros (2002)] have largely fallen out of use.

The NEATM assumes that the asteroid has a spherical shape and does not directly account for thermal inertia nor surface roughness. The surface temperature is given by the instantaneous equilibrium with the insolation, which is proportional to the cosine of the angular distance between local zenith and the Sun and zero at the nightside. The maximum temperature occurs at the subsolar point and it reads

$$(1 - A)S_{\odot}r^{-2} = \eta\sigma\epsilon T_{SS}^4 \quad (1)$$

(nomenclature is defined in Table 1). The parameter  $\eta$  was introduced in the STM of Lebofsky et al. (1986) as a means of changing the model temperature distribution to take into account the observed enhancement of thermal emission at small solar phase angles due to surface roughness. This is known as the beaming effect, and for this reason,  $\eta$  is also called the *beaming parameter*. The  $\eta$  formalism, in the NEATM, allows a first-order description of the effect of a number of geometrical and physical parameters, in particular the thermal inertia and surface roughness on the spectral energy distribution of an asteroid (Delbo et al., 2007). For a large thermal inertia, one would expect  $\eta$  values significantly larger than unity [e.g., 1.5–3, with theoretical maximum values around 3.5 (Delbo et al., 2007)], whereas for low thermal inertia  $\eta \approx 1$  (for  $\Gamma = 0$  and zero surface roughness). Roughness, on the other hand, tends to lower the value of  $\eta$  (for observations at low or moderate phase angles). For instance, a value of  $\eta \sim 0.8$  for a main-belt asteroid (MBA) indicates that this body has low thermal inertia and significant roughness [with minimum theoretical values of 0.6–0.7 (Spencer, 1990; Delbo et al., 2007)]. We note, however, that  $\eta$  is not a physical property of an asteroid, as it can vary due to changing observing and illumination geometry, aspect angle, heliocentric distance of the body, phase angle, and wavelength of observation.

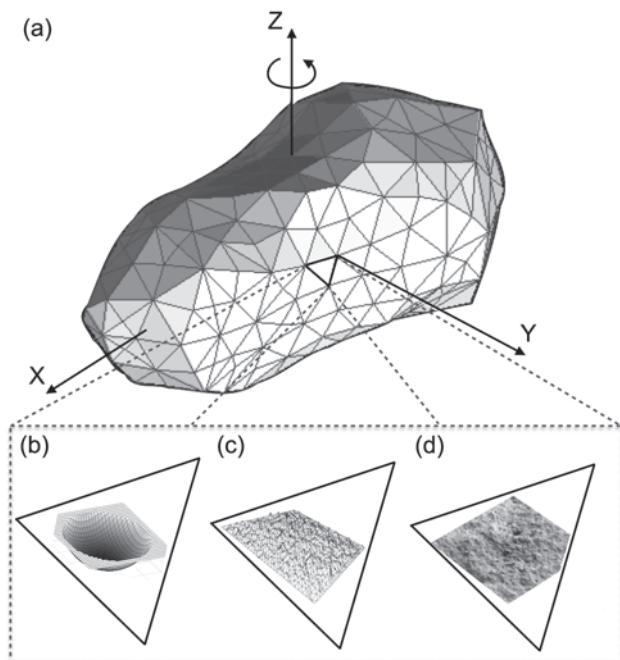

## 4. THERMOPHYSICAL MODELS

### 4.1. Overview

Different TPMs have been proposed to study the thermal emission of asteroids, comets, planets, and satellites. The first models were motivated by thermal observations of the lunar surface, which revealed an almost thermally insulating

surface that emits thermal radiation in a non-Lambertian way (Pettit and Nicholson, 1930; Wesselink, 1948). Heat conduction and radiation scattering models of various rough surfaces were able to reproduce the lunar observations to a good degree (e.g., Smith, 1967; Buhl *et al.*, 1968a,b; Sexl *et al.*, 1971; Winter and Krupp, 1971), and the derived thermal inertia and surface roughness values matched *in situ* measurements by Apollo astronauts (see Rozitis and Green, 2011, and references therein). These early lunar models were adapted to general planetary bodies, albeit with an assumed spherical shape, by Spencer *et al.* (1989) and Spencer (1990). The most commonly used asteroid TPMs of Lagerros (1996a, 1997, 1998), Delbo (2004), Mueller (2007), and Rozitis and Green (2011) are all based on Spencer *et al.* (1989) and Spencer (1990). Here we present the basic principles utilized in TPMs; for implementation details, the reader is referred to the cited works.

All TPMs represent the global asteroid shape as a mesh of (triangular) facets (see Fig. 1) that rotates around a given spin vector with rotation period P. In general, utilized shape models are derived from radar observations, inversion of optical light curves, *in situ* spacecraft images, or stellar occultation timing (for a review of asteroid shape modeling, see the chapter by Durech *et al.* in this volume). If no shape model is available, one typically falls back to a sphere or an ellipsoid (e.g., Müller *et al.*, 2013, 2014a; Emery *et al.*, 2014).

**Fig. 1.** (a) Example of a triangulated three-dimensional shape model as typically used in TPMs [asteroid (2063) Bacchus from <http://echo.jpl.nasa.gov/asteroids/shapes/shapes.html>]. Temperatures are color coded: white corresponds to the maximum and dark gray corresponds to minimum temperature. The three different roughness models sketched at the bottom are (b) hemispherical section craters (Davidsson *et al.*, 2015), (c) Gaussian surface (Rozitis and Green, 2011), and (d) fractal surface (Davidsson *et al.*, 2015).

The goal is to calculate the thermal emission of each facet of the shape model at a given illumination and observation geometry. To this end, the temperature of the surface and, in the presence of thermal inertia, the immediate subsurface need to be calculated. Generally, lateral heat conduction can be neglected as the shape model facets are much larger than the penetration depth of the diurnal heat wave (i.e., the thermal skin depth), and only one-dimensional heat conduction perpendicular to and into the surface needs to be considered. For temperature T, time t, and depth z, one-dimensional heat conduction is described by

$$\rho C \frac{\partial T}{\partial t} = \frac{\partial}{\partial z} \kappa \frac{\partial T}{\partial z} \quad (2)$$

where  $\kappa$  is the thermal conductivity,  $\rho$  is the material density, and C is the heat capacity. If  $\kappa$  is independent of depth (and, implicitly, temperature independent, see section 5.3), equation (2) reduces to the diffusion equation

$$\frac{\partial T}{\partial t} = \frac{\kappa}{\rho C} \frac{\partial^2 T}{\partial z^2} \quad (3)$$

It is useful to define the thermal inertia  $\Gamma$  and the thermal skin depth  $l_s$

$$\Gamma = \sqrt{\kappa \rho C} \quad (4)$$

$$l_s = \sqrt{\kappa P / 2\pi\rho C} \quad (5)$$

These material properties are generally assumed to be constant with depth and temperature in asteroid TPMs, but varying properties have been considered in some Moon, Mars, planetary satellites, and asteroid models (e.g., Giese and Kuehrt, 1990; Urquhart and Jakosky, 1997; Piqueux and Christensen, 2011; Keihm, 1984; Keihm *et al.*, 2012; Capria *et al.*, 2014, see also section 5.3).

Thermophysical model implementations typically employ dimensionless time and depth variables:  $\tau = 2\pi t/P$  and  $Z = z/l_s$ . Then, the only remaining free parameter is the dimensionless thermal parameter [ $\Theta = \Gamma \sqrt{\omega} / \epsilon \sigma T_{ss}^3$  (Spencer, 1990)] describing the combined effect of thermal inertia, rotation period, and heat emission into space on the surface temperature distribution (see Fig. 2).

A numerical finite-difference technique is used to solve the one-dimensional heat conduction equation, and an iterative technique is used to solve the surface boundary condition. This requires a suitable number of time and depth steps to fully resolve the temperature variations and to ensure model stability (typically, at least 360 time steps and 40 depth steps over 8 thermal skin depths are required). Thermophysical models are run until specified convergence criteria are met (e.g., until temperature variations between successive model iterations are below a specified level) and/or until a specified number of model iterations have been made.

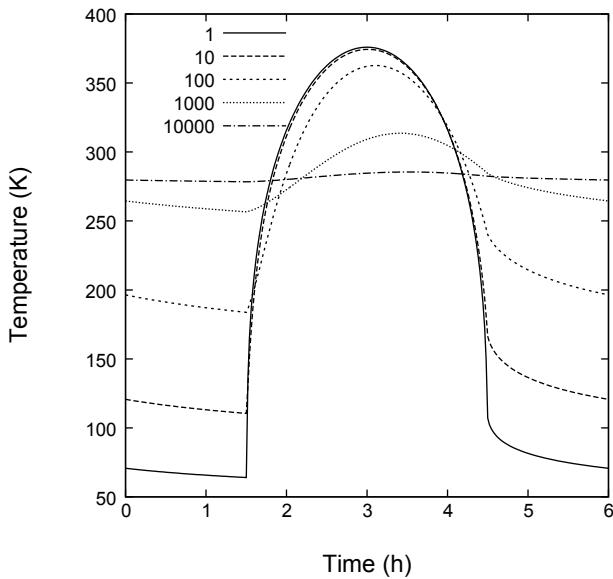

For applications such as the study of the sublimation of water ice from the shallow subsurface of asteroids [e.g., the main-belt comets (MBCs) or 24 Themis], the heat conduction equation must be coupled with a gas diffusion equation (Schorghofer, 2008; Capria et al., 2012; Prialnik and Rosenberg, 2009) (for a review, see also Huebner et al., 2006).

The one-dimensional heat conduction equation is solved with internal and surface boundary conditions to ensure conservation of energy. Since the amplitude of subsurface temperature variations decreases exponentially with depth, an internal boundary condition is required to give zero temperature gradient at a specified large depth

$$\left( \frac{\partial T}{\partial z} \right)_{z \gg l_s} = 0 \quad (6)$$

A typical surface boundary condition for a facet at point  $\bar{r}$  with respect to the asteroid origin, at point  $\bar{r}$  with respect to the Sun, and with surface normal  $\hat{n}$  is then given by

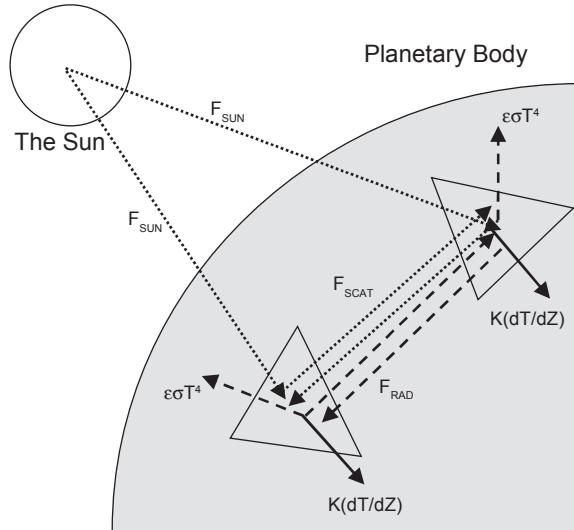

$$\begin{aligned} \varepsilon\sigma T^4(\bar{r}, t) - \left( \frac{\partial T(\bar{r}, t)}{\partial z} \right)_{z=0} &= \\ \frac{(1-A)S_\odot(\bar{r} \cdot \hat{n})(1-S(\bar{r}, \bar{t}))}{\bar{r}^3} + & \\ (1-A) \int J_V(\bar{j}) F_{\bar{r}, \bar{j}} d\alpha' + & \\ \varepsilon\sigma(1-\varepsilon) \int J_{IR}(\bar{j}) F_{\bar{r}, \bar{j}} d\alpha' & \end{aligned} \quad (7)$$

**Fig. 2.** Synthetic diurnal temperature curves on the equator of a model asteroid for different values of thermal inertia (in units of  $J \text{ m}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$ ). Increasing thermal inertia smooths temperature contrasts and causes the temperature peak to occur after the insolation peak at 3 h. The asteroid is situated at a heliocentric distance of  $r = 1.1 \text{ AU}$ , has a spin period of 6 h, Bond albedo of  $A = 0.1$ , and its spin axis is perpendicular to the orbital plane.

The lefthand side of equation (7) gives the thermal energy radiated to space and the heat conducted into the subsurface, and the righthand side gives the input radiation from three different sources: direct solar radiation, multiply scattered solar radiation (i.e., self-illumination), and reabsorbed thermal radiation (i.e., self-irradiation). The two last components are also known as mutual heating (see Fig. 3).

The amount of solar radiation absorbed by a facet depends on the Bond albedo  $A$  and any shadows projected on it, which is dictated by  $S(\bar{r}, \bar{t})$  [i.e.,  $S(\bar{r}, \bar{t}) = 1$  or 0, depending on the presence or absence of a shadow]. Projected shadows occur on globally nonconvex shapes only, which can be determined by ray-triangle intersection tests of the solar illumination ray (e.g., Rozitis and Green, 2011) or by local horizon mapping (e.g., Statler, 2009). Related to shadowing are the self-heating effects arising from interfacing facets, which tend to reduce the temperature contrast produced inside concavities. The problem here is to determine which facets see other facets, and to calculate the amount of radiation exchanged between them. The former can be determined by ray-triangle intersection tests again, and the latter can be solved using view factors. The view factor  $F_{\bar{r}, \bar{j}}$  is defined as the fraction of the radiative energy leaving the local facet  $\bar{r}$  that is received by the remote facet  $\bar{j}$  assuming Lambertian emission (Lagerros, 1998).  $J_V(\bar{j})$  and  $J_{IR}(\bar{j})$  are then the visible and thermal-infrared radiosities of remote facet  $\bar{j}$ . Either single or multiple scattering can be taken into account, and the latter can be efficiently solved using Gauss-Seidel iterations (Vasavada et al., 1999). Most TPMs neglect shadowing and self-heating effects resulting from the global shape for simplicity, but they can be significant on asteroids with large shape concavities [e.g., the south pole of (6489) Golevka (Rozitis and Green, 2013)].

**Fig. 3.** Diagram illustrating the energy balance and radiation transfer between facets (from Rozitis and Green, 2011). The terms  $F_{\text{SUN}}$ ,  $F_{\text{SCAT}}$ ,  $F_{\text{RAD}}$ ,  $k(dT/dx)$ , and  $\varepsilon\sigma T^4$  are direct sunlight, multiply scattered sunlight, reabsorbed thermal radiation, conducted heat, and thermal radiation lost to space, respectively.

## 4.2. Modeling Asteroid Thermal Emission

Once the surface temperature distribution across an asteroid surface has been computed, the emission spectrum (Fig. 4) at a given observation geometry and a specified time can be calculated. The monochromatic flux density, also known as spectral energy distribution (SED), can also be calculated at wavelengths of interest. When these model fluxes are plotted as a function of the asteroid rotational phase, one obtains the so-called thermal light curves (e.g., Fig. 5), which can be used to test the fidelity of shape and albedo models typically used as input in the TPM.

When the temperature for a facet is known, the intensity  $I_\lambda(\tau)$  at which it emits at wavelength  $\lambda$  is given by the Planck function. Assuming Lambertian emission, the spectral flux of the facet seen by an observer is then

$$f_\lambda(\tau) = I_\lambda(\tau) \frac{a}{\Delta^2} \cos \phi \quad (8)$$

where  $a$  is area of the facet,  $\Delta$  is the distance to the observer, and  $\phi$  is the emission angle. The total observed flux is obtained by summing the thermal fluxes of all visible shape model facets, including any contributions from surface roughness elements contained within them. For disk-integrated measurements, this summation is performed across the entire visible side of the asteroid, while for spatially resolved measurements it is summed across facets contained within the detector pixel's field of view.

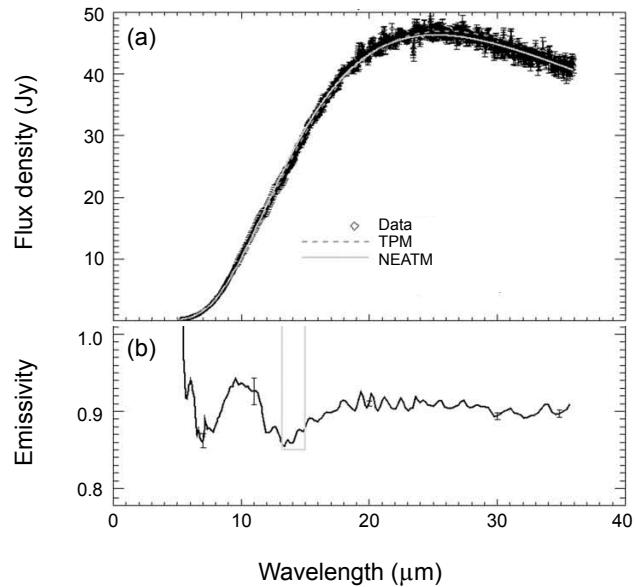

The assumption of Lambertian emission depends on no directionality induced by surface irregularities at scales below the thermal skin depth. Davidsson and Rickman (2014)

show that surface roughness at subthermal-skin-depth scales is quasi-isothermal and is therefore not likely to deviate from Lambertian emission overall. However, radiative transfer processes between the regolith grains could contribute up to 20% of the observed beaming effects (Hapke, 1996). Rozitis and Green (2011, 2012) investigated combined microscopic (regolith grain induced) and macroscopic (surface roughness induced) beaming effects, and demonstrated that the macroscopic effects dominated overall. This was previously found to be the case in directional thermal emission measurements of lava flows on Earth (Jakosky et al., 1990).

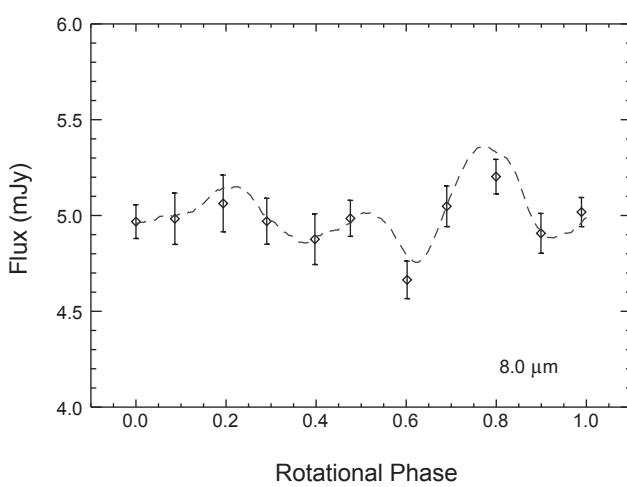

As wavelengths increase to the submillimeter range and above, asteroid regolith becomes increasingly transparent and the observed flux is integrated over increasing depths (Chamberlain et al., 2009; Keihm et al., 2013). Modeling such fluxes with typical thermal models (which derive fluxes from surface temperatures only) requires a significant reduction in effective spectral emissivity. For example, 3.2-mm flux measurements of (4) Vesta require an emissivity of  $\sim 0.6$  to match model predictions (Müller and Barnes, 2007). The reduction in emissivity can be explained by lower subsurface emission temperatures (Lagerros, 1996b) and by different subsurface scattering processes dependent on grain size (Redman et al., 1992; Müller and Lagerros, 1998). Keihm et al. (2012, 2013) attribute the reduced emissivity at submillimeter/millimeter wavelengths to a higher thermal inertia value of the subsurface layers. Reduction in emissivity has also been determined at wavelengths shorter than  $4.9 \mu\text{m}$  for disk-resolved regions of (4) Vesta (Tosi et al., 2014).

## 4.3. Surface Roughness

Roughness causes an asteroid surface to thermally emit in a non-Lambertian way with a tendency to reradiate the absorbed solar radiation back toward the Sun, an effect

**Fig. 4.** (a) Example of SED calculated from a TPM and the NEATM compared to Spitzer spectrum of (87) Sylvia. (b) Spectral emissivity derived from the above; data divided by the NEATM continuum. From Marchis et al. (2012).

**Fig. 5.** Example of a TPM-generated thermal lightcurve (dashed line) and real data for (101955) Bennu. From Emery et al. (2014).

known as thermal-infrared beaming (*Lagerros*, 1998; *Rozitis and Green*, 2011). It is thought to be the result of two different processes: A rough surface will have elements oriented toward the Sun that become significantly hotter than a flat surface, and multiple scattering of radiation between rough surface elements increases the total amount of solar radiation absorbed by the surface. The relevant size scale ranges from the thermal skin depth to the linear size of the facets in the shape model. It is included in thermophysical models by typically modeling an areal fractional coverage ( $f$ ) of spherical-section craters (of opening angle  $\gamma_C$ ) within each shape model facet. Other more complex forms have been considered, such as Gaussian random (*Lagerros*, 1998) or fractal (*Groussin et al.*, 2013) surfaces or parallel sinusoidal trenches (see Fig. 1), but the spherical-section crater produces similar results [in terms of the disk-integrated beaming effect (*Lagerros*, 1998)] and accurately reproduces the directionality of the lunar thermal-infrared beaming effect (*Rozitis and Green*, 2011). However, it has been shown that for disk-resolved data, thermal emission depends on roughness type as well as roughness level (*Davidsson et al.*, 2015).

Spherical-section craters are typically implemented, as the required shadowing and view-factor calculations can be performed analytically (*Emery et al.*, 1998; *Lagerros*, 1998). Heat conduction can be included by dividing the crater into several tens of surface elements for which the same equations listed above can be applied. Alternatively, the temperature distribution within the crater resulting from heat conduction,  $T_{\text{crater}}(\Gamma)$ , can be approximated using

$$\frac{T_{\text{rough}}(\Gamma)}{T_{\text{rough}}(0)} = \frac{T_{\text{smooth}}(\Gamma)}{T_{\text{smooth}}(0)} \quad (9)$$

where  $T_{\text{rough}}(0)$  can be calculated analytically assuming instantaneous equilibrium (*Lagerros*, 1998).  $T_{\text{smooth}}(0)$  and  $T_{\text{smooth}}(\Gamma)$  are the corresponding smooth-surface temperatures, which can be calculated exactly. This approximation is computationally much cheaper than the full implementation. However, it does not work on the nightside of the asteroid, and temperature ratios diverge near the terminator (*Mueller*, 2007). An even simpler alternative is to multiply the smooth-surface temperatures by a NEATM-like  $\eta$  value (e.g., *Groussin et al.*, 2011). While this alternative might produce the correct disk-integrated color temperature of the asteroid, it does not reproduce the directionality of the beaming effect. Indeed, roughness models predict a limb-brightening effect (*Rozitis and Green*, 2011), which is seen in spatially-resolved measurements of (21) Lutetia by Rosetta (*Keihm et al.*, 2012).

The above implementations neglect lateral heat conduction, although the spatial scales representing surface roughness can, in some cases, become comparable to the thermal skin depth. Modeling of three-dimensional heat conduction inside rocks the size of the thermal skin depth has demonstrated that their western sides (for a prograde rotator; eastern sides for a retrograde rotator) are gener-

ally warmer than their eastern sides, which could result in a tangential-YORP effect that predominantly spins up asteroids (*Golubov and Krugly*, 2012). Other than this, it appears that the one-dimensional heat conduction approximation still produces satisfactory results.

In thermophysical models, the degree of surface roughness can be quantified in terms of the Hapke mean surface slope

$$\tan \bar{\theta} = \frac{2}{\pi} \int_0^{\pi/2} a(\theta) \tan \theta \, d\theta \quad (10)$$

where  $\theta$  is the angle of a given facet from horizontal, and  $a(\theta)$  is the distribution of surface slopes (Hapke, 1984). Alternatively, it can be measured in terms of the root mean square (RMS) surface slope (Spencer, 1990). This then allows comparison of results derived using different surface roughness representations [e.g., craters of different opening angles and fractional coverages, or different Gaussian random surfaces (*Davidsson et al.*, 2015)], and comparison against roughness measured by other means. It has been demonstrated that different roughness representations produce similar degrees of thermal-infrared beaming when they have the same degree of roughness measured in terms of these values (Spencer, 1990; *Emery et al.*, 1998; *Lagerros*, 1998; *Rozitis and Green*, 2011).

## 5. DATA ANALYSIS USING A THERMOPHYSICAL MODEL

### 5.1. Thermal Infrared Spectrophotometry

Physical properties that can be derived from TPM fits to disk-integrated thermal observations include diameter, geometric albedo, thermal inertia, and roughness. In practically all cases, the absolute visual magnitude  $H$  is known, establishing a link between  $D$  and  $p_V$  and reducing the number of TPM fit parameters by one

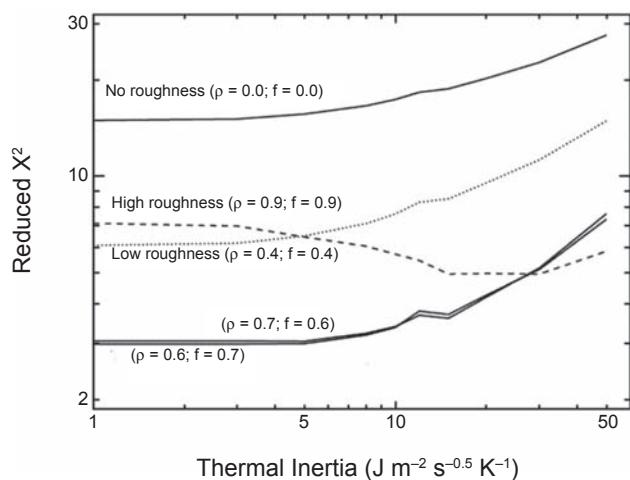

$$D(\text{km}) = 1329 p_V^{-1/2} 10^{-H/5} \quad (11)$$

(*Fowler and Chillemi*, 1992; *Vilenius et al.*, 2012). Frequently, the rotational phase during the thermal observations is not sufficiently well known and has to be fitted to the thermal data (e.g., *Harris et al.*, 2005; *Ali-Lagoa et al.*, 2014). In some cases, TPMs can be used to constrain the orientation of the spin vector of an asteroid, with  $\lambda_p$  and  $\beta_p$  treated as free parameters [as demonstrated by, e.g., *Müller et al.* (2013, 2012); note that in the case of (101955) Bennu the radar-constrained pole solution was not yet known]. Moreover, *Müller et al.* (2014b) successfully performed a TPM analysis of an asteroid [(99942) Apophis] in a non-principal axis rotation state for the first time.

The thermal effects of thermal inertia and surface roughness are difficult to tell apart. A commonly used approach is to use four different roughness models corresponding to no, low, medium, and high roughness, with each model leading

to a different thermal-inertia fit (*Mueller*, 2007; *Delbo* and *Tanga*, 2009); frequently, the scatter between these four solutions accounts for the bulk of the uncertainty in thermal inertia. However, in some lucky cases, data do allow the effects of roughness and thermal inertia to be disentangled. This requires good wavelength coverage straddling the thermal emission peak and good coverage in solar phase angle, such that both the morning and afternoon sides of the asteroid are seen (see Fig. 6 for an illustration).

The best-fitting model parameters are those that minimize  $\chi^2$ . Their uncertainty range is spanned by the values that lead to  $\chi^2$  within a specified threshold of the best fit, depending on the number of free fit parameters. Ideally, the reduced  $\chi^2$  of the best fit should be around unity. However, due to systematic uncertainties introduced in thermal-infrared observations (e.g., flux offsets between different instruments), and/or in the thermophysical modeling, it is not uncommon to get large reduced  $\chi^2$  values. Large  $\chi^2$  values are also obtained when the assumed shape model differs significantly from the asteroid's true shape (*Rozitis* and *Green*, 2014). In particular, if the spatial extent of the shape model's z-axis is wrong, this can lead to diameter determinations that are inconsistent with radar observations [e.g., for 2002 NY<sub>40</sub> and (308635) 2005 YU<sub>55</sub> in *Müller et al.* (2004, 2013), respectively], and/or two different thermal inertia determinations [e.g., the two different results produced for (101955) Bennu by *Emery et al.* (2014) and *Müller et al.* (2012)]. In some works, the asteroid shape model has also been optimized during the thermophysical fitting to resolve inconsistencies with radar observations [e.g., (1862) Apollo and (1620) Geographos in *Rozitis et al.* (2013) and *Rozitis and Green* (2014), respectively].

**Fig. 6.** (21) Lutetia: TPM fit that allows surface roughness to be constrained. The quantity  $\rho$  here is not the bulk density of the body, but the r.m.s. of the slopes on the surface. It is related to the ratio between the diameter and the depth of spherical section craters (*Lagerros*, 1998) in this particular case.  $f$  is the areal fraction of each facet covered with craters. From *O'Rourke et al.* (2012).

We remind the reader that the accuracy of the physical properties (in particular the value of  $\Gamma$ ) of asteroids derived from TPM depends on the quality of the thermal-infrared data and coverage in wavelength, phase, rotational, and aspect angle. The accuracy of the shape model and the H and G values are also important (see, e.g., *Rozitis and Green*, 2014). The derived thermal inertia value often depends on the assumed degree of roughness and it is usually affected by large errors (e.g., 50% or 100%; see Table 2). Care must be used in accepting TPM solutions purely based on the goodness of fit (e.g., the value of the  $\chi^2$ ), as they can be dominated by one or few measurements with unreliable small errors or calibration offsets between measurements from different sources.

## 5.2. Thermal Inertia and Thermal Conductivity

As asteroids rotate, the alternance of day and night causes cyclic temperature variations that are controlled by the thermal inertia [defined by equation (4)] of the soil and the rotation rate of the body. In the limit of vanishing thermal inertia, the surface temperature would be in instantaneous equilibrium with the incoming solar flux, depending only on the solar incidence angle (as long as self-heating can be neglected); surface temperatures would peak at local noon and would be zero at night. In reality, thermal conduction into and from the subsoil causes a certain thermal memory, referred to as *thermal inertia*. This smoothens the diurnal temperature profile, leads to nonzero nightside temperatures, and causes the surface temperature to peak on the afternoon side, as shown in Fig. 2, thereby also causing the Yarkovsky effect (section 5.8).

The mass density  $\rho$ , the specific heat capacity  $c$ , and the thermal conductivity  $\kappa$  — and correspondingly  $\Gamma$  itself — must be thought of as effective values representative of the depth range sampled by the heat wave, which is typically in the range of a few centimeters. In turn, thermal-inertia values inform us about the physical properties of the top few centimeters of the surface, not about bulk properties of the object.

As will be discussed below (section 6.5),  $\rho$  and  $c$  of an asteroid surface can plausibly vary within a factor of several, while plausible values of  $\kappa$  span a range of more than 4 orders of magnitude. It is therefore not unjustified to convert from  $\Gamma$  to  $\kappa$  and back using reference values for  $\rho$  and  $c$  (note that Yarkovsky/YORP models tend to phrase the thermal conduction problem in units of  $\kappa$ , while TPMs tend to be formulated in units of  $\Gamma$ , which is the observable quantity).

Importantly, the  $\kappa$  of finely powdered lunar regolith is 3 orders of magnitude lower than that of compact rock (compact metal is even more conductive, by another order of magnitude). This is because radiative thermal conduction between regolith grains is significantly less efficient than phononic heat transfer within a grain. A fine regolith, an aggregate of very small grains, is a poor thermal conductor and displays a low  $\Gamma$ . Thermal inertia can therefore be used to infer the presence or absence of thermally insulating powdered surface material. In extension, thermal inertia can be

TABLE 2. Published thermal inertia values.

used as a proxy of regolith grain size. The required calibration under Mars conditions (where the tenuous atmosphere enhances thermal conduction within pores compared to a vacuum) was obtained by Presley and Christensen (1997a,b) and used in the analysis of thermal-inertia maps of Mars (see Mellon et al., 2000; Putzig and Mellon, 2007). Similar progress in asteroid science was slowed down by the lack of corresponding laboratory measurements under vacuum conditions (but see below for recent laboratory measurements of meteorites). However, Gundlach and Blum (2013) provided a calibration relation based on heat-transfer modeling in a granular medium.

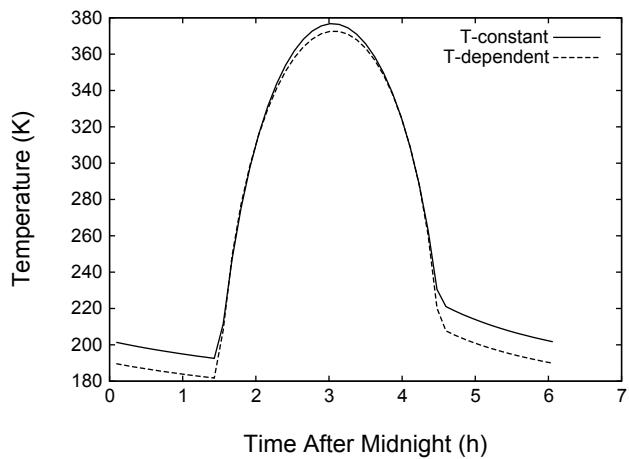

### 5.3. Temperature Dependence of Thermal Inertia

Thermal inertia is a function of temperature (Keihm, 1984), chiefly because the thermal conductivity is. In general, for a lunar-like regolith, the thermal conductivity is given by

$$\kappa = \kappa_b + 4\sigma r_p T^3 \quad (12)$$

where  $\kappa_b$  is the solid-state thermal conductivity (heat conduction by phonons) and  $r_p$  is the radius of the pores of the regolith. The term proportional to  $T^3$  is due to the heat conduction by photons. Equation (12) is often written in the form  $\kappa = \kappa_0(1 + \chi T^3)$  (e.g., Vasavada et al., 1999). Note that  $\kappa_b$  is itself a function of T (Opeil et al., 2010). There is extensive literature on the T-dependence of the conductivity of lunar regolith (e.g., Vasavada et al., 1999, and references therein). A theoretical description of the temperature dependence of  $\kappa$  in regoliths is given by Gundlach and Blum (2013).

Asteroid TPMs typically neglect the temperature dependence of  $\Gamma$ . This is not critical for typical remote observations, which are dominated by the warm sunlit hemisphere (see Fig. 7) (Capria et al., 2014; Vasavada et al., 2012). In the analysis of highly spatially resolved observations, however, the temperature dependence must be considered,

**Fig. 7.** Diurnal temperature curves at the equator of an asteroid with  $A = 0.1$ ,  $P = 6$  h,  $\epsilon = 1.0$  at a heliocentric distance of 1.0 AU. Solid curve: constant thermal conductivity  $\kappa = 0.02$  W K $^{-1}$  m $^{-1}$ . Dashed curve: temperature-dependent heat conductivity  $\kappa = 10^{-2}[1 + 0.5(T/250)^3]$  W K $^{-1}$  m $^{-1}$ .

certainly when analyzing nighttime observations on low- $\Gamma$  asteroids. Note that for temperature-dependent  $\kappa$ , equation (2) must be used instead of equation (3) (see, e.g., Capria *et al.*, 2014).

Caution must be exercised when comparing thermal-inertia results obtained at different heliocentric distances  $r$ , i.e., at different temperatures. All other things being equal,  $T^4 \propto r^{-2}$ . Assuming that the  $T^3$  term dominates in equation (12), the thermal inertia of a test object scales with (see also Mueller *et al.*, 2010)

$$\Gamma \propto \sqrt{\kappa} \propto T^{3/2} \propto r^{-3/4} \quad (13)$$

#### 5.4. Binary Asteroid Thermophysical Models

A rather direct determination of thermal inertia can be obtained by observing the thermal response to eclipses and their aftermath, allowing one to see temperature changes in real time. Such observations have been carried out for planetary satellites such as the Galilean satellites (Morrison and Cruikshank, 1973) and Earth's Moon (Pettit, 1940; Shorthill, 1973; Lawson *et al.*, 2003; Lucey, 2000; Fountain *et al.*, 1976). Mueller *et al.* (2010) report the first thermal observations of eclipse events in a binary Trojan asteroid system, (617) Patroclus, where one component casts shadow on the other while not blocking the line of sight toward the observer.

The thermophysical modeling of eclipse events is relatively straightforward, assuming the system is in a tidally locked rotation state typical of evolved binary systems. In that case, the components' spin rates match one another, and their spin axes are aligned with that of the mutual orbit. The system is therefore at rest in a co-rotating frame and can be modeled like a single object with a nonconvex

(disjointed) global shape. Eclipse effects are fully captured, provided that shadowing between facets is accounted for. The two hemispheres that face one another can, in principle, exchange heat radiatively. This is negligible for typical binary systems, however.

As discussed above, the thermal effects of roughness and thermal inertia can be hard to disentangle. In the case of eclipse measurements, which happen at essentially constant solar phase angle, the effect of surface roughness is much less of a confounding factor. This is because the variation in the thermal signal is dominated by the temperature change induced by the passing shadow, which is a strong function of thermal inertia.

It must be kept in mind that the duration of an eclipse event is short compared to the rotation period. The eclipse-induced heat wave therefore probes the subsoil less deeply than the diurnal heat wave does (the typical heat penetration depth is given by equation (5) with  $P$  equal to the duration of the eclipse event). A depth dependence of thermal inertia (see section 6.6) could manifest itself in different thermal-inertia determinations using the two different measurement methods.

#### 5.5. Thermal-Infrared Interferometry

Interferometric observations of asteroids in the thermal infrared measure the spatial distribution of the thermal emission along different directions on the plane of sky, thereby constraining the distribution in surface temperature and hence thermal inertia and roughness. Provided the asteroid shape is known, interferometry can be used to break the aforementioned degeneracy between thermal inertia and roughness from a single-epoch observation (Matter *et al.*, 2011, 2013). Interferometry also allows precise determination of the size of an asteroid (Delbo *et al.*, 2009).

Spatial resolutions between 20 and 200 milliarcseconds can be obtained from the ground (see the chapter by Durech *et al.* in this volume for a review and future perspectives of the application of this technique). While for the determination of asteroid sizes and shapes from interferometric observations in the thermal infrared, simple thermal models can be used (Delbo *et al.*, 2009; Carry *et al.*, 2015), a TPM was utilized to calculate interferometric visibilities of asteroids in the thermal infrared for the observations of (41) Daphne (Matter *et al.*, 2011) and (16) Psyche (Matter *et al.*, 2013).

Mid-infrared interferometric instruments measure the total flux and the visibility of a source, the latter related to the intensity of the Fourier transform (FT) of the spatial flux distribution along the interferometer's baseline projected on the plane of sky. Thus, the data analysis procedure consisted of generating images of the thermal-infrared emission of the asteroids at different wavelengths as viewed by the interferometer and then obtaining the model visibility and flux for each image. The former is related to the FT of the image, the latter is simply the sum of the pixels. The free parameters of the TPM (size, thermal-inertia value, and roughness) are adjusted in order to minimize the distance between the disk-integrated flux and visibility of the model,

and the corresponding observed quantities (see *Matter et al.*, 2011, 2013; see also the chapter by Durech et al.). Some results from these observational programs are discussed in section 6 and in the chapter by Durech et al.

### 5.6. Disk-Resolved Data and Retrieval of Temperatures

The availability of disk-resolved thermal-infrared observation has been steadily increasing over the years. The European Space Agency's (ESA) Rosetta mission performed successful flybys of the asteroids (2867) Steins (in 2008) and (21) Lutetia (in 2010) (see the chapter by Barucci et al. in this volume). In 2011, NASA's Dawn mission began its one-year orbit of (4) Vesta (*Russell et al.*, 2012), and is reaching (1) Ceres at the time of this writing. JAXA's Hayabusa-2 sample-return mission will map its target asteroid (162173) Ryugu (1999 JU<sub>3</sub>) using the thermal infrared imager (TIR) onboard the spacecraft (*Okada et al.*, 2013); NASA's OSIRIS-REx mission and its thermal spectrometer (OTES) will do likewise for its target asteroid (101955) Bennu (in 2018–2019). These data can be used to derive surface-temperature maps, from which maps of thermal inertia and roughness can be derived.

Three different methods are used to measure surface temperatures from orbiting spacecraft: bolometry, mid-infrared spectroscopy, and near-infrared spectroscopy. In the following, we will elaborate on the challenges posed by these different methods, and on their dependence on spectral features, surface roughness, illumination geometry, and viewing geometry.

Bolometers measure thermal flux within a broad bandpass in the infrared, approximating the integral of the Planck function,  $U = \sigma T_e^4$  (e.g., *Kieffer et al.*, 1977; *Paige et al.*, 2010). The temperature derived in this way (*effective temperature*) is directly relevant to the energy balance on the surface. Since the bolometric flux is spectrally integrated, the resulting temperature is fairly insensitive to spectral emissivity variations, as long as the bolometric emissivity (weighted spectrally averaged emissivity) is known or can be reasonably approximated.

Temperatures derived from mid-infrared spectrometry, on the other hand, are typically *brightness temperatures*, i.e., the temperature of a black body emitting at the wavelength in question. It is generally assumed that at some wavelength, the spectral emissivity is very close to 1.0, and the brightness temperature at this wavelength is taken as the surface temperature.

Spacecraft sent to asteroids (and/or comets) have more commonly been instrumented with near-infrared spectrometers (e.g.,  $\lambda < 5 \mu\text{m}$ ) rather than mid-infrared spectrometers. The long-wavelength ends of these spectrometers often extend into the range where thermal emission dominates the measured flux (for the daytime surface temperatures of most asteroids). At these wavelengths, one cannot assume that the emissivity is close to 1.0. It is therefore not practical to derive brightness temperatures. Instead, the *color temperature* is derived, i.e., the temperature of a blackbody

that emits with the same spectral shape. Such derivations have to separate temperature from spectral emissivity. The problem is underconstrained ( $N + 1$  unknowns, but only  $N$  data points), so there is no deterministic solution. Spectral emissivities for fine-grained silicates trend in the same direction as the blackbody curve, so it would be very easy to mistake spectral emissivity variations for different temperatures. The most statistically rigorous approach that has been applied to separating temperature and spectral emissivity in the 3–5-μm region is that of *Keihm et al.* (2012) and *Tosi et al.* (2014) for Rosetta's Visible and Infrared Thermal Imaging Spectrometer (VIRTIS) data of Lutetia and Dawn's Visual and Infrared Spectrometer (VIR) data of Vesta.

Temperatures thus measured represent an average temperature in the field of view of a given pixel: Illuminated hot zones and shadowed colder parts will both contribute. They do not directly correspond to a physical temperature of the soil; rather, they depend sensitively on the observation and illumination geometry (see *Rozitis and Green*, 2011, in particular their Fig. 9), especially in the case of large illumination angles.

Microwave spectrometers such as the Microwave Instrument for Rosetta Orbiter (MIRO) (*Gulkis et al.*, 2007) can provide both day- and nightside thermal flux measurements. At submillimeter, millimeter, and longer wavelengths, asteroid soils become moderately transparent. Subsurface layers contribute significantly to the observable thermal emission, thus providing information on the subsurface temperature. Observable fluxes depend on the subsurface temperature profile, weighted by the wavelength-dependent electrical skin depths, so both a thermal and an electrical model are required to interpret such data (*Keihm et al.*, 2012).

We remind the reader here that thermal-infrared fluxes should be used as input data for TPMs and not (effective, color, or brightness) temperatures derived from radiometric methods, because of their dependence on illumination and observation angles.

### 5.7. Sample Return Missions

Space agencies across the planet are developing space missions to asteroids, notably sample return missions to primitive (C- and B-type) NEAs: Hayabusa-2 was launched by JAXA toward (162173) 1999 JU<sub>3</sub> on December 3, 2014, and OSIRIS-REx is to be launched by NASA in 2016 (*Lauretta et al.*, 2012). A good understanding of the expected thermal environment, which is governed by thermal inertia, is a key factor in planning spacecraft operations on or near asteroid surfaces. For example, OSIRIS-REx is constrained to sampling a regolith no hotter than 350 K, severely constraining the choice of the latitude of the sample selection area on the body, the local time, and the arrival date on the asteroid.

Both Hayabusa-2 and OSIRIS-REx are required to take regolith samples from the asteroid surface back to Earth. Obviously, this requires that regolith be present in the first place, which needs to be ascertained by means of groundbased thermal-inertia measurements. The sampling

mechanism of OSIRIS-REx, in particular, requires relatively fine (centimeter-sized or smaller) regolith.

### 5.8. Accurate Yarkovsky and YORP Modeling from Thermophysical Models

Scattered and thermally emitted photons carry momentum. Any asymmetry in the distribution of outgoing photons can, after averaging over an orbital period, impart a net recoil force (Yarkovsky effect) and/or a net torque (YORP effect) on the asteroid. Both effects are more noticeable as the object gets smaller. For objects that are small enough, the orbits can be significantly affected by the Yarkovsky effect, and their rotation state can be significantly affected by the YORP effect (*Bottke et al.*, 2006; see also the chapter by Vokrouhlický et al. in this volume).

The strength of the Yarkovsky effect is strongly influenced by thermal inertia (*Bottke et al.*, 2006, and references therein) and by the degree of surface roughness (*Rozitis and Green*, 2012). However, the strength and sign of the YORP rotational acceleration on an asteroid is independent of thermal inertia (*Čapek and Vokrouhlický*, 2004), but it is highly sensitive to the shadowing (*Breiter et al.*, 2009), self-heating (*Rozitis and Green*, 2013), and surface roughness effects (*Rozitis and Green*, 2013) that are incorporated in TPMs.

Accurate calculations of the instantaneous recoil forces and torques require an accurate calculation of surface temperatures as afforded by TPMs; *Rozitis and Green* (2012, 2013) report on such models. Other than on thermal inertia, the Yarkovsky-induced orbital drift depends on the bulk mass density. Therefore, Yarkovsky measurements combined with thermal-inertia measurements can be used to infer the elusive mass density (*Mommert et al.*, 2014a,b; *Rozitis and Green*, 2014; *Rozitis et al.*, 2013, 2014). In the case of (101955) Bennu, the uncertainties in published values of thermal inertia (*Emery et al.*, 2014) and measured Yarkovsky drift (*Chesley et al.*, 2014) are so small that the accuracy of the inferred mass density rivals that of the expected *in situ* spacecraft result ( $1260 \pm 70 \text{ kg m}^{-3}$ , i.e., a nominal uncertainty of only 6%). *Rozitis et al.* (2014) derived the bulk density of (29075) 1950 DA and used it to reveal the presence of cohesive forces stabilizing the object against the centrifugal force.

In turn, the measured Yarkovsky drift can be used to infer constraints on thermal inertia. This was first done by *Chesley et al.* (2003), studying the Yarkovsky effect on (6489) Golevka, and by *Bottke et al.* (2001), studying the Koronis family in the main asteroid belt; both studies revealed thermal inertias consistent with expectations based on the observed correlation between thermal inertia and diameter (see section 6.2).

While the YORP effect is highly sensitive to small-scale uncertainties in an asteroid's shape model (*Statler*, 2009), it can be used to place constraints on the internal bulk density distribution of an asteroid (*Scheeres and Gaskell*, 2008). For instance, *Lowry et al.* (2014) explain the YORP detection on (25143) Itokawa — which was opposite in sign to that

predicted — by Itokawa's two lobes having substantially different bulk densities. However, unaccounted lateral heat conduction in thermal-skin-depth-sized rocks could also explain, at least partially, this opposite sign result (*Golubov and Krugly*, 2012).

## 6. LATEST RESULTS FROM THERMOPHYSICAL MODELS

In the *Asteroids III* era, thermal properties were known for only a few asteroids, i.e., (1) Ceres, (2) Pallas, (3) Juno, (4) Vesta, (532) Herculina from *Müller and Lagerros* (2002), and (433) Eros from *Lebofsky and Rieke* (1979). Since then, the number of asteroids with known thermal properties has increased steadily. We count 59 minor bodies with known value of  $\Gamma$  (see Table 2). Of these, 16 are NEAs, 27 are MBAs, 4 are Jupiter Trojans, 5 are Centaurs, and 7 are TNOs.

These classes of objects present very different physical properties, such as size, regolith grain size, average value of the thermal inertia, and composition. Other important differences are their average surface temperatures, due to their very different heliocentric distances and orbital elements. The illumination and observation geometry are also diverse for different classes of objects. For instance, for TNOs and MBAs the phase angle of observation from Earth and Earth-like orbits is typically between a few and a few tens of degrees, respectively. On the other hand, NEAs can be observed under a much wider range of phase angles that can approach  $100^\circ$  or more (see also *Müller*, 2002). Special care should be used in these cases to explicitly calculate the heat diffusion in craters instead of using the approximation of equation (9).

### 6.1. Ground Truth from Space Missions to Asteroids

A number of asteroids have been, or will be, visited by spacecraft, providing ground-truth for the application of TPMs to remote sensing thermal-infrared data.

(21) *Lutetia*: Based on groundbased data and a TPM, *Müller et al.* (2006) measured Lutetia's effective diameter and  $p_V$  to within a few percent of the later Rosetta result (*Sierks et al.*, 2011). Their thermal-inertia constraint ( $\Gamma < 50 \text{ J m}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$ ) was refined by *O'Rourke et al.* (2012) based on the Rosetta shape model and more than 70 thermal-infrared observations obtained from the ground and by Spitzer, AKARI, and Herschel:  $\Gamma = 5 \text{ J m}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$  with a high degree of surface roughness. *Keihm et al.* (2012) used MIRO onboard Rosetta to obtain a surface thermal inertia  $\leq 30 \text{ J m}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$ . The low thermal inertia can be explained by a surface covered in fine regolith; *Gundlach and Blum* (2013) infer a regolith grain size of about  $200 \mu\text{m}$ . The study of the morphology of craters by *Vincent et al.* (2012) indicates abundant, thick (600 m), and very fine regolith, confirming the TPM results.

(433) *Eros* was studied by the NASA Near Earth Asteroid Rendezvous (NEAR)-Shoemaker space mission, which allowed determination of the shape and size of this

asteroid [mean radius of 8.46 km with a mean error of 16 m (*Thomas et al.*, 2002)]. *Mueller* (2007) performed a TPM analysis of the groundbased thermal-infrared data by *Harris and Davies* (1999), obtaining a best-fit diameter of 17.8 km that is within 5% of the *Thomas et al.* (2002) result of 16.9 km, and  $\Gamma$  in the range  $100\text{--}200 \text{ J m}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$ . The latter value, in agreement with TPM results of *Lebofsky and Rieke* (1979), implies coarser surface regolith than that on the Moon and larger asteroids (see, e.g., *Mueller*, 2007; *Delbo et al.*, 2007). From the value of  $\Gamma$  of *Mueller* (2007), *Gundlach and Blum* (2013) calculated a 1–3-mm typical regolith grain size for Eros. Optical images of the NEAR-Shoemaker landing site at a resolution of about 1 cm/pixel (*Everka et al.*, 2001) show very smooth areas at the scale of the camera spatial resolution (Fig. 8), likely implying millimeter or submillimeter grain size regolith, consistent with TPM results.

(25143) *Itokawa* physical properties were derived *in situ* by the JAXA sample-return mission Hayabusa, allowing us to compare the size, albedo, and regolith nature derived from the TPMs with spacecraft results. *Müller et al.* (2014a) show an agreement within 2% between the size and the geometric visible albedo inferred from TPM analysis of thermal-infrared data and the value of the corresponding parameters from Hayabusa data. The TPM thermal inertia value for Itokawa is around  $750 \text{ J m}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$ , significantly higher than the value of Earth's Moon (about  $50 \text{ J m}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$ ) and of other large MBAs, including (21) Lutetia, implying a coarser regolith on this small NEA. The corresponding average regolith grain size according to *Gundlach and Blum* (2013) is ~2 cm. Hayabusa observations from the optical navigation camera (ONC-T), obtained during the descent of the spacecraft to the "Muses Sea" region of the asteroid, reveal similar grain sizes, at a spatial resolution of up to 6 mm/pixel. In particular, *Yano et al.* (2006) describe "Muses Sea" as composed of numerous size-sorted granular materials ranging from several centime-

ters to subcentimeter scales. Itokawa's regolith material can be classified as "gravel," larger than submillimeter regolith powders filling in ponds on (433) Eros (Fig. 8).

It is worth pointing out, however, that "Muses Sea" is not representative of Itokawa's surface as a whole. Rather, it was selected as a touchdown site because, in earlier images of Hayabusa, it appeared as particularly smooth (minimizing operational danger for the spacecraft upon touchdown) and apparently rich in regolith (maximizing the chance of sampling regolith). Grain sizes measured at "Muses Sea" are therefore lower limits on typical grain sizes rather than values typical for the surface as a whole.

## 6.2. Thermal Inertia of Large and Small Asteroids

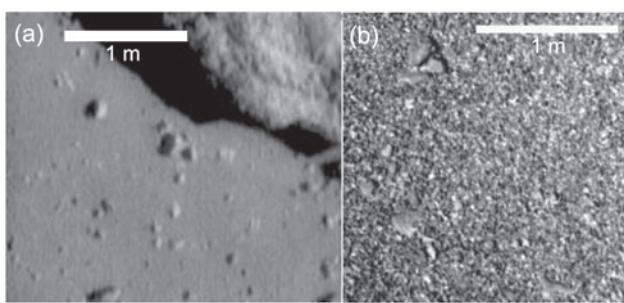

An inverse correlation between  $\Gamma$  and D was noticed by *Delbo et al.* (2007), then updated by *Delbo and Tanga* (2009) and *Capria et al.* (2014). This supported the intuitive view that large asteroids have, over many hundreds of millions of years, developed substantial insulating regolith layers, responsible for the low values of their surface thermal inertia. On the other hand, much smaller bodies, with shorter collisional lifetimes (*Marchi et al.*, 2006; *Bottke et al.*, 2005, and references therein), have less regolith and/or larger regolith grains (less mature regolith), and therefore display a larger thermal inertia.

In light of the recently published values of  $\Gamma$  (Table 2), the said inversion correlation between  $\Gamma$  and D is less clear, in particular when the values of the thermal inertia are temperature corrected (Fig. 9). However, the  $\Gamma$  vs. D distribution of  $D > 100 \text{ km}$  (large) asteroids is different than that of  $D < 100 \text{ km}$  (small) asteroids. Small asteroids typically have higher  $\Gamma$  values than large asteroids, which present a large scatter of  $\Gamma$  values, ranging from a few to a few hundreds of  $\text{J m}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$ . This is a clear indication of a diverse regolith nature among these large bodies. A shortage of low  $\Gamma$  values for small asteroids is also clear, with the notable exception of 1950 DA, which has an anomalously low  $\Gamma$  value compared to other NEAs of similar size (*Rozitis et al.*, 2014).

Figure 9 also shows previously unnoticed high-thermal-inertia C types, perhaps related to CR carbonaceous chondrites, which contain abundant metal phases. We also note that all E types in our sample appear to have a size-independent thermal inertia.

## 6.3. Very Low $\Gamma$ Values

We also note that some of the C-complex outer MBAs and Jupiter Trojans have very low thermal inertia, in the range between a few and a few tens of  $\text{J m}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$ . In order to reduce the thermal inertia of a material by at least 1 order of magnitude [from the lowest measured thermal inertia of a meteorite,  $\sim 650 \text{ J m}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$  at 200 K (*Opeil et al.*, 2010)] to the typical values for these large asteroids (Table 2 and Fig. 9), a very large porosity (>90%) of the first few millimeters of the regolith is required (*Vernazza et al.*,

**Fig. 8.** Higher  $\Gamma$ -values correspond to coarser regoliths. (a) Close-up image of (433) Eros from the NASA NEAR Shoemaker mission reveals coarse regolith with grain size in the millimeter range (adapted from *Everka et al.*, 2001). The value of  $\Gamma$  is  $\sim 150 \text{ J m}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$  for Eros. (b) Image from the JAXA Hayabusa mission of the surface of (25143) Itokawa displaying gravel-like regolith (from *Yano et al.*, 2006). The value of  $\Gamma$  is  $\sim 750 \text{ J m}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$  for Itokawa.

2012). This is consistent with the discovery that emission features in the mid-infrared domain (7–25  $\mu\text{m}$ , Fig. 4) are rather universal among large asteroids and Jupiter Trojans (Vernazza *et al.*, 2012), and that said features can be reproduced in the laboratory by suspending meteorite and/or mineral powder (with grain sizes  $<30\ \mu\text{m}$ ) in infrared-transparent potassium bromide (KBr) powder (Vernazza *et al.*, 2012). As KBr is not supposed to be present on the surfaces of these minor bodies, regolith grains must be “suspended” in void space, likely due to cohesive forces and/or dust levitation. On the other hand, radar data indicate a significant porosity (40–50%) of the first  $\sim 1\ \text{m}$  of regolith (Magri *et al.*, 2001; Vernazza *et al.*, 2012), indicating decreasing porosity with increasing depth (see Fig. 5 of Vernazza *et al.*, 2012, for a regolith schematic).

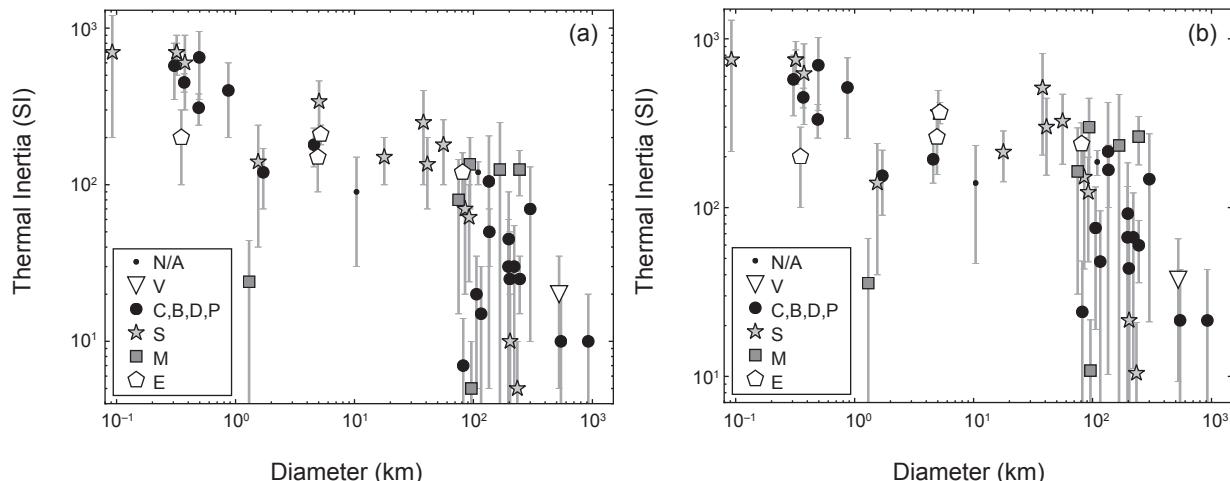

#### 6.4. Average Thermal Inertia of Asteroid Populations

As described previously, the thermal inertia of an asteroid can be directly derived by comparing measurements of its thermal-infrared emission to model fluxes generated by means of a TPM. Typically, more than one observation epoch is required to derive the thermal inertia, in order to “see” the thermal emission from different parts of the asteroid’s diurnal temperature distribution. Unfortunately, the large majority of minor bodies for which we have thermal-infrared observations have been observed at a single epoch and/or information about their gross shape and pole orientation is not available, precluding the use of TPMs. However, if one assumes the thermal inertia to be roughly constant within a population of asteroids (e.g., NEAs) one can use observations of different asteroids under non-identical illumination and viewing geometries, as if they were from a unique object. Delbo *et al.* (2003) noted that qualitative information about the average thermal

properties of a sample of NEAs could be obtained from the distribution of the  $\eta$  values of the sample as a function of the phase angle,  $\alpha$ . Delbo *et al.* (2007) and Lellouch *et al.* (2013) developed a rigorous statistical inversion method, based on the comparison of the distributions of published NEATM  $\eta$  values vs.  $\alpha$  (or vs.  $r$ ) with that of a synthetic population of asteroids generated through a TPM, using realistic distributions of the input TPM parameters such as the rotation period, aspect angle, etc. Delbo *et al.* (2007) found that the average thermal inertia value for kilometer-sized NEAs is around  $200\ \text{J m}^{-2}\ \text{s}^{-1/2}\ \text{K}^{-1}$ . The average thermal inertia of binary NEAs is higher than that of nonbinary NEAs, possibly indicating a regolith-depriving mechanism for the formation of these bodies (Delbo *et al.*, 2011). The same authors also found that NEAs with slow rotational periods ( $P > 10\ \text{h}$ ) have higher-than-average thermal inertia. From a sample of 85 Centaurs and TNOs observed with the Multi-Band Imaging Photometer for Spitzer (MIPS) and Herschel’s Photodetector Array Camera and Spectrometer (PACS), Lellouch *et al.* (2013) found that surface roughness is significant, a mean thermal inertia  $\Gamma = 2.5 \pm 0.5\ \text{J m}^{-2}\ \text{s}^{-1/2}\ \text{K}^{-1}$ , and a trend toward decreasing  $\Gamma$  with increasing heliocentric distance. The thermal inertias derived by Lellouch *et al.* (2013) are 2–3 orders of magnitude lower than expected for compact ices, and generally lower than on Saturn’s satellites or in the Pluto/Charon system. These results are suggestive of highly porous surfaces.

#### 6.5. Relevant Astronomical and Laboratory Data

Physical interpretations of thermal-inertia estimates depend strongly on laboratory and ground-truth measurements of relevant material properties. While in the *Asteroids III* era we based interpretation of thermal inertia on Earth analog materials, in the last few years laboratory measurements

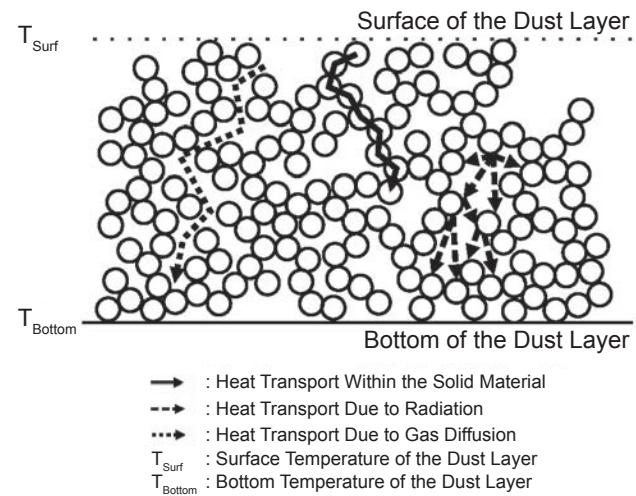

**Fig. 9.**  $\Gamma$  values vs.  $D$  from Table 2 for different taxonomic types (see key). **(a)** Original measurements; **(b)**  $\Gamma$  corrected to 1 AU heliocentric distance for temperature-dependent thermal inertia assuming equation (13) and the heliocentric distance at the time of thermal infrared observations reported in Table 2. Trojans, Centaurs, and transneptunian objects are not displayed.

were performed on asteroid analog materials, i.e., meteorites. Meteorite grain densities range from  $\sim 2800 \text{ kg m}^{-3}$  for CM carbonaceous chondrites to  $\sim 3700 \text{ kg m}^{-3}$  for enstatite chondrites (*Consolmagno et al.*, 2006; *Macke et al.*, 2010, 2011a,b). Heat capacities have been measured for a wide sampling of meteorites by *Consolmagno et al.* (2013), who find that values for stony meteorites are between 450 and  $550 \text{ J kg}^{-2} \text{ K}^{-1}$ , whereas C for irons tends to be smaller ( $330\text{--}380 \text{ J kg}^{-2} \text{ K}^{-1}$ ). *Opeil et al.* (2010, 2012) present thermal conductivity measurements of stony meteorites, finding values of  $0.5 \text{ W K}^{-1} \text{ m}^{-1}$  for the carbonaceous chondrite Cold Bokkeveld to  $5.5 \text{ W K}^{-1} \text{ m}^{-1}$  for the enstatite chondrite Pillistfer. Their one iron meteorite sample has a  $\kappa$  of  $22.4 \text{ W K}^{-1} \text{ m}^{-1}$ . They also find a linear correlation between and the inverse of the porosity, from which *Opeil et al.* (2012) conclude that the measured  $\kappa$  of the samples is controlled more by microfractures than by composition.

Grain size and packing, more than compositional heterogeneity, are responsible for different thermal inertias of different surfaces. This also explains why TPMs are capable of deriving asteroid physical parameters independently of the asteroid mineralogy. Conduction between grains is limited by the area of the grain contact (*Piqueux and Christensen*, 2009a,b). As grain size decreases to diameters less than about a thermal skin depth (a few centimeters on most asteroids), conduction is more and more limited (e.g., *Presley and Christensen*, 1997b). On bodies with atmospheres, conduction through the air in pores can often efficiently transport heat. On airless bodies, however, radiation between grains, which is not very efficient, particularly at low T (e.g., *Gundlach and Blum*, 2012), is the only alternative to conduction across contacts (Fig. 10). Considering these two modes of energy transport and their dependence on grain size, *Gundlach and Blum* (2013) developed an analytical approach for determining grain size from thermal inertia measurements. They incorporated the measurements of material properties of meteorites measured above along with results of their own laboratory studies of heat transport in dusty layers. Additional laboratory measurements of conductivities of powdered meteorites under high vacuum would be valuable for more precise interpretation of asteroid thermal inertias.

The classic opportunity for ground-truth thermal measurements came with the Apollo missions. Astronauts on Apollos 15 and 17 carried out bore-hole-style temperature measurements to depths of 1.4 m below the surface on Apollo 15 and 2.3 m below the surface on Apollo 17 (*Langeseth and Keihm*, 1977; *Vaniman et al.*, 1991). Thermal conductivity of about  $0.001 \text{ W K}^{-1} \text{ m}^{-1}$  was found in the top 2 to 3 cm of the lunar regolith, increasing to about  $0.01 \text{ W K}^{-1} \text{ m}^{-1}$  over the next few centimeters, then to values as high as  $2 \text{ W K}^{-1} \text{ m}^{-1}$  deeper into the surface where the regolith appears to have been very compacted (*Langeseth and Keihm*, 1977). Low thermal inertias derived from remote thermal-infrared measurements (e.g., *Wesselink*, 1948; *Vasavada et al.*, 2012) agree with the very low  $\kappa$  in the topmost few centimeters of the lunar

**Fig. 10.** Diagram of the modes of heat transport in regoliths. On airless bodies, heat can flow by conduction through grain boundaries (solid line) or by radiation between grains (dashed line). The dotted line showing transport by gas diffusion is not relevant to asteroid surfaces. From Gundlach and Blum (2012).

surface, and the Apollo measurements provide the necessary ground-truth for interpreting such low thermal inertias as very fine-grained, “fluffy” regolith. These measurements fostered, for instance, development of detailed models of lunar regolith (Keihm, 1984). Detailed thermal-infrared observations and thermal models of the lunar regolith today allows estimating the subsurface rock abundance (e.g., Bandfield *et al.*, 2011), which allows geological studies of the regolith production rate.

## 6.6. Dependence of $\Gamma$ with Depth

The depth dependence of typical asteroid regolith properties is poorly constrained at this point, which is why physical constants are typically assumed to be constant with depth. MIRO observations of (21) Lutetia, however, showed the existence of a top layer with  $\Gamma < 30 \text{ J m}^{-2} \text{ s}^{-1/2} \text{ K}^{-1}$ , while the thermal inertia of subsurface material appears to increase with depth, much like on the Moon (*Keihm et al.*, 2012) (see also section 5.3).

### 6.7. Infrared Limb Brightening

Recent modeling and observations show that, contrary to expectations, the flux enhancement measured in disk-integrated observations of the sunlit side of an asteroid (e.g., Lebofsky *et al.*, 1986) is dominated by limb surfaces rather than the subsolar region (Rozitis and Green, 2011; Keihm *et al.*, 2012). This suggests that for the sunlit side of an asteroid, sunlit surfaces directly facing the observer in situations where they would not be if the surface was a smooth flat one are more important than mutual self-heating between interfacing facets raising their temperatures. Figure 9 of

*Rozitis and Green* (2011) pictures this effect for a Gaussian random surface during sunrise viewed from different directions. The thermal flux observed is enhanced when viewing hot sunlit surfaces (i.e., Sun behind the observer), and is reduced when viewing cold shadowed surfaces (i.e., Sun in front of the observer).

*Jakosky et al.* (1990) also studied the directional thermal emission of Earth-based lava flows exhibiting macroscopic roughness. They found that enhancements in thermal emission were caused by viewing hot sunlit sides of rocks and reductions were caused by viewing cold shadowed sides of rocks. This agrees precisely with the model and adds further evidence that thermal-infrared beaming is caused by macroscopic roughness rather than microscopic roughness.

The effect of limb brightening has also been measured from disk-resolved thermal-infrared data ( $<5\text{ }\mu\text{m}$ ) acquired during sunrise on the nucleus of Comet 9P/Tempel 1 by NASA's Deep Impact mission (*Davidsson et al.*, 2013), and from VIRTIS and MIRO measurements of the asteroid (21) Lutetia (*Keihm et al.*, 2012).

## 6.8. Asteroid Thermal Inertia Maps

Disk-resolved thermal-infrared observations, in the range between 4.5 and  $5.1\text{ }\mu\text{m}$ , were provided by the VIR instrument (*De Sanctis et al.*, 2012) onboard NASA's Dawn (*Russell et al.*, 2012) spacecraft (*Capria et al.*, 2014, and references therein). From TPM analysis of VIR measurements, *Capria et al.* obtained a map of the roughness and the thermal inertia of Vesta. The average thermal inertia of Vesta is  $30 \pm 10\text{ J m}^{-2}\text{ s}^{-1/2}\text{ K}^{-1}$ , which is in good agreement with the values found by groundbased observations (*Müller and Lagerros*, 1998; *Chamberlain et al.*, 2007; *Leyrat et al.*, 2012). The best analog is probably the surface of the Moon, as depicted by *Vasavada et al.* (2012) and *Bandfield et al.* (2011): A surface whose thermal response is determined by a widespread layer of dust and regolith with different grain sizes and density increasing toward the interior. Exposed rocks are probably scarce or even absent. *Capria et al.* (2014) also show that Vesta cannot be considered uniform from the point of view of thermal properties. In particular, they found that the thermal inertia spatial distribution follows the global surface exposure age distribution as determined by crater counting in *Raymond et al.* (2011), with higher thermal inertia displayed by younger terrains and lower thermal inertia in older soils.

*Capria et al.* (2014) also found higher-than-average thermal-inertia terrain units located in low-albedo regions that contain the highest abundance of OH, as determined by the  $2.8\text{-}\mu\text{m}$  band depth (*De Sanctis et al.*, 2012). These terrains are associated with the dark material, thought to be delivered by carbonaceous-chondrite-like asteroids that have impacted Vesta at low velocity. Note that in general carbonaceous chondrites have lower densities and lower thermal conductivity (*Opeil et al.*, 2010) than basaltic material, which constitute the average vestan terrain. This consideration would point to a lower thermal inertia rather than a higher one, as observed on Vesta. *Capria et*

*al.* (2014) conclude that the factor controlling the thermal inertia in these areas could be the degree of compaction of the uppermost surface layers, which is higher than in other parts of the surface.

## 6.9. Thermal Inertia of Metal-Rich Regoliths

In principle, the composition of the regolith and not only its average grain size, but also the degree of compaction, also affects the thermal inertia of the soil (*Gundlach and Blum*, 2013). For instance, iron meteorites have a higher thermal conductivity than ordinary and carbonaceous chondrites (*Opeil et al.*, 2010). We thus expect that a metal-iron-rich regolith would display a higher thermal inertia than a soil with a deficiency of this component. *Harris and Drube* (2014) compared values of the NEATM  $\eta$  parameter derived from WISE data with asteroid taxonomic classifications and radar data, and showed that the  $\eta$  value appears to be a useful indicator of asteroids containing metal. *Matter et al.* (2013) performed interferometric observations with the MID-infrared Interferometric instrument (MIDI) of the European Southern Observatory's (ESO) Very Large Telescope Interferometer (VLTI) in thermal infrared of (16) Psyche and showed that Psyche has a low surface roughness and a thermal inertia value around  $120 \pm 40\text{ J m}^{-2}\text{ s}^{-1/2}\text{ K}^{-1}$ , which is one of the higher values for an asteroid of the size of Psyche ( $\sim 200\text{ km}$ ). This higher-than-average thermal inertia supports the evidence of a metal-rich surface for this body.

## 7. EFFECTS OF TEMPERATURES ON THE SURFACE OF ASTEROIDS

### 7.1. Thermal Cracking

The surface temperature of asteroids follows a diurnal cycle (see Fig. 2) with typically dramatic temperature changes as the Sun rises or sets. The resulting, repeated thermal stress can produce cumulative damage on surface material due to opening and extension of microscopic cracks. This phenomenon is known as *thermal fatigue* (*Delbo et al.*, 2014).

Growing cracks can lead to rock breakup when the number of temperature cycles is large enough. For typical asteroid properties, this process is a very effective mechanism for comminuting rocks and to form fresh regolith (*Delbo et al.*, 2014). For centimeter-sized rocks on an asteroid at 1 AU from the Sun, thermal fragmentation is at least an order of magnitude faster than comminution by micrometeoroid impacts, the only regolith-production mechanism previously considered relevant (*Hörz and Cintala*, 1997; *Hoerz et al.*, 1975).

The efficiency of thermal fragmentation is dominated by the amplitude of the temperature cycles and by the temperature change rate (*Hall and André*, 2001), which in turn depends on heliocentric distance, rotation period, and the surface thermal inertia. The rate of thermal fragmentation increases with decreasing perihelion distance: At 0.14 AU from the Sun, thermal fragmentation may erode asteroids such as (3200) Phaethon and produce the Geminids (*Jewitt*

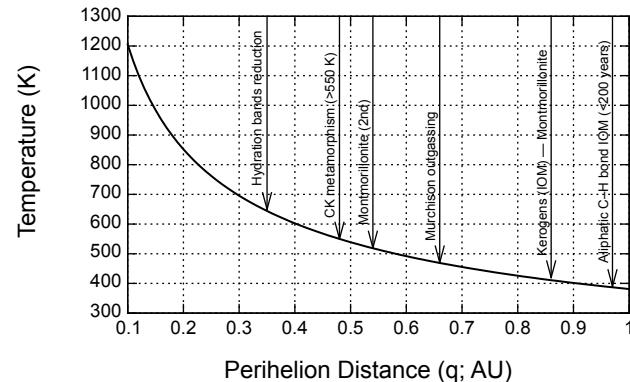

and Li, 2010), whereas in the outer main belt, this process might be irrelevant. Thermal fragmentation of surface boulders is claimed by Dombard et al. (2010) to be the source of fine regolith in the so-called “ponds” on the asteroid (433) Eros. Production of fresh regolith originating in thermal fatigue fragmentation may be an important process for the rejuvenation of the surfaces of NEAs (Delbo et al., 2014).

Thermal cracking is reported on other bodies as well: on Earth, particularly in super-arid environments (Hall, 1999; Hall and André, 2001); the Moon (Levi, 1973; Duennbier and Sutton, 1974); Mercury (Molaro and Byrne, 2012); Mars (Viles et al., 2010); and meteorites (Levi, 1973). Moreover, Tambovtseva and Shestakova (1999) suggest that thermal cracking could be an important process in the fragmentation and splitting of kilometer-sized comets while in the inner solar system. Furthermore, Čapek and Vokrouhlický (2010) initially proposed that slowly rotating meteoroids or meteoroids with spin vectors pointing toward the Sun can be broken up by thermal cracking. In a further development of their model, Čapek and Vokrouhlický (2012) showed that as the meteoroid approaches the Sun, the stresses first exceed the material strength at the surface and create a fractured layer. If intermolecular forces (e.g., Rozitis et al., 2014) are able to retain the surface layer, despite the competing effects of thermal lifting and centrifugal forces, the particulate surface layer is able to thermally shield the core, preventing any further damage by thermal stresses.

## 7.2. Sun-Driven Heating of Near-Earth Asteroids and Meteoroids

It is known that heating processes can affect the physical properties of asteroids and their fragments, the meteorites (see, e.g., Keil, 2000). Internal heating due to the decay of short-lived radionuclides was considered early on (Grimm and McSween, 1993). Marchi et al. (2009) discuss close approaches to the Sun as an additional surface-altering heating mechanism. In the present NEA population, the fraction of bodies with relatively small perihelion ( $q$ ) is very small: About 1/2, 1/10, and 1/100 of the population of currently known NEOs (11,000 as of the time of this writing) have a perihelion distance below 1, 0.5, and 0.25 AU, where maximum temperatures exceed 400, 550, and 780 K, respectively (see Fig. 11). However, dynamical simulations show that a much larger fraction of asteroids had small perihelion distances for some time, hence experiencing episodes of strong heating in their past (Marchi et al., 2009). For instance, the asteroid 2004 LG was approaching the Sun to within only  $\sim$ 5.6 solar radii some 3 k.y. ago, and its surface was baked at temperatures of 2500 K (Vokrouhlický and Nesvorný, 2012).

Solar heating has a penetration depth of typically a few centimeters (see equation (5) and Spencer et al., 1989). Organic components found on meteorites break up at temperatures as low as 300–670 K (see Fig. 11 and Kebukawa et al., 2010; Frost et al., 2000; Huang et al., 1994), thus solar heating can remove these components from asteroid surfaces.

**Fig. 11.** Surface temperature of an asteroid or meteoroid as a function of the distance from the Sun. Vertical arrows indicate the threshold temperature for the thermal alteration/desiccation for a variety of chemical compounds discussed in the text (for additional information, see Delbo and Michel, 2011, and references therein). The temperature range for thermal metamorphism of the CK chondrites is from Chaumard et al. (2012).

## 7.3. Thermal Metamorphism of Meteorites

Radiative heating from the Sun has been invoked as a mechanism for the thermal metamorphism of meteoritic CK carbonaceous chondrites (Chaumard et al., 2012). The matrix of these chondrites shows textures consistent with a transient thermal event during which temperatures rose between 550 and 950 K. The inferred duration of these events is on the order of days to years, much longer than the timescale of shock events but shorter than the timescale for heating by the decay of radiogenic species such as  $^{26}\text{Al}$  (e.g., Kalleymen et al., 1991).

## 7.4. Subsurface Ice Sublimation

Observational evidence for the presence of ice on asteroid surfaces stems from the discovery of MBCs (Hsieh and Jewitt, 2006), the localized release of water vapor from the surface of (1) Ceres (Küppers et al., 2014), and the detection of spectroscopic signatures interpreted as water ice frost on the surfaces of (24) Themis (Rivkin and Emery, 2010; Campins et al., 2010) and (65) Cybele (Licandro et al., 2011).

The lifetime of ices on the surface and in the subsurface depends strongly on temperature. Thermophysical models have been used to estimate these temperatures. This requires a modification of the “classical” TPM as presented in section 4, such that heat conduction is coupled with gas diffusion (Schorghofer, 2008; Capria et al., 2012; Prialnik and Rosenberg, 2009). The referenced models assume a spherical shape. As for the interior structure, Capria et al. (2012) and Prialnik and Rosenberg (2009) assume a comet-like structure, i.e., an intimate mixture of ice and dust throughout the entire body, while Schorghofer (2008) consider an ice layer underneath a rocky regolith cover.

Sublimation of ice and the transport of water molecules through the fine-grained regolith is modeled in all cases.

All authors agree that water ice exposed on asteroid surfaces sublimates completely on timescales much shorter than the age of the solar system. Asteroid surfaces were therefore expected to be devoid of water ice, contrary to the observational evidence quoted above. However, water ice can be stable over 4.5 G.y. in the shallow subsurface, at a depth of ~1–10 m. In particular, *Fanale and Salvail* (1989) showed that ice could have survived in the subsurface at the polar regions of Ceres. Large heliocentric distances, slow rotation, and a fine-grained regolith leading to low thermal conductivity and short molecular free path all favor the stabilization of subsurface water ice (*Schorghofer*, 2008). The same authors conclude that rocky surfaces, in contrast to dusty surfaces, are rarely able to retain ice in the shallow subsurface.

To be observable on the surface, buried ice must be exposed. *Campins et al.* (2010) describe several plausible mechanisms such as impacts, recent change in the obliquity of the spin pole, and daily or orbital thermal pulses reaching a subsurface ice layer.

## 8. FUTURE CHALLENGES FOR THERMOPHYSICAL MODELS

The Spitzer and WISE telescopes have opened up a new era of asteroid thermal-infrared observations, and the exploitation of their data through TPMs has just begun (e.g., *Ali-Lagoa et al.*, 2014; *Rozitis et al.*, 2014; *Emery et al.*, 2014). At the moment, the limiting factor is the availability of accurate asteroid shape models. However, optical-wavelength all-sky surveys such as the Panoramic Survey Telescope and Rapid Response System (Pan-STARRS), Large Synoptic Survey Telescope (LSST), and Gaia are expected to produce enormous photometric datasets leading to thousands of asteroid models. We envision the availability of thousands of thermal-inertia values in some years from now, enabling more statistically robust studies of thermal inertia as a function of asteroid size, spectral class, albedo, rotation period, etc.

For instance, the distribution of  $\Gamma$  within asteroid families will be crucial in the search of evidence of asteroid differentiation: Asteroid formation models and meteorite studies suggest that hundreds of planetesimals experienced complete or partial differentiation. An asteroid family formed from the catastrophic disruption of such a differentiated asteroid should contain members corresponding to the crust, the mantle, and the iron core. However, the observed spectra and albedos are very homogeneous across asteroid families. Thermal inertia might help in separating iron-rich from iron-poor family members, supposedly originating respectively from the core and mantle of the differentiated parent body (e.g., *Matter et al.*, 2013; *Harris and Drube*, 2014).

At any size range, Fig. 9 shows an almost tenfold variability in thermal inertia, corresponding to differences in average regolith grain size of almost 2 orders of magnitude

(*Gundlach and Blum*, 2013). For small NEAs, this could be due to a combination of thermal cracking (*Delbo et al.*, 2014), regolith motion (see the chapter by Murdoch et al. in this volume), and cohesive forces (*Rozitis et al.*, 2014). Faster rotation periods allow more thermal cycles, which then enhances thermal fracturing. It also encourages regolith to move toward the equator where the gravitational potential is at its lowest (*Walsh et al.*, 2008). And for the extremely fast rotators, large boulders/rocks could be selectively lofted away, because they do not stick as well to the surface as smaller particles. For  $D > 100$ -km-sized asteroids,  $\Gamma$  values might be help to distinguish between primordial and more recently reaccumulated asteroids. The former had ~4 G.y. of regolith evolution, while the latter have a less-developed and therefore coarser regolith.

The high-precision thermal-infrared data of WISE and Spitzer pose new challenges to TPMs, as model uncertainties are now comparable to the uncertainty of the measured flux. This will become even more important with the launch of the James Webb Space Telescope (JWST). In particular, the accuracy of the shape models might represent a limiting factor (e.g., *Rozitis and Green*, 2014). The next challenge will be to allow TPMs to optimize the asteroid shape. This seems to be possible, as infrared photometry is also sensitive to shape, provided good-quality thermal data are available (see the chapter by Durech et al. in this volume).

New interferometric facilities, such as the Multi AperTure mid-Infrared SpectroScopic Experiment (MATISSE), Large Binocular Telescope Interferometer (LBTI), and Atacama Large Millimeter Array (ALMA), will become available in the next few years, requiring TPMs to calculate precise disk-resolved thermal fluxes (see chapter by Durech et al. in this volume). The wavelengths of ALMA, similar to those of MIRO, will allow measurement of thermal-infrared radiation from the subsoil of asteroids, thus providing further information about how thermal inertia varies with depth.

Certainly, constraining roughness is one of the future challenges for TPMs. To do so from disk-integrated data requires a range of wavelengths and solar phase angles. Low-phase-angle measurements are enhanced by beaming, while high-phase-angle measurements are reduced by beaming. In particular, shorter wavelengths are affected more than longer wavelengths.

Moreover, the future availability of precise sizes and cross sections of asteroids from stellar occultation timing (*Tanga and Delbo*, 2007), combined with shape information derived from lightcurve inversion (chapter by Durech et al. in this volume) will allow elimination of the necessity of constraining the object size from TPM analysis. Infrared fluxes will therefore be converted into highly reliable thermal inertia and roughness values.

Asteroid photometry has three major applications: providing clues about asteroid surface physical properties and compositions, facilitating photometric corrections, and helping design and plan groundbased and spacecraft observations. The most significant advances in asteroid photometry in the past decade were driven by spacecraft observations that collected spatially resolved imaging and spectroscopy data. In the meantime, laboratory measurements and theoretical developments are revealing controversies regarding the physical interpretations of models and model parameter values. We will review the new developments in asteroid photometry that have occurred over the past decade in the three complementary areas of observations, laboratory work, and theory. Finally, we will summarize and discuss the implications of recent findings.

## 1. INTRODUCTION

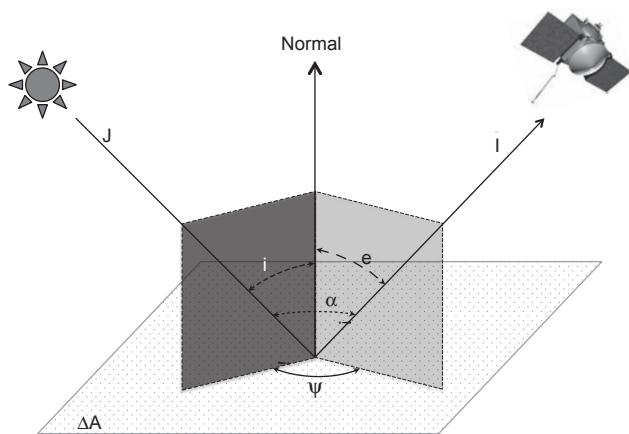

### 1.1. Importance of Planetary Photometry

Planetary photometry concerns how the brightness of a planetary surface depends on the illumination and observing geometry. Figure 1 shows the scattering geometry and definition of terms that will be important for the rest of this chapter. The angle between the light source and local surface normal is incidence angle,  $i$ ; the angle between the observer and the local surface normal is emission angle,  $e$ ; and the angle between light source and observer, as seen from the object, is phase angle,  $\alpha$ . The dependence of the brightness of the surface on ( $i, e, \alpha$ ) is determined by the optical and mechanical properties of the surface.

Why is asteroid photometry important? We broadly divide the applications of planetary photometry, especially with spatially resolved data, into three major aspects.

First, it provides clues about the physical properties and compositions of asteroidal surfaces. How the reflectance of a particulate surface responds to the illumination and viewing geometry is fully determined by the optical and mechani-

cal properties of a surface, such as particle size, porosity, roughness, complex refractive index, etc. The ultimate goal of photometric modeling is to derive these fundamental properties of a surface by measuring the reflectance under various light-scattering geometries. Despite the development of various theoretical models, empirical or semiphysical, over the past several decades, we are still far from being able to determine all surface physical conditions from photometric observations and modeling of asteroids. The major reason is that real asteroidal surfaces have complex physical conditions that are difficult to fully parameterize. We still do not fully understand the light-scattering effects of some physical conditions, such as roughness, porosity, etc. Therefore it is nearly impossible to find exact, unique solutions of radiative transfer equations that describe real asteroidal surfaces. Some assumptions and approximations have to be made in order to derive practical analytical models, such as the Hapke model (Hapke, 1981, 1984, 1986, 2002, 2008, 2012a), the Shkuratov model (Shkuratov et al., 1999), etc. Observationally, due to the limited observing geometries available for groundbased and spacecraft observations of any asteroid, it is often difficult to fully constrain a photometric model for a particular object.

**Fig. 1.** Schematic diagram of bidirectional reflectance from a surface element  $\Delta A$ , showing the various angles. The plane containing  $J$  and  $I$  is the scattering plane. If the scattering plane also contains  $N$ , it is called the principal plane.  $\psi$  is the azimuthal angle between the planes of incidence and emission [ $\cos(\alpha) = \cos(i)\cos(e) + \sin(i)\sin(e)\cos(\psi)$ ].

Second, because the spectral reflectance of a surface depends on illumination and viewing geometry, it is necessary to correct observations (imaging or spectral) to a common (reference) geometry in order to make comparisons between different areas on an asteroid, between different asteroid surfaces, and with laboratory measurements. Photometric modeling provides such a means for this purpose. For example, phase reddening is a common phenomenon, first reported by Gehrels *et al.* (1964) and recognized on many asteroids for a long time (e.g., Clark *et al.*, 2002, and references therein; Reddy *et al.*, 2012a; Li *et al.*, 2013a) (see also section 4.1.2), that causes the spectrum of a surface to have redder slopes and stronger spectral absorptions at higher phase angles. One has to correct for this in order to make meaningful mineralogical interpretations of reflectance spectra. Other examples include mosaicking albedo and color maps of the whole surface of an asteroid from spacecraft data taken at vastly different illumination geometries (e.g., Li *et al.*, 2013a). In addition, photometric correction makes it possible to compare asteroid observations with laboratory measurements, which are usually made at a standard geometry. The general procedure of photometric correction is to fit a photometric model,  $r_{\text{model}}(i, e, \alpha)$ , to the observations,  $r(i, e, \alpha)$ , then follow equation (1) below to calculate the corrected reflectance under a reference geometry  $r(i_0, e_0, \alpha_0)$

$$r(i_0, e_0, \alpha_0) = \frac{r(i_{\text{measure}}, e_{\text{measure}}, \alpha_{\text{measure}})}{r_{\text{model}}(i_{\text{measure}}, e_{\text{measure}}, \alpha_{\text{measure}})} \times r_{\text{model}}(i_0, e_0, \alpha_0) \quad (1)$$

where  $(i_{\text{measure}}, e_{\text{measure}}, \alpha_{\text{measure}})$  is the scattering geometry of measured reflectance. The most commonly used reference

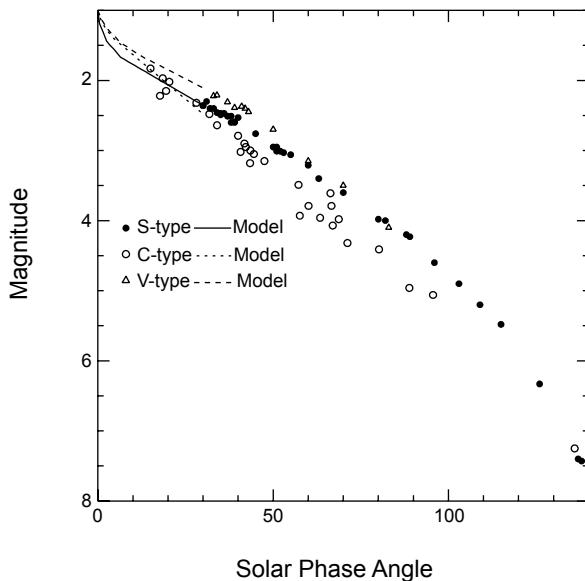

geometries for correction are  $(i_0, e_0, \alpha_0) = (0^\circ, 0^\circ, 0^\circ)$ , which corresponds to the normal reflectance, and  $(i_0, e_0, \alpha_0) = (30^\circ, 0^\circ, 30^\circ)$ , which is a common laboratory setting.

The third application of photometry (that we consider) is to predict the reflectance of an asteroidal surface at arbitrary illumination and viewing geometries for designing and planning observations, especially for asteroid spacecraft exploration missions. Spacecraft generally observe target asteroids at substantially different viewing geometries from groundbased observers. It is therefore necessary to extrapolate or interpolate the photometric measurements from the ground to calculate the nominal brightness of a target for planning purposes. For spatially resolved images, it is necessary to know the dependence of reflectance on local scattering geometry. This practical application is important for essentially all spacecraft missions with imaging or spectroscopy components.

## 1.2. Scope of This Chapter

Except for several of the largest asteroids, most asteroids appear to be point sources when observed from the ground, and the dependence of reflectance on local scattering geometry is unavailable. Therefore, up until the first asteroid flyby of (951) Gaspra by the Galileo spacecraft *en route* to the Jupiter system in 1991 (Belton *et al.*, 1992), asteroid photometry focused only on studying the dependence of total brightness of an object on solar phase angle, the so-called phase function (Fig. 2). In order to retrieve physical properties of the surface from photometric phase functions, empirical and experimental models have been developed (cf. Muinonen *et al.*, 2002, and references therein). For example, it has long been recognized that the brightness of dark objects generally decreases with phase angle faster than bright objects, resulting in relatively steeper slopes of their phase functions, a phenomenon attributed to relatively stronger multiple scattering in brighter objects (cf. Bowell and Lumme, 1979, and references therein). In addition, higher surface roughness also contributes to the steeper slope of a phase function (e.g., Veverka, 1971), although it is not possible to entirely disentangle the effects of multiple scattering and surface roughness from a disk-integrated phase function.

The most significant development in observational studies of the photometric properties of asteroids over the past decade has come from the availability of high-resolution, spatially resolved images of the surfaces of many more asteroids from flyby and rendezvous missions with asteroids (e.g., Li *et al.*, 2006, 2013a; Kitazato *et al.*, 2008; Spjuth *et al.*, 2012; Magrin *et al.*, 2012; Schröder *et al.*, 2013). From these data, we can observe how the reflectance of an asteroidal surface depends on local scattering geometries. This additional information is more powerful for retrieving the physical properties of a surface than the disk-integrated solar phase function only. The most notable advantage is to resolve the ambiguity between fitting the surface roughness and the phase function, because the effect of roughness is especially important at phase angles  $>40^\circ$  (Helfenstein, 1988).

**Fig. 2.** The phase functions of three asteroid classes, all normalized at zero degree phase angle. The lines at phase angles less than  $\sim 30^\circ$  are the respective best-fit models using the data from Helfenstein and Veverka (1989) for S and C types (*Asteroids II* book), and a composite Vesta curve from Hicks et al. (2014) for V types. Data from Mathilde (Clark et al., 1999) and Bennu (B-type) (Takir et al., 2015) are used for additional C types beyond  $30^\circ$  phase angle. Data for Gaspra (Helfenstein et al., 1994), Lutetia (Masoumzadeh et al., 2014), and Eros (Li et al., 2004) are used for S types beyond  $30^\circ$  phase angle.

In this chapter, we will focus on disk-resolved photometric studies of asteroids based on photometric theories and high-resolution data returned by asteroid exploration missions. Photometric modeling based primarily on ground-based photometric surveys have been thoroughly reviewed in previous *Asteroids* books in this series (Bowell and Lumme, 1979; Bowell et al., 1989; Helfenstein and Veverka, 1989; Muinonen et al., 2002). It is important to keep in mind that physical laws dictate that the photometric signatures from planetary surfaces necessarily correlate with polarimetric signatures. In this chapter we strictly limit the scope of our discussion to asteroid photometry, and readers are referred to a companion chapter in this volume by Belskaya et al. for a comprehensive review on asteroid polarimetry. In section 2, we will review the basic concepts of photometric measurements and models, the most recent developments in theoretical models, and the controversy about several analytical models. In section 3, we will summarize observational results reported over the past decade, focusing on disk-resolved photometry based on spacecraft observations. We will then discuss applications and implications of photometric modeling to the study of general asteroid properties in section 4. In section 5, we provide a summary and a perspective on the future of asteroid photometry for the next decade to come.

## 2. OVERVIEW OF THEORIES

### 2.1. Basic Concepts

The fundamental quantity of light-scattering characteristics of a surface is reflectance. Several different quantities of reflectance and albedo exist under various illumination and observing conditions. Here we follow the definitions and conventions described in Hapke (2012b). Generally, reflectance is defined by the ratio of scattered radiance (or intensity) to incident irradiance (or flux), while albedo is defined with respect to an ideal surface that scatters all incident light isotropically (or a perfectly scattering Lambert surface). Reflectance quantities use two adjectives as prefixes to specify the collimation of incident light and the measurement conditions for scattered light, such as *directional-directional* reflectance, *directional-hemispherical* reflectance, etc. In the case where the two adjectives are the same, a prefix *bi-* is used, e.g., *bidirectional* reflectance. The most commonly used quantities in light-scattering theories and measurements are listed in Table 1. Here we describe a few of the most important quantities.

*Bidirectional reflectance*,  $r$ , is an idealized quantity, because the incident irradiance,  $J$ , is assumed to be strictly collimated (Fig. 1). For observations of most asteroids, the apparent angular size of the Sun is  $<0.5^\circ$  (at  $>1$  AU from the Sun), so the collimation assumption for incident irradiance is a good approximation except for at near-zero phase angle, where the finite size of the Sun rounds off the peak. The measurements of scattered intensity are made at the pixel scale of the camera or spectrometer, which is typically less than a few tens of milliradians per pixel.  $J$  has a unit of [ $\text{W m}^{-2}$ ] or [ $\text{W m}^{-2}$  per unit wavelength or per unit frequency]. The scattered radiance,  $I$ , has a unit of [ $\text{W m}^{-2} \text{ sr}^{-1}$ ] or [ $\text{W m}^{-2} \text{ sr}^{-1}$  per unit wavelength or unit frequency]. Therefore, bidirectional reflectance has a unit of [ $\text{sr}^{-1}$ ].

*Radiance factor* (or RADF),  $R$ , and *reflectance factor* (or REFF) are often used in laboratory measurement by ratioing the reflected light from the sample to that from a reference surface, which is usually close to a Lambert disk. A Lambert surface has a bidirectional reflectance  $r_L(0,e,e) = 1/\pi$  in any direction, with a unit of [ $\text{sr}^{-1}$ ]. Therefore, both RADF and REFF are dimensionless. Note that non-isotropic scattering, especially a phenomenon known as the “opposition effect” near zero phase (a nonlinear increase of reflectance as phase angle approaches  $0^\circ$ ; see section 2.3), can make a surface brighter than a perfectly scattering Lambert surface, producing RADFs greater than unity.

RADF is equivalent to the commonly used but often confusing notation  $I/F$ , which is usually annotated in the literature as “ $I$  is the scattered radiance, and  $\pi F$  is the incident solar irradiance.” Note, however, that the  $\pi$  here originates from the division of the bidirectional reflectance quantity of a perfectly scattering Lambert surface, which is  $1/\pi$  with a unit of [ $\text{sr}^{-1}$ ]. As such, the  $\pi$  actually has a unit of [sr]. Therefore,  $F$  has a unit of radiance rather than irradiance, making  $I/F$  dimensionless.

TABLE 1. The definitions of some commonly used reflectance quantities.

Quantity	Definition	Formula	Ref.*
Bidirectional reflectance	Ratio of the scattered radiance toward $(i, e, \alpha)$ to the collimated incident irradiance	$r(i,e,\alpha) = I(i,e,\alpha)/J [\text{ster}^{-1}]$	p. 195
Bidirectional reflectance distribution function (BRDF)	Ratio of the scattered radiance toward $(i, e, \alpha)$ to the collimated power incident on a unit area of the surface	$\text{BRDF} = I(i,e,\alpha)/J\mu_0 = r/\mu_0 [\text{ster}^{-1}]$	p. 263
Radiance factor (RADF)	Ratio of the bidirectional reflectance of a surface to that of a perfectly scattering surface <sup>†</sup> illuminated at normal direction	$\text{RADF} = \pi r(i,e,\alpha) = [I/F]$	p. 264
Reflectance factor (or reflectance coefficient, REFF)	Ratio of the reflectance of a surface to that of a perfectly diffused surface under the same conditions of illumination and viewing	$\text{REFF} = \pi r/\mu_0 = [I/F]/\mu_0$	p. 263
Lambertian albedo	Ratio of the total scattered irradiance toward all directions from a Lambert surface to incident power per unit area	$A_L = P_L/J\mu_0$ Perfectly scattering surface has $A_L = 1$	p. 187
Normal albedo	Ratio of the reflectance of a surface observed at zero phase angle from an arbitrary direction to that of a perfectly diffuse surface located at the same position, but illuminated and observed perpendicularly	$A_n = \pi r(e,e,0)$	p. 296
Geometric albedo (physical albedo)	Ratio of the integral brightness of a body at zero phase angle to the brightness of a perfect Lambert disk of the same size and at the same distance, but illuminated and observed perpendicularly. It is the weighted average of the normal albedo over the illuminated area of the body	$A_p = \int_{2\pi} r(e,e,0)\mu d\Omega^{\ddagger}$	p. 298
Bond albedo (spherical albedo, or global albedo)	Total fraction of incident irradiance scattered by a body into all directions	$A_s = \frac{1}{\pi} \int_{2\pi} \int_{2\pi} r(i,e,\alpha)\mu d\Omega_e d\Omega_i$	p. 301
Bolometric albedo (radiometric albedo)	Average of the spectral albedo $A_s(\lambda)$ weighted by the spectral irradiance of the Sun $J_s(\lambda)$	$A_b = \frac{\int_0^\infty A_s(\lambda) J_s(\lambda) d\lambda}{\int_0^\infty J_s(\lambda) d\lambda}$	p. 302
Phase integral		$q = 2 \int_0^\pi \Phi_p(\alpha) \sin \alpha d\alpha$	p. 302

<sup>\*</sup> Page numbers in Hapke (2012b).<sup>†</sup> Perfectly scattering Lambert surface has  $r = \frac{1}{\pi}\mu_0$ .<sup>‡</sup>  $d\Omega = 2\pi \sin e de = -2\pi d\mu$ .

Other important concepts include geometric albedo (or physical albedo) and Bond albedo (or spherical albedo). Similar to RADF, *geometric albedo*,  $A_p$ , is defined with respect to a perfectly scattering Lambert surface. The use of geometric albedo simplifies the modeling of the disk-integrated brightness of an object at any phase angle, which can now be expressed as the product of  $A_p$  and its disk-integrated phase function,  $\Phi(\alpha)$ , normalized to unity at zero phase angle. Note that, similar to RADF, for extremely bright and strongly backscattering objects, the geometric albedo can approach or exceed unity. For example, the geometric albedo of Enceladus is 1.38, Tethys 1.23, and Dione 1.00 (Verbiscer *et al.*, 2007).

*Bond albedo*,  $A_B$  (also known as the spherical Bond albedo), is a key quantity to measure the ability of an object to absorb incident energy, therefore critical for understanding energy balance and volatile transport on a planetary body. By definition, Bond albedo cannot exceed unity. Since Bond albedo is an integrated quantity of the disk-averaged reflectance, it can be expressed as

$$A_B = A_p q \quad (2)$$

where  $q$  is the phase integral, defined as

$$q = 2 \int_0^\pi \Phi(\alpha) \sin \alpha d\alpha \quad (3)$$

Important for thermal modeling is the bolometric Bond albedo, which is the average Bond albedo over wavelength, weighted by the solar spectrum,  $F_{\odot}(\lambda)$

$$A_B = \frac{\int_0^{\infty} A_B(\lambda) F_{\odot}(\lambda) d\lambda}{\int_0^{\infty} F_{\odot}(\lambda) d\lambda} \quad (4)$$

Because the solar spectrum peaks at about 500 nm with about half of the total flux in the visible wavelengths, the V-band Bond albedo is often taken as an approximation to the bolometric Bond albedo for asteroids.

## 2.2. Empirical Models

Sophisticated modern photometric models need to describe two types of photometric data: “whole-disk” or “disk-integrated” observations and “disk-resolved” or “surface-resolved” reflectance measurements when they are available; the latter most often obtained from spacecraft-borne instruments. Disk-resolved photometric measurements provided a new ability to detect the photometric effects of physical phenomena like macroscopic surface texture much more reliably and unambiguously than could be achieved with whole-disk data.

Surface-resolved photometric models that are applied to asteroid observations seek to relate the local scene viewing and illumination geometry to the radiance factor, RADF, or, more simply, R. In the simplified treatment of the empirical equations to model R, such as that of *Lambert* (1759) and *Minnaert* (1941), the dependence of reflectance on i and e, usually called the *disk-function* or *limb-darkening function*,  $d(i, e)$ , is often separated from the dependence on phase angle, called the *surface phase function*,  $f(\alpha)$ . The RADF of a surface is expressed as

$$R = d(i, e) f(\alpha) \quad (5)$$

Sometimes a scaling factor is added to equation (5), so that the surface phase function can be normalized, e.g., to unity at zero phase angle. Generally, the disk-function is affected by the amount of multiple scattering (therefore albedo) and surface roughness. The phase function includes the effects of single-scattering phase function, opposition surge (see section 2.3), roughness, and multiple scattering. Historically, this separation is a result of the lack of surface-resolved data before spacecraft missions, where the only available geometric variable was phase angle. Modern photometric theories indicate that when multiple scattering is not significant (i.e., for relatively dark surfaces), the disk-function and phase function can be separated in functional forms.

The most commonly used empirical photometric models are listed in Table 2. Most empirical photometric models specify the disk-function, including the Lambert model (*Lambert*, 1759), the Lommel-Seeliger (LS) model (*Seeliger*, 1887), the Minnaert model (*Minnaert*, 1941), and the lunar-Lambert model (e.g., *Buratti* and *Vercka*, 1983; *McEwen*, 1991, 1996), while leaving the phase function implicit or

unspecified. These models can describe surfaces with a wide range of different albedos. Generally, high-reflectance objects with geometric albedo close to or greater than unity are well described by the Lambert model, although essentially no asteroids scatter light following the Lambert law because the majority have albedos <0.5 (*Masiero et al.*, 2011). On the other hand, low-reflectance objects with geometric albedo <0.2 generally follow an LS scattering law. All primitive asteroids (C-, D-, P-types) and most S-type asteroids are in this category. For the highest-albedo S-type asteroids and high-albedo asteroid classes such as V- and E-types, the hybrid lunar-Lambert model is a good disk-function. The higher the albedo, the greater the partition to the Lambertian term. The Minnaert model can also describe surfaces with a wide range of albedos. The two Minnaert parameters  $A_M$  and k depend on phase angle. For a dark surface where multiple scattering is negligible, k = 0.5; for a Lambert scattering law, k = 1; and in general the higher the albedo of the surface, the higher the value of k (*McEwen*, 1991). *Buratti* (1984) showed that k = 0.5 applied to normal reflectances  $\leq 0.6$ , which include most asteroids.

The surface phase function is often expressed in various empirical forms in the literature (Table 3), including the combination of an exponential term and a polynomial term (*Hillier et al.*, 1999; *Buratti et al.*, 2011), or a linear-exponential function (*Piironen*, 1994; *Kaasalainen et al.*, 2001, 2003; *Muinonen et al.*, 2009), or a linear function in magnitude scale ( $-2.5\log(r)$ ) (*Li et al.*, 2009, 2013b), or exponentials and a polynomial in a magnitude scale (*Takir et al.*, 2015).

Disk-integrated photometric models, as the name implies, compute the whole-disk brightness of an asteroid at a given apparition by integrating the predicted surface-resolved radiance factors over the fraction of the surface that is both illuminated and visible to the observer. A *disk-integrated phase function*,  $\Phi(\alpha)$ , can be calculated as

$$\Phi(\alpha) = \frac{f(\alpha)}{\pi} \int_{\Omega(i,v)} d(i, e) \mu d\Omega \quad (6)$$

$\Phi(\alpha)$  is generally normalized to unity at zero phase angle (note that equation (6) is not normalized), and constrained by observational data spanning a range of phase angles. The disk-integrated phase function is therefore different from the surface phase function by including the integral term in equation (6) that also depends on phase angle. For simplicity and in the absence of information about the actual shape of an asteroid, the whole-disk brightness is often analytically evaluated for a sphere that has the same equivalent dimensions assumed for the asteroid. The disk-integrated phase functions calculated based on the commonly used photometric models are listed in Table 4.

Another form of empirical disk-integrated photometric model simply parameterizes the total brightness of an object measured at a range of phase angles, such as the International Astronomical Union (IAU) H-G model (next section). In addition, the three-parameter model of *Shevchenko* (1996)

TABLE 2. Commonly used empirical photometric models.

Model	RADF*	Normal Albedo ( $A_n$ )	Geometric Albedo ( $A_p$ )	Reference
Lambert	$A_L \mu_0 f(\alpha)$	$A_L f(0)$	$\frac{2}{3} A_L f(0)$	
Lommel-Seeliger	$A_{LS} \frac{\mu_0}{\mu_0 + \mu} f(\alpha)$	$\frac{1}{2} A_{LS} f(0)$	$\frac{1}{2} A_{LS} f(0)$	
Lunar-Lambert	$A_{LL} \left[ L(\alpha) \frac{2\mu_0}{\mu_0 + \mu} + (1 - L(\alpha)) \mu_0 \right] f(\alpha)^{\dagger}$ $L(\alpha) = 1 + A_1 \alpha + A_2 \alpha^2 + A_3 \alpha^3$	$A_{LL} f(0)$	$A_{LL} f(0)$	<i>McEwen</i> (1991, 1996)
Minnaert	$A_M \mu_0^{k(\alpha)} \mu^{k(\alpha)-1} f(\alpha)^{\ddagger}$ $k(\alpha) = k_0 + b\alpha$	$A_M \mu_0^{2k_0-1} f(0)$	$\frac{2}{2k+1} A_M f(0)$	<i>Minnaert</i> (1941), <i>Li et al.</i> (2009, 2013b)
Akimov	$A_n \cos \frac{\alpha}{2} \cos \left( \frac{\pi}{\pi - \alpha} \left( \Lambda - \frac{\alpha}{2} \right) \right) \frac{\cos^{\frac{\alpha}{\pi-\alpha}} \beta}{\cos \Lambda} f(\alpha)$	$A_n f(0)$	$A_n f(0)$	<i>Shkuratov et al.</i> (2011)

\*  $f(\alpha)$  is a surface phase function, generally normalized to unity at zero phase angle.  $A$  with various subscripts are constants that are directly proportional to the normal albedo and geometric albedo of the surface. Therefore, the RADF can also be expressed in terms of normal albedo or geometric albedo.

†  $L(\alpha)$  is a partition parameter between the LS term and the Lambert term. It usually depends on phase angle.

‡ This is an empirical model of  $k(\alpha)$  as adopted by *Li et al.* (2009, 2013a). *Masoumzadeh et al.* (2014) show, from their work on asteroid Lutetia using Rosetta flyby data, that the phase angle dependence of  $k$  might be better described with a second-order polynomial.

has recently been used to describe the opposition effect of (4) Vesta (*Hasegawa et al.*, 2014). This model, like the IAU H-G one, is expressed in terms of reduced magnitude

$$M(\alpha) = M(0^\circ) + \frac{a\alpha}{1+\alpha} + b\alpha \quad (7)$$

where the model parameters are  $M(0^\circ)$ , the reduced magnitude at zero phase;  $a$  characterizes the opposition effect, and  $b_\lambda$  describes the slope of the linear part of the phase curve, analogous to the phase coefficient.

### 2.3. Physically Motivated Models

Physically motivated models (e.g., *Hapke*, 1963, 1981, 1984, 1986, 2002, 2008, 2012a; *Goguen*, 1981; *Lumme and Bowell*, 1981a, 1985; *Shkuratov et al.*, 1999) approximate the solution for radiative transfer from a rough, particulate surface. A typical modern analytical photometric model can be best considered as an assemblage of mathematical components, each of which describes a functional dependence of directional light scattering on a different parameterized quasiphysical property, or a group of related properties that act in concert. The main functional components of typical models rely on (1) a component to describe albedo and directional singly scattered light by an average regolith grain,

(2) a component to describe how wave fronts are multiply scattered among and from an aggregate volume of average grains, (3) a parameterized component to describe the effects of macroscopic surface texture on reflected light, and (4) component functions to describe the opposition effect — a conspicuous nonlinear surge in brightness with decreasing phase angle that is observed at small phase angles on particulate-covered bodies. So complex are the interactions between these components that even the best available analytical models are still in development. They have continued to evolve over a span of at least three decades as laboratory testing and refinement of theory identify new deficiencies and new corrections, respectively.

Among the analytical models used for asteroid work, the *Hapke* (1981, 1984, 1986, 2002, 2008, 2012a) model, the *Shkuratov* (1999) model, and the *Lumme-Bowell* model (*Lumme and Bowell*, 1981a,b; *Bowell et al.*, 1989) have seen the widest application to both photometric and spectroscopic data. The *Lumme-Bowell* (*Lumme and Bowell*, 1981a,b) model is described in detail and discussed in the *Asteroids II* volume in this series (*Bowell et al.*, 1989) and later discussion was given in *Asteroids III* (*Muinonen et al.*, 2002). In all cases, there are both a surface-resolved expression and a disk-integrated expression in the model. In the case of the *Hapke* model, there are many variants. So in practice, whole-disk modeling is done by numerical integration over an assumed spherical or triaxial-shape, or

a three-dimensional shape model, any of which is oriented at the appropriate geometry to match the observation. We discuss below recent advances in these models.

**2.3.1. Hapke models.** The Hapke (1981, 1984, 1986) model was discussed in detail in the *Asteroids II* volume (Bowell et al., 1989; Helfenstein and Veverka, 1989). Since then, the model has continued to evolve through experimental variants (cf. Helfenstein et al., 1997), diverse choices in the particle phase functions used in the model, and numerous improvements introduced by Hapke (2002, 2008, 2012a) and others. Hapke (2002) improved his treatment of multiple scattering by grains with anisotropic phase functions and added

the coherent backscattering as a mechanism to account for a narrow (less than a few degrees) opposition spike that acts in addition to the shadow hiding mechanism. By far, the most significant improvement is in Hapke (2008), which identifies and corrects a serious error in how the effects of porosity and compaction are treated in nearly all similar models.

Although Hapke provides analytical expressions for the whole-disk behavior (cf. Hapke, 2012b), because of the many variants of the model in use, whole-disk phase curves predicted by the Hapke model are often obtained by numerical integration of RADF over the illuminated portion of the planetary disk or asteroid shape model.

The current form of Hapke's radiance factor equation can be expressed as

$$R(\mu_0, \mu, \alpha) = K \frac{\bar{\omega}_0}{4} \frac{\mu'_0}{\mu'_0 + \mu'} \left[ (1 + B_{SH}(\alpha)) P(\alpha) + M\left(\frac{\mu'_0}{K}, \frac{\mu'}{K}, \alpha\right) \right] (8)$$

$$(1 + B_{CB}(\alpha)) S(\mu_0, \mu, \alpha)$$

where  $\mu'_0$  and  $\mu'$  are the cosines, respectively, of the *effective* angles of incidence and emission angles after adjustment for the average slope angle of macroscopic scale topographic roughness (Hapke, 1984),  $\alpha$  is the phase angle, and  $\bar{\omega}_0$  is the average particle single-scattering albedo. The function,  $S(\mu'_0, \mu', \alpha)$  describes the shadowing and occlusion effects of macroscopic roughness,  $P(\alpha)$  is the average particle single-scattering phase function (also known as the single particle phase function, SPPF),  $(1 + B_{SH}(\alpha))$  describes the shadow-hiding opposition effect (Hapke, 1986),  $M(\mu'_0, \mu', \alpha)$  describes multiply scattered light between particles (Hapke, 2002), and  $1 + B_{CB}(\alpha)$  models the coherent backscatter opposition effect (Hapke, 2002). The porosity coefficient,  $K$ , was introduced in Hapke (2008) as an explicit adjustable parameter to more realistically model how the areal fraction of light that is blocked by grains within a quasicontinuous particulate medium increases as the particle arrangement converges to a closely packed state.

**2.3.1.1. Single scattering by average regolith grains:** Light that is scattered once by an average regolith grain is generally described by the product  $\bar{\omega}_0 P(\alpha)$  where  $\bar{\omega}_0$  is the average particle single-scattering albedo and  $P(\alpha)$  is known as the average particle single-scattering phase function. The latter describes the directional scattering behavior of average regolith grains. Since the first models of Hapke (1963, 1966), a wide variety of particle phase function expressions have been introduced to the Hapke equations (Table 5), many of which are still in use.

Currently, the most often used representation is that from McGuire and Hapke (1995). Hapke (2012a) recently introduced a simplification of the 2PHG, and found from laboratory studies that the  $b$  and  $c$  parameters could be defined in terms of one another using an empirical "hockey-stick relation" (Hapke, 2012a) so named because of the shape defined in  $b$  vs.  $c$  plots of model fits to laboratory data. The hockey-stick diagram (i.e., plot of the  $c$  vs.  $b$ ) is particularly useful for interpreting the physical structure of regolith particles from their particle phase functions with respect to the complexity of the particle shape and the density of internal scatterers (cf. McGuire and Hapke, 1995; Souchon et al., 2011).

**2.3.1.2. Opposition Surge: Shadow Hiding Opposition Effect (SHOE):** The treatment of Hapke (1986) is most widely in current use. This model uses two adjustable parameters, here called  $h_{SH}$  and  $B_{0,SH}$ , to describe the angular width and amplitude of the SHOE, respectively. It takes

into account how non-uniform states of compaction with depth can influence the angular width of SHOE and how the transparency of regolith grains affects the strength of SHOE. The angular half-width of the SHOE is  $\Delta\alpha_{SH} \approx 2 h_{SH}$  (in radians). While the Hapke model can describe SHOE for many different gradients in compaction state and particle size-distributions, most workers assume a uniform distribution of particles and compaction. In this case  $h_{SH}$  can be easily related to the regolith porosity,  $p$ , in terms of the packing factor  $\phi = (1-p)$ . Then,  $h_{SH} = -0.375 \ln(1-\phi)$ .

However, in a related paper, Hapke (2008) identified a fundamental error in the way that his own and almost all other radiative transfer approximations for regolith surfaces. Nearly all these models fail to account for the increase in reflectance seen in laboratory experiments when particulate surfaces are compacted from a more fluffy state. Hapke (2008) corrects for this effect of porosity at the expense of adding an explicit model parameter called the porosity coefficient,  $K$ , where

$$K = -\frac{\ln(1 - 1.209\phi^{2/3})}{1.209\phi^{2/3}} \quad (9)$$

A less rigorous version of  $K$  figured in earlier versions of Hapke's model where it is called the porosity factor. The porosity factor figures in Hapke's (1986) derivation of the SHOE function, which strongly depends on porosity. Helfenstein and Shepard (2011) introduced a correction to the Hapke (1986) SHOE model to make it consistent with Hapke (2008). However, it is important to note that the Hapke (2008) correction is strictly valid only for porosities in the range  $0.248 < p < 1.0$ .

**2.3.1.3. Opposition Surge: Coherent-Backscatter Opposition Effect (CBOE):** Coherent-backscatter is now known to cause the prominent, very narrow phase-curve spike that is observed most often within a few degrees of opposition (Muinonen et al., 2012). How the mechanism operates in the complex architecture of planet, satellite, and asteroid regoliths is still not fully understood (cf. Hapke et al., 2012). [Muinonen et al. (2012) have recently derived a coherent-backscatter model on the basis of a rigorous solution of Maxwell's equation (see section 2.3.3).] In his most recent treatment (Hapke, 2012a), the approximation is updated to include the dependence on the porosity factor

$$B_{CB}(\alpha) = \frac{B_{0,CB}}{1 + 1.42K} \left[ \frac{1 + \frac{1 - e^{-(1.42K/h_{CB})\tan(\alpha/2)}}{(1/h_{CB})\tan(\alpha/2)}}{\left[ 1 + (1/h_{CB})\tan(\alpha/2) \right]^2} \right] \quad (10)$$

where  $B_{0,CB}$  is the amplitude of the CBOE,  $h_{CB} = \lambda/4\pi L_T$ ,  $\lambda$  is wavelength, and  $L_T$  is the photon transport mean free path length in the medium. The angular half-width of the CBOE in radians is  $\Delta\alpha_{CB} = 0.36\lambda/2\pi L_T$ . While it is explicitly proportional to the spectral wavelength, it is important to note that

TABLE 5. Particle single-scattering phase functions.

Name	Expression	Parameters	Reference
Modified Schoenberg	$P(\alpha) = \left[ \sin \alpha  + (\pi \alpha ) \cos( \alpha ) / \pi + 0.1(1 - \cos( \alpha ))^2 \right]$		Hapke (1963, 1966)
Two-Parameter Legendre Polynomial (2PLP)	$P(\alpha) = 1 + b \cos(\alpha) + c \left( \frac{3}{2} \cos^2(\alpha) - \frac{1}{2} \right)$	b,c	Hapke (1981)
One-Parameter Henyey-Greenstein (1PHG)	$P(\alpha) = (1 - g^2) / (1 + 2g \cos(\alpha) + g^2)^{3/2}$	g	Buratti and Veranka (1983)
Two-Parameter Henyey-Greenstein (2PHG, form #1)	$P(\alpha) = \frac{(1+c)}{2} \frac{(1-b^2)}{(1-2b \cos(\alpha) + b^2)^{3/2}} + \frac{(1-c)}{2} \frac{(1-b^2)}{(1+2b \cos(\alpha) + b^2)^{3/2}}$	b,c	McGuire and Hapke (1995)
Two-Parameter Henyey-Greenstein (2PHG, form #2)	$P(\alpha) = (1-c) \frac{(1-b^2)}{(1+2b \cos(\alpha) + b^2)^{3/2}} + c \frac{(1-b^2)}{(1-2b \cos(\alpha) + b^2)^{3/2}}$	b,c	Hartman and Domingue (1998)
Three-Parameter Henyey-Greenstein (3PHG, form #1)	$P(\alpha) = (1-f) \frac{(1-g_1^2)}{(1+2g_1 \cos(\alpha) + g_1^2)^{3/2}} + (f) \frac{(1-g_2^2)}{(1+2g_2 \cos(\alpha) + g_2^2)^{3/2}}$	g <sub>1</sub> ,g <sub>2</sub> ,f	Helfenstein et al. (1991)
Three-Parameter Henyey-Greenstein (3PHG, form #2)	$P(\alpha) = (f) \frac{(1-g_1^2)}{(1+2g_1 \cos(\alpha) + g_1^2)^{3/2}} + (1-f) \frac{(1-g_2^2)}{(1-2g_2 \cos(\alpha) + g_2^2)^{3/2}}$	g <sub>1</sub> ,g <sub>2</sub> ,f	Deau and Helfenstein (2015)
Lumme-Bowell	$P(\alpha) = 0.95e^{-0.4\alpha} + 16.15e^{-4.0\alpha}$		Lumme and Bowell (1981b)

the transport mean free path length in the medium is often strongly wavelength-dependent. Hence, the angular width of the CBOE in a complex regolith can be difficult to predict.

**2.3.1.4. Multiple-scattering of light:** Hapke's (1981, 1984, 1986) model approximated multiple scattering with an analytical simplification of Chandrasekhar's (1960) H-functions for isotropically scattering grains (known as the isotropic multiple scattering approximation, or IMSA). This approximation has long been assumed to be adequate for relatively low- to moderate-albedo bodies where the contribution of multiply scattered light was small compared with the emitted singly scattered signal. For relatively high-albedo objects where multiple-scattering contributes significantly, some workers replace the approximation with the exact numerical calculation for isotropic scatterers (cf. Verbiscer, 1991) and first-order anisotropic scatterers (cf. Verbiscer and Veranka, 1992, 1994). To account for the possible strongly anisotropic scatterers, Hapke (2002) ultimately introduced an expansive treatment of multiple scattering (anisotropic multiple scattering approximation, or AMSA) that can be applied to strongly anisotropic grains.

**2.3.2. Shkuratov model.** The Shkuratov model (Shkuratov et al., 1999) is also physically motivated and describes a macroscopically fractal-like surface, and it includes a

description of both SHOE and CBOE. Unlike the Hapke and Lumme-Bowell models, in which the single-scattering and multiple-scattering contributions can be separated, the Shkuratov model is the product of three component functions and a normal reflectance coefficient  $A_n$ . In terms of the radiance factor

$$R(\mu_0, \mu, \alpha) = A_n f_{\text{SHOE}}(\alpha) f_{\text{CBOE}}(\alpha) d(\Lambda, \beta, \alpha) \quad (11)$$

where the  $f_{\text{SHOE}}$  describes the shadow-hiding opposition effect,  $f_{\text{CBOE}}$  the coherent-backscatter opposition effect, and  $d(\Lambda, \beta, \alpha)$  is the Akimov disk-distribution function that describes how the brightness of the surface at any given phase angle varies with photometric longitude,  $\Lambda$ , and photometric latitude,  $\beta$ . The Shkuratov model has four adjustable parameters. The coefficient  $A_n$  is the normal albedo. The function  $f_{\text{SHOE}} = \exp(-\kappa\alpha)$ , where  $\kappa$  is a parameter that decreases with increasing albedo to model the attenuation of projected shadows by multiple-scattering. The  $f_{\text{CBOE}}$  function has two parameters:  $\Delta_E$ , the extinction mean free path of a photon; and  $d$ , a size-scale parameter that defines the separation distance of scatterers that contribute to coherent backscatter interactions. The Akimov disk-distribution of brightness has no model parameters (Table 2).

**2.3.3. Muinonen radiative transfer-coherent backscatter model.** Many of the recent efforts to improve physically motivated photometric models have focused on incorporating a description of the coherent backscatter opposition effect. In the analytical models above, the treatment of coherent backscatter is made tractable through the use of physically reasonable simplifying assumptions and mathematical approximations — none represent exact solutions of Maxwell's equations. At present, numerical methods provide the most rigorous approach to test and model how coherent backscatter operates in the context of planetary regoliths.

A breakthrough was achieved by *Muinonen et al.* (2012), who developed a Monte Carlo integration approach that combines radiative transfer and coherent backscatter (RT + CB) from an assumed spherical assemblage of randomly distributed spherical scatterers of known size, packing, and optical constants. A particularly important aspect of this approach is that it can be independently verified by direct computer solution of Maxwell's equations (*Mackowski and Mishchenko*, 1996, 2011). While earlier works demonstrated the behavior of coherent backscatter among widely dispersed scatterers, the recent work of *Muinonen et al.* (2012) has definitively verified how the mechanism operates within loosely packed aggregates of scatterers. Their Monte Carlo simulation accurately predicts not only the contribution of coherent backscatter to the photometric opposition effect, but also accurately models the polarization behavior at small phase angles (known as the polarization opposition effect) and the circular polarization. While most tests were done assuming uniformly sized scatterers, in a preliminary experiment in which a size-distribution of scatterers was used, the results qualitatively matched the opposition behavior seen in high-albedo planetary objects, such as bright icy satellites.

The studies in *Muinonen et al.* (2012) were limited to sparsely packed arrangements of scatterers (packing factors only as large as 6.25%). To be more directly applicable to regolith-covered bodies, more work will be needed to determine the method's applicability to densely packed arrangements of scatterers.

Further numerical modeling techniques were developed by *Muinonen et al.* (2011) and *Wilkman et al.* (2014a) with the lunar mare data acquired by the Advanced Moon micro-Imager Experiment (AMIE) on the European Space Agency's Small Missions for Advanced Research in Technology-1 (SMART-1) mission. They employed a numerical approach to solve for the shadowing function resulted from the surface roughness using ray-tracking technique with the LS sphere as the auxiliary tool. Combining the numerical shadowing function solution and the RT-CB model with the classic 2PHG function and LS phase function as the volume phase function, *Wilkman et al.* (2014a) achieved good fit to the lunar mare data using Bayesian techniques and Markov chain Monte Carlo. *Wilkman et al.* (2014b) provided a numerical representation of the shadowing function for close-packed spherical volume of LS particles to facilitate the photometric modeling of low-albedo surfaces.

**2.3.4. IAU magnitude phase curve system.** The Lumme-Bowell model (*Lumme and Bowell*, 1981b) is of special

importance to asteroid studies because it was the original basis of the official IAU magnitude system for classifying and modeling the albedos and photometric behavior of whole-disk phase curves. Details of the Lumme-Bowell model and its adaptation to the H-G system are given in the *Asteroids II* volume (*Bowell et al.*, 1989). This long-used model was derived prior to the recognition of a narrow “opposition spike” that is caused by coherent backscatter and typically observed on airless bodies at phase angles less than a couple of degrees. *Muinonen et al.* (2010) developed a three-parameter model, called the H-G<sub>1</sub>-G<sub>2</sub> model, that is similar to the H-G model above but that significantly improves fits to asteroid phase curves that have a detectable opposition spike. In this model, that now officially replaces the previous IAU system, the reduced magnitude of an asteroid, V(α), is expressed as

$$V(\alpha) = H - 2.5 \log_{10} \left[ G_1 \Phi_1(\alpha) + G_2 \Phi_2(\alpha) + (1 - G_1 - G_2) \Phi_3(\alpha) \right] \quad (12)$$

where two numerically optimized, cubic-spline basis functions,  $\Phi_1(\alpha)$  and  $\Phi_2(\alpha)$  replace the basis functions of the H-G model, and a third basis function,  $\Phi_3(\alpha)$ , is introduced to describe the opposition effect. These basis functions are numerically defined by their values at their phase angle grids and the first derivatives at the two ends, as given in Tables 3 and 4 of *Muinonen et al.* (2010). The definition of H remains the same as in the H-G model. A few characteristic parameters of a phase function can now be expressed in terms of G<sub>1</sub> and G<sub>2</sub>, including the phase integral, q = 0.009082 + 0.4061G<sub>1</sub> + 0.8092G<sub>2</sub>, the photometric phase coefficient, k =  $\frac{1}{5\pi} \frac{30G_1 + 9G_2}{G_1 + G_2}$ , and the amplitude of the opposition effect, ζ - 1 = (1 - G<sub>1</sub> - G<sub>2</sub>)/(G<sub>1</sub> + G<sub>2</sub>). Since the G<sub>1</sub> and G<sub>2</sub> parameters of many asteroids appear to be somehow correlated, and can be described by a two-segment linear function (*Muinonen et al.*, 2010; *Oszkiewicz et al.*, 2011), the three-parameter model can be further reduced to a two-parameter model, parameterized by H and G<sub>12</sub>. These new phase function models significantly improve the fits to existing asteroid phase function data over a wide range of phase angles up to 140°. It has been shown that asteroid taxonomy classes generally have their G<sub>1</sub>, G<sub>2</sub> parameters, and therefore G<sub>12</sub> parameters as well, clustered in parameter space (*Oszkiewicz et al.*, 2011, 2012). For example, the G<sub>12</sub> parameters of the C complex peak at ~0.65, while that of S complex peak at ~0.45.

## 2.4. Effects of Shape Models on Photometric Modeling

Among the most important photometry-related innovations in recent years has been the development and standardization of three-dimensional digital shape models for asteroids, comets, and irregularly shaped moons of the outer planets. With the advent of close-up imaging of asteroids and

other irregularly shaped bodies by spacecraft, radar observations and shape reconstruction from Earth, and sophisticated computer modeling of telescopic rotational lightcurves, it has become possible to measure the non-uniform topography of these objects and represent them in digital form. Details of these models and how they are derived can be found in the chapter by Ďurech et al. in this volume.

In photometric studies of asteroids from spacecraft missions, shape models play a critical role in the sampling of disk-resolved photometric observations from imaging data and spectrometers. That is, for disk-resolved observations, it is important to determine the photometric geometry (i.e., local angles of incidence, emission, and phase) for each point on the surface for which a corresponding brightness (i.e., radiance factor) is to be sampled. At any such point, the shape model, ephemeris, and spacecraft navigation and pointing data provide the means for computing the orientation of the local vector surface normal from which photometric angles are measured (Fig. 1).

A pitfall in the use of shape models is that, at large incidence angles (to which properties like macroscopic roughness are very sensitive), even tiny errors in the estimated angle of incidence derived from the model can lead to large errors in photometric model fits. The presence of inaccurately represented topography, e.g., small craters or ridges that are not below the spatial resolution of the topographic model, almost invariably introduce errors in the measured photometric angles. Consequently, it is common practice to exclude or otherwise apply weak statistical weighting to observations at large incidence angles from fits of photometric models to disk-resolved asteroid data.

## 2.5. Testing of Physically Motivated Models

**2.5.1. Hapke model controversy.** Shkuratov et al. (2012, 2013; see also Zhang and Voss, 2011) criticized Hapke's model on the basis of 15 alleged failures and deficiencies. While it is beyond the scope of this chapter to provide a point-by-point discussion, these criticisms about Hapke's model fall into four categories: (1) it is not rigorous in its application of electromagnetic theory and violates conservation of energy; (2) it makes unrealistic assumptions about light scattering by natural, particulate regolith surfaces and incompletely describes the dependence of scattering on photometric geometry; (3) it employs too many adjustable parameters, some of which are not truly independent variables, making it cumbersome and ambiguous to use; and (4) in the authors' tests the model exhibits unrealistic behavior in comparison to their ray-tracing predictions, showing that parameter values retrieved from fits of the model to the laboratory and lunar photometric data are unreliable.

Hapke (2013) argued that 9 of the 15 criticisms are invalid because they are based on a profound misunderstanding of his model and the assumptions that he made in deriving its components. He acknowledged that the greatest weakness in his model is that CBOE as it applies to regolith surfaces is poorly understood and consequently its treatment in his

model is imperfect and necessarily preliminary. He notes that CBOE is known to occur in regolith surfaces and it was necessary to include at least a preliminary description to model observed regolith opposition effects. Hapke does not dispute that his model is not rigorously derivable from Maxwell's equations. He argues, however, that his model is nonetheless useful when it is applied and interpreted within the limitations that are imposed by his simplifying assumptions, all of which are stated in his published derivations. In response to one criticism, Hapke acknowledged that his recent porosity correction indeed violates the conservation of energy at distances that are smaller than the interparticle separation distance. However, he points out that the violation is irrelevant because the definitions in his model are specifically made such that energy is conserved over all distances larger than the interparticle separation, which is the minimum distance over which the radiative transfer equation is applicable.

In practice, the most difficult criticism for users of the Hapke model to overcome is that its numerous coupled (i.e., non-independent) model parameters can lead to ambiguous or unreliable parameter value retrievals when applied to observations of planetary regoliths (see below). Hapke attributes the mutual dependence of the modeled regolith properties to a true property of nature and not a failure of his model. The ability to reliably retrieve meaningful values of model parameters first and necessarily depends on the availability of sufficient photometric data coverage to fully constrain the model parameters — coverage that is often neither fully available from photometric observations of planetary surfaces, nor is adequate to constrain the Hapke model fits often tested by practitioners before application. Second, judiciously chosen fitting methods can often overcome difficulties with potentially ambiguous model retrievals (cf. Hapke, 2012a; Hapke et al., 2012). In addition, it is sometimes possible to constrain some of the model parameters, even when data are insufficient to simultaneously constrain all of them by exploiting ranges of photometric angles for which the unconstrained parameters have insignificant effect (cf. Souchon et al., 2011). Finally, as discussed in Helfenstein and Shepard (2011), it is critically important to perform a thorough error analysis on the results so that ambiguous or unreliable values can be identified.

**2.5.2. Recent tests.** Investigations to validate the fidelity and physical interpretability of physically motivated photometric models fall into three broad categories: laboratory studies, computer modeling studies, and *in situ* studies. The focus of many laboratory studies has been to test and validate the Hapke model (Buratti and Veverka, 1985; Kamei and Nakamura, 2002; Cord et al., 2003, 2005; Gunderson et al., 2005; Shkuratov et al., 2007; Shepard and Helfenstein, 2007, 2011; Helfenstein and Shepard, 2011; Hapke et al., 2009; Souchon et al., 2011), as well as compare the predictions of Hapke's model to numerical light-scattering simulations (Helfenstein, 1988; Shepard and Campbell, 1998; Ciarniello et al., 2014). Finally, *in situ* studies rely on using well-sampled planetary observation datasets to derive information about the validity of Hapke's model (cf. Guiness et al., 1997;

*Verbiscer and Veverka, 1990; Domingue et al., 1997; Helfenstein et al., 1997; Helfenstein and Shepard, 1999; Hapke et al., 2012; Shepard et al., 2001, 1993.*

Studies that exploit *a priori* knowledge of the optical properties of soil components to perform forward-modeling of surface reflectance are often (but not always) more successful than efforts that aim to invert the Hapke model to assess properties of particulate surfaces from photometric observations. Forward-modeling of remotely sensed reflectance spectra with Hapke theory has been routinely accomplished for many years for a wide range of planetary objects (cf. Roush et al., 1990; Calvin and Clark, 1991; Lucey, 1998; Verbiscer et al., 2006; Wilcox et al., 2006; Denevi et al., 2008; Warell and Davidsson, 2010). The model successfully predicts the scattering behavior of idealized soil samples (Hapke et al., 2009; Hapke and Wells, 1981; Hapke, 2012b). Computer simulation studies have investigated the geological interpretation of Hapke's (1984) correction for macroscopic roughness (Helfenstein, 1988; Shepard and Campbell, 1998). More recently, for lunar soils and laboratory analog materials, photometric roughness best matches lunar regolith relief at submillimeter size scales (Helfenstein and Shepard, 1999; Cord et al., 2003; Goguen et al., 2010). Buratti and Veverka (1985) showed that photometrically detected roughness is sensitive to the albedo of the surface, with high albedos causing dilution of shadows via multiple-scattering. Tests of the opposition surge model conclude that both coherent backscatter and shadow hiding contribute to the opposition effect (Helfenstein et al., 1997; Hapke, 1998; Hapke et al., 2012). Hapke et al. (2012) found that the angular width of the lunar opposition effect does not significantly vary with optical wavelength, contrary to the current analytical treatments of coherent backscatter, which, for the Moon, predict that the width should be proportional to the square of the wavelength. In combination with experimental evidence, the observed absence of a wavelength dependence to the opposition effect suggests that our current understanding of coherent backscatter is deficient. In Monte Carlo simulation experiments verified by direct solution of Maxwell's equations, Muinonen et al. (2012) modeled scattering from a spherical volume of sparsely distributed smaller spherical scatterers (see section 2.3.4). They found that the angular width of the CBOE was independent of the packing density of small scatterers, which is best explained if the mean length of the interference base is controlled by the size-parameter of the spherical scattering volume rather than the transport mean free path that is often assumed in analytical approximations.

Attempts to validate Hapke's (1981, 1984, 1986, 2002) theory by comparing the known characteristics of laboratory samples to those predicted by fits of the model parameters to photometric observations of the samples found no compelling evidence that individual photometric parameters could be uniquely interpreted to reveal the physical state of the samples, either in an absolute or relative sense. Instead, combinations of physical properties such as particle single-scattering albedo, roughness, and porosity were convolved within each retrieved photometric parameter (Gunderson et

al., 2005; Shepard and Helfenstein, 2007; Shkuratov et al., 2007, 2012; Souchon et al., 2011). In general, the best agreement was found, at least qualitatively, between the observed microstructure of natural soil grains and the physical interpretation of retrieved particle phase function model parameters (Souchon et al., 2011; Shepard and Helfenstein, 2007).

Only recently have tests of Hapke's (2008) correction for the effects of porosity been published (see also section 2.5.1). Helfenstein and Shepard (2011) performed a preliminary test of the model by applying it to analyze laboratory analog samples from their 2007 suite of measurements (Shepard and Helfenstein, 2007). Their results suggest that Hapke's porosity correction improves the fidelity of fits to samples composed of low- and moderate-albedo particles and may allow for more reliable retrieval of porosity estimates in these materials. However, the test also suggested that in high-albedo surfaces, the effects of porosity may be difficult to detect. More recently, Ciarniello et al. (2014) use Monte Carlo simulations of ray-tracing in particulate media to test three formulations of Hapke's model: the multiple-scattering IMSA, AMSA, and an updated version of Hapke (2008). They found that, excluding the opposition effect, the Hapke (2008) model is the most accurate to describe the reflectance behaviors of particulate media with arbitrary porosities. It is also able to characterize anisotropic scattering, unless the medium exhibits a strongly forward-scattering behavior. The IMSA and AMSA models were effective only for soils with extremely large porosities.

### 3. OBSERVATIONAL DEVELOPMENTS

Prior to the advent of interplanetary space probes, all photometric observations of asteroids were telescopic, in which objects were seen only as point sources. Thus, only disk-integrated data were available. Except for Earth-crossing asteroids, the observable phase angle range was generally limited to less than 25°–30°. When spacecraft encounters with asteroids became reality, it was possible to measure an asteroid's three-dimensional shape, to observe how the brightness of the asteroid's surface varied with local photometric geometry, and to detect terrain-dependent albedo and color heterogeneities.

Spacecraft data have their own limitations in photometric modeling, too. For some orbit missions, such as Dawn (Russell et al., 2012; see also the Russell et al. chapter in this volume) that use polar orbits, there may be a correlation between latitude and phase angle since the cameras observe the surface in the nadir direction ( $e \approx 0^\circ$ ) (e.g., Li et al., 2013a). When the field-of-view of the camera is small compared to the angular size of the target, this can introduce a bias to the observations. For fast flyby observations, the illumination geometry does not change much from image to image taken within a short duration (typically  $<1$  h), which is much shorter than the rotation period of most asteroids, and the flyby. Derivation of a shape model may then be restricted by very limited illumination and surface coverage, and the photometric analysis would be subject to

the same limitations. Spatial resolution and uncertainties in shape can also limit the accuracy of photometric models. These limitations should be considered in the modeling and interpretation of disk-resolved photometric data.

Since the first asteroid flyby of (951) Gaspra by the Galileo spacecraft in 1991 (Belton et al., 1992; Veverka et al., 1994), 13 asteroids have been imaged by spacecraft either from flybys or rendezvous. Seven asteroids were visited since the publication of *Asteroids III*, and (1) Ceres is being visited by Dawn as of early 2015. Of the seven newly imaged asteroids, the data of (25143) Itokawa (see the chapter by Yoshikawa et al. in this volume; Kitazato et al., 2008), (2867) Šteins (Barucci et al., this volume; Spjuth et al., 2012), (21) Lutetia (Barucci et al., this volume; Magrin et al., 2012; Masoumzadeh et al., 2014), and (4) Vesta (Russell et al., this volume; Li et al., 2013a; Schröder et al., 2013; Longobardo et al., 2014) are of sufficient resolution and quality to perform detailed, disk-resolved photometric studies. The images of (5535) Annefrank from the Stardust flyby were of low resolution, and only disk-integrated analysis has been performed from the spacecraft data (Hillier et al., 2011). The flyby of (132524) APL by New Horizons was serendipitous at a large distance and the returned images resemble point sources, and therefore no photometric modeling was performed. No report about the photometric properties of (4179) Toutatis from the Chinese Chang'e 2 flyby images (Huang et al., 2013; Barucci et al., this volume) has yet become available. (1) Ceres was observed by the Hubble Space Telescope (HST) in 2003/2004 with the Advanced Camera for Surveys (ACS) High Resolution Channel (HRC), and resolved to  $\sim 30$  km/pixel, facilitating the study of its disk-resolved photometric properties (Li et al., 2006). In this section, we will summarize the photometric results for Ceres, Itokawa, Šteins, Lutetia, Vesta, and Annefrank.

### 3.1. (1) Ceres

Ceres represents a thus-far unique category of asteroids or dwarf planets (cf. Rivkin et al., 2011). Ample evidence suggests that water must have played an important role in its evolutionary history and its current status (Rivkin et al., 2011). The recent unambiguous discovery of water vapor associated with localized sources on Ceres indicates a possibly active surface at the present (Küppers et al., 2014).

Li et al. (2006) reported a detailed photometric analysis of Ceres based on the images collected by the HST/ACS through three broadband filters centered at 535, 335, and 223 nm obtained in 2003/2004 at a narrow range of phase angles of  $5^\circ$ – $7^\circ$ . The disk-resolved analysis focused on studying the limb-darkening behavior to derive the roughness, and determining the single-scattering albedo. Li et al. reported a Hapke roughness parameter of  $44^\circ \pm 5^\circ$  for Ceres, much higher than those of all other objects that have been modeled with Hapke functions that include roughness (Table 6). Given that the roughness of all other objects were derived from images with much higher spatial resolution than those of Ceres, it is a question whether this high roughness is real

or an observational artifact. Indeed, the small angular size of Ceres ( $\sim 30$  pixels across) and the point spread function of the optical system could blur the edge of Ceres' disk, so that the brightness decreases toward the limb are much faster than the real surface, yielding higher roughness in the modeling. This effect probably also explains the fact that the Hapke and Minnaert model could only fit Ceres' disk within  $40^\circ$ – $50^\circ$  photometric longitude/latitude as shown by Li et al. On the other hand, the high photometric roughness of Ceres is consistent with its high radar roughness of  $20^\circ$ – $50^\circ$  (Mitchell et al., 1996), although the same radar observations also indicate that the surface of Ceres is very smooth at centimeter to decimeter scales, probably indicating different roughness at different scale sizes.

The photometric analysis in the visible and near-infrared wavelengths suggested a remarkably uniform surface of Ceres in its albedo and color (Li et al., 2006; Carry et al., 2008, 2012). The albedo maps at all three wavelengths show variations of only 4% full-width-at-half-maximum (FWHM), and about  $\pm 6\%$  peak-to-peak. Compared with other solar system objects with their surface photometric variations determined, Ceres certainly has the most uniform surface so far (Li et al., 2006). Of course, with much higher spatial resolutions in the data to be collected by Dawn, it cannot be excluded that some local areas on Ceres that are much smaller than the HST image resolution have larger albedo and/or color variations from the global average. But those small areas should not dramatically change the overall distribution of the surface albedo and color on Ceres.

### 3.2. (25143) Itokawa

Lederer et al. (2005) used broadband BVRI photometry of the S-type asteroid Itokawa between  $4^\circ$  and  $90^\circ$  phase angles obtained from the ground to characterize this target asteroid of Hayabusa prior to its launch. The authors used a Hapke model to derive a single-scattering albedo of 0.36, and a highly backscattering single particle phase function with  $g = -0.51$ , although the roughness and opposition surge parameters were assumed and could have driven this number to be large. Lederer et al. found that Itokawa has a higher albedo than average main-belt S-class asteroids. However, limited by disk-integrated observations and the lack of data at small phase angles, their models have to assume an opposition surge and the common values of roughness of  $20^\circ$  and  $36^\circ$ .

The Japanese Hayabusa spacecraft visited Itokawa in 2005 (see chapter by Yoshikawa et al. in this volume; Fujiwara et al., 2006). Kitazato et al. (2008) conducted a photometric analysis of Itokawa using disk-resolved reflectance spectra measured by the Near-infrared Spectrometer (NIRS) over multiple wavelengths ranging from 0.85 to  $2.10\text{ }\mu\text{m}$  covering phase angles from near  $0^\circ$  to  $38^\circ$ . Using a Hapke photometric model analysis, the authors found that Itokawa has a single-scattering albedo that is 35–40% less than that of asteroid (433) Eros, consistent with the results of Lederer et al. (2005). The data at low phase angles enables modeling of opposition effect. While Kitazato et al. (2008) only included

TABLE 6. Comparison of the Hapke photometric parameters of asteroids.

Object	Type	$\pi$ (visible)	h	$B_0$	g	$\theta(^{\circ})$	Reference
Average S		0.23	0.08	1.6	-0.27	20	Helfenstein and Veverka (1989)
Average C		0.037	0.025	1.03	-0.47	20	Helfenstein and Veverka (1989)

(4) Vesta	V	0.51	0.07	1.7	-0.24	18	Li et al. (2013a)
(951) Gaspra	S	0.36	0.06	1.63	-0.18	29	Helfenstein et al. (1994)
(243) Ida	S	0.22	0.02	1.53	-0.33	18	Helfenstein et al. (1996)
Dactyl	S	0.21	(0.020)	(1.53)	-0.33	23	Helfenstein et al. (1996)
(433) Eros	S	0.43	0.022	1.0	-0.29	28	Li et al. (2004)
(25143) Itokawa	S	0.36	(0.022)	(1.0)	-0.51	(20)	Lederer et al. (2005)
(25143) Itokawa	S	0.42	0.01	0.87	-0.35	26	Kitazato et al. (2008)
(5535) Annefrank	S	0.41	0.015	1.32	-0.19	20	Hillier et al. (2011)
(1862) Apollo	S						Helfenstein and Veverka (1989)
(253) Mathilde	C	0.034	0.094	3.18	-0.27 (two-term fit)	25	Clark et al. (1999)
(1) Ceres	C	0.070	0.06	1.6	-0.4	44	Helfenstein and Veverka (1989), Li et al. (2006)
(2867) Šteins	E	0.57	0.062	0.60	-0.30	28	Spjuth et al. (2012)
(21) Lutetia	M	0.23	0.044	1.93	-0.25	25	Masoumzadeh et al. (2014)

Values inside parentheses are assumed.

SHOE but not CBOE in the Hapke modeling, they observed wavelength dependence of the width of opposition effect, and attributed it to coherent backscattering. Compared to Eros, the lower-opposition amplitude indicates weaker contribution of the SHOE component, and the narrower width is consistent with relatively more densely packed particles in the regolith of Itokawa. The roughness parameter for Itokawa was estimated to be  $26^{\circ}$ , similar to that of Eros'. The modeled parameters of opposition effect and roughness justify the assumptions made in Lederer et al.'s (2005) work, although those studies were performed at a different wavelength regime.

### 3.3. (2867) Šteins

Spjuth et al. (2012) performed detailed photometric analyses of asteroid Šteins, the first E-type asteroid visited by spacecraft, using multi-spectral images acquired by the OSIRIS Wide Angle Camera (WAC) onboard the Rosetta spacecraft (Keller et al., 2007). An extremely wide range of phase angles from  $0.36^{\circ}$  to  $130^{\circ}$  was achieved through one filter centered at 630 nm, allowing for modeling of the opposition effect. The authors estimated the single-scattering albedo to be 0.57, the highest ever found for small bodies visited by spacecraft. The roughness is  $28^{\circ}$ , and the asymmetry factor of the 1PHG single-particle phase function is -0.27. The geometric and Bond albedos of Šteins were derived to be  $0.39 \pm 0.02$  and  $0.24 \pm 0.01$ , respectively. The high albedo of Šteins is consistent with the iron-poor

surface composition of the asteroid (Barucci et al., 2012). To study the photometric variations across the surface of Šteins, Spjuth et al. (2012) generated maps of Hapke photometric parameters, including the single-scattering albedo, roughness, and asymmetry factor of the 1PHG function, by assuming that the reflectance variation is entirely caused by one single parameter while keeping the others fixed at their respective global averages. These maps probably represent the highest possible variations in each single photometric parameter. As indicated by these maps, the surface of Šteins seems to be highly homogeneous, with a standard deviation of 0.01 for its single-scattering albedo,  $3.4^{\circ}$  for roughness, and 0.003 for the asymmetry factor. The uniform surface of Šteins is consistent with the results reported by Leyrat et al. (2010), who applied photometric correction to the flyby images with a Hapke (2002) model and performed a statistical analysis, and find no surface inhomogeneities larger than 4% at the 95% confidence level.

The photometric properties of Šteins are interpreted as the consequence of its regolith properties (Spjuth et al., 2012). The strong opposition effect and high albedo are consistent with porous, fine-grained regolith, which is consistent with the studies of aubrite meteorites, which are considered to be analog to E-type asteroids, and laboratory work (Gaffey et al., 1989; Shepard and Helfenstein, 2007). The low amplitude of SHOE indicates relatively transparent regolith particles, and/or a large density of internal scatterers of opaques. The width of opposition effect is also consistent with a high porosity of ~84% for the regolith particles.

### 3.4. (21) Lutetia

*Belskaya et al.* (2010) obtained groundbased BVRI photometric and V-band polarimetric measurements of Lutetia over a wide range of phase angles ( $0.5^\circ$ – $22.2^\circ$ ). The authors found that Lutetia has a nonconvex shape and heterogeneous surface properties, due possibly to a large crater and the variations in the texture and/or mineralogy, respectively. The polarimetric properties of Lutetia suggest a fine-grained regolith with a mean grain size smaller than  $20\text{ }\mu\text{m}$ , and a carbonaceous composition (CO, CV, CH). The Rosetta spacecraft flew by Lutetia at a close encounter distance of  $\sim 3200\text{ km}$  on July 10, 2010. The flyby geometry at Lutetia is similar to that at Šteins, while multicolor images were acquired through both WAC and the narrow angle camera (NAC) throughout the flyby, providing phase angle coverage from less than  $1^\circ$  to  $130^\circ$  at multiple wavelengths. Based on these data, *La Forgia* (2014) conducted a photometric analysis of Lutetia with a disk-integrated Hapke model. They showed that all the modeled parameters depend on wavelength. However, it has to be noted that their modeling is based on disk-integrated phase functions, and therefore strong coupling exists between at least the roughness parameter and the phase function. The photometric analysis of Lutetia showed that the asteroid's surface is composed of particles that have high reflectivity. *La Forgia* also found that Lutetia's surface is generally smooth and characterized by a low porosity. These results are consistent with the conclusion that Lutetia is an ancient planetesimal rather than a reaccumulated object, as indicated by its large diameter of  $98 \pm 2\text{ km}$  (*Sierks et al.*, 2011a) and its high density of  $3.4 \pm 0.3 \times 10^3\text{ kg m}^{-3}$  (*Pätzold et al.*, 2011). *Masoumzadeh et al.* (2014) performed a disk-resolved photometric analysis with the Hapke model and the Minnaert model using the Rosetta flyby data. They reported no wavelength dependence on the Minnaert k parameters, which is different from the *La Forgia* (2014) results. In addition, in their Hapke modeling, they derived very different single-scattering albedo with 1PHG and 2PHG single-particle phase function (0.26 vs. 0.49, respectively).

### 3.5. (4) Vesta

Dawn's rendezvous with Vesta provided us with high-resolution imaging data (*Russell et al.*, 2012, 2013; see also the chapter by Russell et al. in this volume). *Li et al.* (2013a) performed a thorough analysis of the global photometric properties of Vesta using Dawn Framing Camera (FC) (*Sierks et al.*, 2011b) images with pixel scale  $>0.25\text{ km/pixel}$  through all filters, including one clear filter and seven mid-band ( $\sim 100\text{-nm bandpass}$ ) color filters with center wavelengths from 440 nm to 960 nm. Dawn data cover a range of phase angles from  $\sim 7^\circ$  to  $\sim 90^\circ$  for disk-resolved data in all filters, and from  $\sim 24^\circ$  to  $\sim 108^\circ$  for disk-resolved data through the clear filter. *Li et al.* (2013a) found that the photometric behavior of the surface of Vesta is well described by a Hapke model and a Minnaert model, but the LS model cannot reproduce the limb-to-terminator brightness trends. The phase

functions of Vesta show weak dependence on wavelength, qualitatively consistent with previous groundbased observations (*Reddy et al.*, 2012a), but about a factor of 0.5 weaker (*Li et al.*, 2013a). The phase reddening of Vesta as observed by Dawn is similar to, or slightly stronger than, that of Eros observed by the Near Earth Asteroid Rendezvous (NEAR) mission (*Clark et al.*, 2002). The Hapke roughness parameter of Vesta is consistent at all wavelengths studied. While roughness parameter is a geometric parameter and is not supposed to depend on wavelength, for high-albedo surfaces, multiple scattering into shadows could in principle wash out shadows and result in lower modeled roughness. The lack of such effects on Vesta suggests that this effect is small for a single-shattering albedo of  $<0.55$  and a roughness of  $\sim 20^\circ$ . Compared with other asteroids studied so far, the globally averaged photometric properties of Vesta are similar to those of S-type asteroids, except for its albedo, which is about twice the average albedo of S-types.

Vesta has a highly heterogeneous surface in almost all aspects (*Reddy et al.*, 2012b; *Jaumann et al.*, 2012; *Prettyman et al.*, 2012; *De Sanctis et al.*, 2012a, 2013; *Ammanito et al.*, 2013). Its albedo and color variations have been recognized previously from groundbased and HST observations (*Gaffey*, 1997; *Binzel et al.*, 1997; *Li et al.*, 2010; *Reddy et al.*, 2013). The albedo and color maps generated from Dawn FC data further show that such heterogeneity is at almost all scale sizes, and reveal many localized areas with distinctly high and low albedos (*McCord et al.*, 2012). The overall distribution of albedo on Vesta has a FWHM of  $\sim 17\%$ , but the localized bright and dark areas have albedos from about one-half to greater than twice the average (*Li et al.*, 2013a). The single-peaked albedo distribution on Vesta is presumably a result of strong regolith mixing on Vesta caused by the complicated impact history of Vesta (*Pieters et al.*, 2012), different from the bimodal distribution on the Moon as dominated by compositional heterogeneity (e.g., *Helfenstein and Veverka*, 1987; *Hillier et al.*, 1999; *Yokota et al.*, 2011).

*Schröder et al.* (2013) reported correlations between the spatial variations in the surface phase function of Vesta and geology. After correcting the limb-to-terminator brightness trend on Vesta, they were able to map out the slopes of the surface phase functions over the whole illuminated surface of Vesta. The slope of phase function shows clear global distribution correlated with albedo and mineralogical units. Eucrite-dominated regions (*Ammanito et al.*, 2013) have relatively steeper phase functions. Since those regions are also correlated with the enriched distribution of dark material, which is interpreted as exogenous carbonaceous material delivered by impactors (*McCord et al.*, 2012; *Reddy et al.*, 2012c; *Prettyman et al.*, 2012; *De Sanctis et al.*, 2012b; *Turrini et al.*, 2014), such correlation between albedo and phase function on Vesta probably manifests the general correlation in the asteroid belt (e.g., *Bowell and Lumme*, 1979). Furthermore, on local scales, the phase function slopes are steeper on crater floors than on crater walls, interpreted as a variation in roughness due to the accumulation of loose material inside craters causing higher roughness.

*Longobardo et al.* (2014) and *Li et al.* (2013c) analyzed the visible and NIR data collected by Dawn's Visible and Infrared (VIR) instrument (*De Sanctis et al.*, 2011), but this work is still ongoing as of the writing of this chapter. The preliminary results reported by *Li et al.* (2013c) using VIR data were inconsistent in the overlapping wavelengths with those derived from the FC data taken at similar mission phases, tentatively attributed to instrumental effects. *Longobardo et al.* (2014) took a completely empirical approach with the Akimov model to fit VIR data and study the dependence of pyroxene band parameters on scattering geometry with the focus on bright and dark regions on Vesta. Their results should be less dependent on instrumental effects. The trend of band parameters with respect to scattering geometry derived from VIR data is shown to be consistent with previous observations from the ground (*Reddy et al.*, 2012a).

### 3.6. (5535) Annefrank

Disk-integrated Stardust observations of Annefrank obtained between  $47^\circ$  and  $135^\circ$  were combined with ground-based measurements obtained between  $2^\circ$  and  $18^\circ$  and analyzed by *Hillier et al.* (2011). This asteroid exhibits a steep phase curve, resulting in a very large roughness parameter of  $49^\circ$ , an unusually large single-particle-scattering albedo of 0.62, and a Henyey-Greenstein phase function,  $g$ , of  $-0.09$ , which is more isotropic than the usual strongly backscattering S-type asteroids. The shadow-hiding opposition surge width  $h = 0.015$  is more typical of the S-types. Because the shape of Annefrank is irregular, these fits to a full excursion in solar phase angle may not be unique, especially with disk-integrated data only. *Li et al.* (2004) have shown that the assumption of sphericity can lead to an overestimate of both the single-scattering albedo and the roughness parameter and a more isotropic phase function, particularly if measurements at large solar phase angles are included in modeling. *Hillier et al.* (2011) restricted their fits to  $90^\circ$  and found more typical parameters of  $20^\circ$  for the roughness parameter, 0.41 for the single-scattering albedo, and  $-0.19$  for  $g$ . Still, the single-scattering albedo of Annefrank is high.

## 4. APPLICATIONS AND INTERPRETATIONS

### 4.1. Correction for Spectral Analysis

**4.1.1. Photometric correction.** Most of the changes in the reflectance of an asteroid surface are not intrinsic but rather due to variations in viewing geometry. With a description of the photometric functions of the surface, all the non-intrinsic variations can be removed and a map of the normal reflectance or a physical parameter such as the single-scattering albedo can be produced. Since the three geometric parameters for the scattering,  $i$ ,  $e$ , and  $\alpha$ , are known *a priori* (if one possesses an accurate shape model for nonspherical bodies, which is often a requirement for asteroids), fitting a photometric function or model to space-

craft or groundbased images provides all the information needed to perform photometric corrections.

The usual procedure for photometric correction as in equation (1) is to (1) use the observed data to fit a global average photometric model, (2) calculate the ratio of the measured reflectance over the model reflectance for each surface element, and (3) multiply the ratio by the model reflectance at the desired reference geometry. In this procedure, the ratio calculated is a measure of the deviation between the actual surface reflectance and the best-fit model, and the user has a choice of reference geometries for the correction. The implicit assumptions behind the photometric correction are that (1) any deviation between the measured reflectance and the best-fit model must be real, and not due to imperfections in the photometric model or the shape model; and (2) the deviation factor is independent of scattering geometry. We shall now discuss the implications of these two assumptions.

The first assumption can sometimes be verified by fitting several different models to the same data and comparing the resultant photometric corrections, but this is often limited by data availability. Therefore, one has to judge what features in the photometrically corrected maps are real and what are artifacts based on the magnitude, scale size and shape, geologic and compositional context, etc., on a case-by-case basis. In our discussion about the second assumption (next), we will assume that the first assumption is true.

For the second assumption, two different cases exist. The first case is that the reflectance variation from the best-fit model prediction is dominated by the single-scattering albedo variation rather than variations in other photometric properties such as phase function or roughness. If albedo is low and multiple scattering is insignificant, then the reflectance is approximately proportional to the single-scattering albedo (see section 2). Thus, the deviation factor represents how much the albedo at a particular surface location deviates from the global average, and should not depend on scattering geometry. The assumption is justified. On the other hand, for high-albedo cases where multiple scattering is significant, the proportionality between single-scattering albedo and reflectance is broken, and photometric correction needs to be performed taking into account the nonlinear effect. This is a complicated process but feasible. The second case is the opposite of the first case: The variation in phase function and/or roughness dominates the deviation factors. Since the effects of phase function and roughness always depend on phase angle, so does the deviation factor. In this case, photometric correction cannot be reliably applied. For example, it is well known that variations in photometric properties other than albedo exist on the Moon, where multiple photometric models are derived for different regions based on their albedos, and photometric corrections are performed based on the corresponding models (e.g., *Yokota et al.*, 2011; *Besse et al.*, 2013; *Wu et al.*, 2013). The work of *Schröder et al.* (2013) also shows that this case exists on Vesta. One has to be aware of this constraint when interpreting data products that involve a photometric correction of a bright surface.

The selection of an appropriate photometric model for the surface is important when performing a photometric correction. In principle, any photometric model that can describe the photometric behavior of the target asteroid surface sufficiently well can be used for photometric correction, whether or not physical interpretations of model parameters are possible. Although radiative transfer models can be used to derive intrinsic physical parameters such as the single-scattering albedo or normal reflectance, unless a wide range in solar phase angles is available, unique fits to parameters in Hapke-type models are not possible (Helfenstein *et al.*, 1988). For practical photometry, empirical functions are often preferred due to their simple mathematical forms and fewer free parameters.

**4.1.2. Phase reddening.** It is well known that spectra of asteroids, and many other airless bodies, become redder as the solar phase angle increases (see review in Gehrels, 1970; Gradie and Veverka, 1986). This phenomenon of “phase reddening” is most pronounced in S-type asteroids: Bowell and Lumme (1979) found that between 0.35  $\mu\text{m}$  and 0.55  $\mu\text{m}$  the effect was 2–3 $\times$  greater for S-type asteroids than for C- or M-types. It is generally considered that phase reddening is related to the increase in spectral reflectance with wavelength. For example, the albedo of S-type asteroids doubles between 0.35  $\mu\text{m}$  and 0.8  $\mu\text{m}$  (Tedesco *et al.*, 1989). The physical reason for the reddening probably lies in the relative importance of multiple scattering: As the albedo increases, the amount of radiation that has been multiply scattered also increases. The singly scattered radiation is backscattering, while the multiply scattered radiation tends to be isotropic. Thus, at large solar phase angles, in the forward-scattered direction, the multiply scattered photons are relatively more important. Since there are more such photons as the albedo increases, the reflectance becomes redder at large phase angles. The spectra of S-type and A-type asteroids exhibit the most significant changes in albedo through the visible range of the spectrum, so they should exhibit more phase reddening than the flat C- or M-types. The spectrally unique C-class asteroid Ceres has an almost featureless spectrum between 0.4  $\mu\text{m}$  and 2.4  $\mu\text{m}$  and it exhibits no phase reddening (Tedesco *et al.*, 1983). But the connection between phase reddening and albedo is not straightforward. For example, the bright V-type asteroids, for which a composite solar phase curve was constructed from near-Earth objects (NEOs), exhibit phase reddening of only 0.002 mag/deg in B-R and 0.0016 mag/deg in I-R, even though this class of asteroids typically changes in albedo by a factor of 2 between the B and I filters (Hicks *et al.*, 2014).

Even with a spectrally flat body it is possible to get phase reddening. At larger solar phase angles, shadows cast by rough features occupy an increasing fraction of the face of the object as seen by an observer. Although these shadows are dark shadows for low-albedo surfaces, they are partly illuminated by multiply scattered photons for high-albedo objects. Thus, only low-albedo objects with flat spectra should exhibit no solar phase reddening, which is the case for Ceres, which has a visible geometric albedo of 0.09.

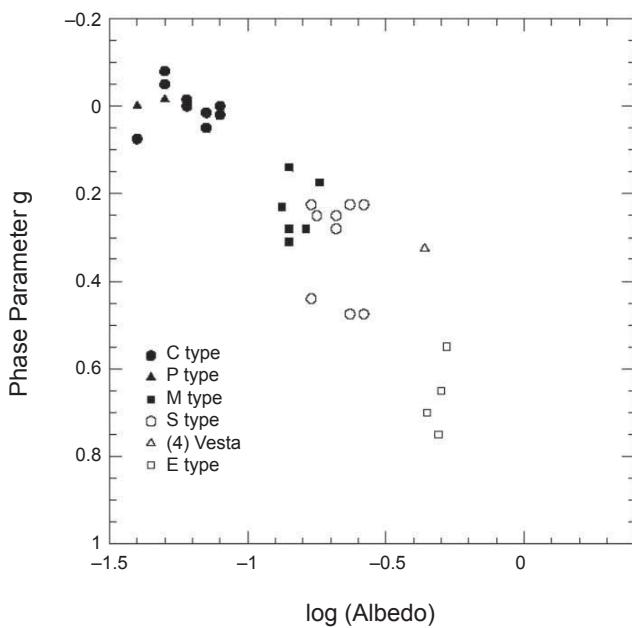

## 4.2. Taxonomic Classes

The application of photometric models to spacecraft images, coupled with the acquisition of measurements of near-Earth asteroids (NEAs) at large solar phase angles not attainable from the ground for asteroids in the main belt, has led to the robust modeling of a sufficient number of asteroids so that trends among the various classes of asteroids can be studied. Asteroid spacecraft observations that have been fit with photometric models are listed in Table 6, together with the modeling results. Photometric modeling of groundbased measurements of NEAs has been done for (1862) Apollo, a rare Q-type asteroid (Helfenstein and Veverka, 1989). In addition, a composite solar phase curve of V-type asteroids was created from NEA observations and fit with both Hapke and Lumme-Bowell models (Hicks *et al.*, 2014). The phase functions of C-, S-, and V-type asteroids are plotted in Fig. 2.

Asteroid (1862) Apollo, an NEA that is a member of the rare Q-type class, was observed extensively during its apparitions in 1980 and 1982 (Harris *et al.*, 1987). Q-types are similar to S-types, but have higher albedos and are consistent with non-space-weathered materials, relative to the S-types (Binzel *et al.*, 2010). The Q-types have a slightly more isotropic phase function, due possibly to this higher albedo: Multiply scattered photons tend to be more isotropic than singly scattered photons. The smaller roughness parameter may also be the result of the asteroid’s higher albedo, as multiply scattered photons partly illuminate shadows cast by rough features and lead to an underestimate of the roughness parameter.

Helfenstein and Veverka (1989) derived an average S- and C-type asteroid over the range of solar phase angles for the main belt ( $\sim 0^\circ$ – $30^\circ$ ). The small number of S-type asteroids that have been observed with spacecraft, and thus over a larger excursion in solar phase angles, have not shown a strong correlation in derived Hapke parameters (Table 6). This lack of correlation may be due to different solar phase angle sampling, or to non-unique fits, or to the models not fully accounting for the effects of multiple scattering, which partly illuminate primary shadows for both the roughness model and for the opposition surge shadow-hiding model. Or perhaps it is due to the lack of correlations between Hapke parameters and physical properties (Shepard and Helfenstein, 2007). It is also important to separate NEA and main-belt populations because the NEAs are not as weathered and are smaller and thus expected to have less substantial regoliths.

Nevertheless, Belskaya and Shevchenko (2000) noted the correlations in Fig. 3 of the Lumme-Bowell two-parameter IAU convention. Higher-albedo asteroids have larger single-scattering albedos and larger slope parameters (G-parameter). The Henyey-Greenstein parameter is slightly more forward scattering for high-albedo asteroids, which is to be expected if they are more isotropic. The opposition surge parameter also tends to decrease as the albedo increases, with a slight decrease in the compaction state. The only C-type asteroid modeled (Mathilde) seems to confirm this trend: Its

**Fig. 3.** The H and G parameters of the Lumme-Bowell model correlate well with asteroid class. The low-albedo primitive type have lower phase parameters G, while the higher-albedo asteroids have larger G. Figure based on Belskaya and Shevchenko (2000) and Hicks et al. (2014).

opposition surge amplitude of  $3.18 \pm 1.0$  (Clark et al., 1999) is significantly higher than the typical S-type of 1–2. Whether this effect is due to actual physical changes or a decrease in multiple scattering, which is not fully accounted for in Hapke's models, remains to be seen as more asteroids are studied using radiative transfer models over more uniform phase angle sampling. Ceres, an atypical asteroid that is difficult to classify but is akin to the C-types, has an amplitude of only 1.6, so perhaps as more observations are gathered, Mathilde will be shown to be anomalous.

Benner et al. (2008) found a correlation between the roughness of NEA asteroid classes at radar wavelengths and asteroid class, with E- and V-types being the roughest. However, in visible wavelength imaging data, Vesta appears to have a typical (not unusually rough) surface (Li et al., 2013a). This could be explained by the infilling of facets and asperities on the surface by fine particles, similar to the “ponding” seen on Itokawa and Eros, but on a smaller scale, so as not to be detected by radar wavelengths. With the larger gravity field of Vesta, small particles would be more likely to be retained than on the smaller asteroids.

#### 4.3. Context of Geological Process

**4.3.1. Roughness.** The roughness and size scale of features on planetary surfaces yield clues to a wide range of geophysical processes. Heavily cratered surfaces tend to exhibit large slope angles, while bodies that have undergone resurfacing due to volcanism are smoother. The accretion of

dust or volatiles onto a surface could also infill facets to form a smooth surface. For example, the low-albedo hemisphere of Iapetus is smooth because features have been infilled with dust from Saturn's Phoebe ring (Lee et al., 2009). Regions with low surface roughness could be indicative of recent activity involving possible debris flows or ponding (Veverka et al., 2006; Robinson et al., 2001). On Vesta, crater walls tend to be smoother than crater floors due to the accumulation of mass-wasted materials in the crater (Schröder et al., 2013). Differences in roughness also provide a basis for chronology of various terrains, as rougher surfaces have been subjected to more impacts. Global roughness is also affected by the mass of the body: Stronger gravitational wells tend to hold particles that are the result of meteoritic bombardment and that infill surface asperities. Viscous relaxation, which is a function of surface temperature and composition, can also smooth out a surface.

**4.3.2. Particle size and packing status.** Irvine's (1966) model of the opposition shadow hiding effect assumes that particles comprising the regolith are in the geometric optics limit ( $r \gg \lambda$ ), spherical, single-sized, and sufficiently low in albedo so that multiple scattering can be neglected. The amplitude of the surge is determined primarily by a compaction parameter, defined by  $(3/4\pi)(\rho/\rho_0)$ , where  $\rho$  is the bulk density of the regolith particles and  $\rho_0$  is the density of an individual particle. Irvine's model is an analytical one that keeps track of shadows cast by regolith particles, as well as the fraction of individual particles that are visible to the observer and illuminated, as a function of solar phase angle. As compaction parameter increases and the surface becomes less porous, the amplitude of the opposition surge decreases. For Hapke's model of shadow hiding the amplitude of the opposition effect,  $B_{0,SH}$  depends on the transparency of regolith grains;  $B_{0,SH} = 0$  for ideally transparent grains, and  $B_{0,SH} = 1$  for opaque ones. In a collection of uniform particles with no multiple scattering, the angular width parameter  $h_{SH}$  is equal to  $(3/8)K(1-\rho/\rho_0)$  (Hapke, 2012b). As the voids increase,  $h_{SH}$  decreases. In addition, Hapke's latest model (Hapke, 2008, 2012a) presents a more complicated picture where, in general, increasing filling factor (decreasing the porosity) increases the reflectance of low- and medium-albedo powders, but decreases reflectance for those with very high albedos.

Geophysical processes that cause porous surfaces include micrometeoritic bombardment, fallout of frost or dust from volcanic processes, and infall of ambient dust from interplanetary space or from rings. Mechanisms causing more compacted surfaces include annealing by high-energy particles, extrusion of fluids or dust-laden slurries, and viscous slumping. Intermediate porosities are caused by processes such as fluid-like flow of dust and “ponding” of regolith particles.

In the geometric optics limit it is difficult to derive particle sizes, not only because the shadowing process is scale invariant, but also because different combinations of size distributions give similar porosities. The current shadow-hiding models also do not fully account for the effect of multiply scattered photons. These photons will partly illuminate primary shadows so that additional photons are

scattered back into the direction of the observer with the result that the porosity will be underestimated.

## 5. SUMMARY AND FUTURE PERSPECTIVES

In conclusion, we have summarized the most recent developments in asteroid photometry since the publication of *Asteroids III*. Advancements have been made in all three areas of theory, laboratory measurement, and spacecraft observation.

We have shown that photometric modeling is important for understanding what the light-scattering behavior of an asteroid surface can tell us about the physical and compositional properties of the asteroid. We have shown that photometric modeling is important for “correcting” all spectral and imaging data to a common reference viewing geometry before intercomparisons can be made between spectral and imaging observations. And, finally, we have shown that photometric modeling is important for extrapolating specific reflectance calculations to yet-unobserved viewing geometries for the purposes of observation planning, either from the ground or from spacecraft platforms.

As discussed earlier, the past decade has seen improvements in the ability of physically motivated photometric models to accurately relate the observed photometric behavior of a regolith-covered body to the physical properties of the surface and the optical properties of its constituents. Studies suggest that, in particular, the Hapke model is realistic when macroscopic surface relief and complex particle shapes can be ignored (Hapke et al., 2009). However the approach is not entirely reliable and work is especially needed to better understand the opposition effect. In particular, the roles of coherent-backscatter, shadow-hiding, and macroscopic surface roughness need to be clearly resolved and tested. Hapke et al. (2012), for example, found no wavelength dependence of the opposition effect for lunar terrains — a result that conflicts with his model for the CBOE (Hapke, 2002, 2012). The relative contributions of CBOE and SHOE have yet to be clearly resolved in photometric studies. When both opposition effects are fit to planetary data, CBOE typically models a very narrow “opposition spike” at phase angles less than a few degrees, while SHOE, which was formerly invoked to model the entire opposition effect, now typically describes a broader angular component that may extend to a few tens of degrees in width (cf. Helfenstein et al., 1997). This range overlaps with the predicted phase angle effects from macroscopic surface roughness (Hapke, 1984). It may turn out that the individual contributions of each mechanism cannot be uniquely identified by photometric observation alone, and that polarimetric modeling may provide important missing clues (see the chapter by Belskaya et al. in this volume). Furthermore, theoretical models have been tested to the point that the viewing geometry conditions necessary for the retrieval of important physical properties (porosity, and average particle phase functions) of the asteroid surface are now defined (Hapke, 2008; Souchon et al., 2011; Helfenstein and

Shepard, 2011). These developments should be considered in future investigations, specifically from spacecraft platforms.

Laboratory measurements have been critical to the advancement of the theory and the interpretation of spacecraft measurements (e.g., Helfenstein and Shepard, 2011 and references therein).

Finally, spacecraft measurements have been obtained of Ceres, Itokawa, Šteins, Lutetia, Annefrank, and Vesta, and all these data have been fit with photometric models that have deepened our understanding of both asteroid surfaces and the photometric modeling process. We have reviewed how these additional observations can be compared with the existing observations of Gaspra, Ida, and Eros to form the basis of a developing dataset of asteroid light-scattering studies as a function of asteroid spectroscopic classification and mineralogical composition.

Future work should be informed by the need for observations at a wide range of solar phase angles, including near opposition and near or greater than 100° — for the purposes of determining asteroid surface physical characteristics. Future work should also increase the sampling of the spectral classes in observations obtained from spacecraft platforms. Finally, future work should synthesize spacecraft, laboratory, and groundbased surveys of asteroid surface physical properties and their compositional dependence.

Other future work in asteroid photometry might result in sufficient sampling of spatially resolved scattering behavior such that actual physically meaningful scattering model parameters can be mapped across the surface, such as in the work of Sato et al. (2014), who present and interpret Hapke model parameter maps of the lunar surface. These workers find decreased backscattering in the maria relative to the lunar highlands, consistent with known compositional and space weathering differences between maria and highlands, and suggesting powerful new ways to potentially study variations across the surface of an asteroid. For example, the near-future Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) mission will obtain large numbers of repeated observations of the surface of asteroid (101955) Bennu, sampling a wide range of viewing angles for each surface facet, conceivably enabling the first Hapke model parameter maps of an asteroid surface.

---

The application of the polarimetric technique to asteroid studies progressed significantly during the last decade. The most interesting results were the discovery of asteroids with peculiar polarimetric properties, new findings on wavelength dependence of polarization, and some improvements in the polarimetric method of albedo determination. We review instruments that have been and are currently used for asteroid optical polarimetry and summarize the main results of observational surveys. Recent advances in theoretical and laboratory modeling of polarization phase effects and their implications are discussed. We focus on the most important open questions and identify promising avenues for future polarimetric investigations.

## 1. INTRODUCTION

Polarimetry is a powerful tool to study surface properties, putting constraints on albedo and surface texture. The state of partial linear polarization of the sunlight scattered by planetary surfaces in different illumination conditions is diagnostic of refractive index, particle size, packing density, optical heterogeneity, etc.

The application of the polarimetric technique to asteroid studies has a long history beginning in 1934, when the first polarization measurements of bright asteroids were obtained by B. Lyot using a photographic polarimeter. Since 1954, photoelectric polarimeters have been used to measure asteroid polarization with better accuracy. Results of polarimetric observations of six asteroids were discussed by A. Dollfus in the first review devoted to polarimetry of asteroids (Dollfus *et al.*, 1971). In the first *Asteroids* book, the chapter on optical polarimetry included a review of polarimetric observations for about 100 asteroids and their interpretation based on laboratory studies (Dollfus and Zellner, 1979). All measured asteroids were found to show so-called negative polarization at small phase angles. This is better expressed using, as a fundamental parameter, the polarization degree

$P_p$  defined in terms of the intensities of the scattered light polarized along the planes perpendicular  $I_{\perp}$  and parallel  $I_{\parallel}$  to the scattering plane

$$P_p = \frac{I_{\perp} - I_{\parallel}}{I_{\perp} + I_{\parallel}}$$

Such a definition means that the sign of the polarization degree  $P_p$  can be negative when the component  $I_{\parallel}$  with the electric vector parallel to the scattering plane predominates over the perpendicular component  $I_{\perp}$ . To achieve a detailed physical explanation of the phenomenon of negative polarization is a challenging task. In the *Asteroids II* volume, Dollfus *et al.* (1989) reviewed the first attempts of theoretical modeling of negative polarization, but these were later found to give unrealistic results (Shkuratov *et al.*, 1994). Dollfus *et al.* (1989) also described telescopic observations of asteroids and relevant laboratory data obtained after the review published in the first *Asteroids* book (Dollfus and Zellner, 1979).

In *Asteroids III*, Muinonen *et al.* (2002) reviewed some new theoretical and experimental findings on both photometric and polarimetric phase effects, and reported significant progress in understanding the physical nature of negative

polarization in terms of the multiple-scattering mechanism of coherent backscattering.

Detailed reviews on various aspects of the application of the polarimetric technique to study solar system bodies can also be found in the books by *Mishchenko et al.* (2010) and *Kolokolova et al.* (2015). In the latter, the chapters by *Cellino et al.* (2015a), *Muinonen et al.* (2015), and *Levasseur-Regourd et al.* (2015) summarize the role of polarimetric investigations in asteroid science and the status of theoretical modeling and laboratory measurements, respectively.

In the present chapter, we focus on the achievements in optical polarimetry of asteroids since *Asteroids III*. In section 2, we review the instruments and telescopes available for asteroid polarimetry. Section 3 summarizes the new findings obtained from recent observational surveys. A review of progress in analytical, numerical, and laboratory modeling of polarization phase effects is given in section 4. We discuss the main applications of the polarimetric observations to study asteroid surfaces in section 5. Finally, in section 6, we outline the future prospects for polarimetric studies.

## 2. TELESCOPES AND INSTRUMENTS

In the 1980s, and up to the end of the 1990s, the majority of the asteroid polarimetric observations were made using multichannel photopolarimeters of a kind originally designed by *Pirola* (1973). These instruments allowed simultaneous measurements in the UBVRI bands using five separate photomultipliers. One such instrument has been operated at the 1.25-m telescope of the Crimean Astrophysical Observatory in Ukraine since 1983. A detailed description of this instrument and a review of the obtained results are given by *Mishchenko et al.* (2010).

Another essentially identical instrument, built at the Astronomical Observatory of Torino in Italy (*Scaltriti et al.*, 1989), began operations in 1994 at the 2.1-m telescope of the Complejo Astronómico El Leoncito (CASLEO) in Argentina (*Cellino et al.*, 1999, 2005a). These two instruments, often used for joint observational programs, provided a large set of multi-band polarimetric observations of main-belt asteroids (*Belskaya et al.*, 2009a). The main limitation was a bright magnitude limit ( $V \sim 13$  mag). Since 2000, a new double-hole aperture polarimeter with rapid modulation provided by a rotating achromatic half-wave retarder and a Wollaston prism beam-splitter started operations at CASLEO (*Gil-Hutton et al.*, 2008), and allowed the observers to reach fainter magnitudes ( $V \sim 15$  mag). The CASLEO instruments were used for a long-term observational survey that provided polarimetric observations of more than 250 main-belt asteroids (see, e.g., *Gil-Hutton et al.*, 2014).

A new epoch in asteroid polarimetric observations has begun with new polarimeters developed around CCD detectors and the use of modern multi-mode instruments in polarimetric mode. In the period 2002–2006, a polarimetric survey of about 40 asteroids was carried out using the polarimetric mode of the Faint Object Spectrographic Camera (AFOSC) mounted at the 1.8-m telescope of the Astrophysical Ob-

servatory of Asiago in Italy (*Fornasier et al.*, 2006a). This polarimeter allows simultaneous measurements of the polarized flux at angles  $0^\circ$ ,  $45^\circ$ ,  $90^\circ$ , and  $135^\circ$  using a wedged double Wollaston prism (*Oliva*, 1997). These four beams are sufficient to determine the linear polarization parameters I, Q, and U with a single exposure. The great advantage of the instrument is that the obtained data do not depend on atmospheric changes as in the case of multiple exposures. The Asiago polarimeter has been moved to the Nordic Optical Telescope (NOT) in La Palma (Canary Islands, Spain) in 2010 and continued to be used for asteroid polarimetry (*Fornasier et al.*, 2015). An identical instrument has been recently built at the Torino observatory, and attached to a 1-m telescope of the observatory of Nice (France), located in Calern (*Pernechele et al.*, 2012). At the same time, the old polarimeters at CASLEO based on photomultiplier tubes were recently replaced by a new dual-beam imaging polarimeter, CASPOL (*Gil-Hutton et al.*, 2014), allowing a gain of about 2–3 mag over the previous instruments.

There are also other instruments that have been used for asteroid polarimetry during the last decade, including the dual-beam imaging polarimeter installed at the 2.2-m telescope of the University of Hawaii at Mauna Kea (*Masiero et al.*, 2007) and the Bologna Faint Object Spectrograph and Camera (BFOSC) in the imaging-polarimetry mode at the 1.52-m Cassini telescope of the Astronomical Observatory of Bologna, Italy. Recently, polarimetry of asteroids started with the SPOL spectropolarimeter at the Steward Observatory 2.3-m and 1.54-m telescopes (*Maleszewski et al.*, 2013).

Major part of the polarimetric observations of asteroids have been obtained using telescopes up to  $\sim 2$  m in diameter, allowing measurement of only relatively bright objects. The first polarimetric observations using large telescopes took place in 2005 when one of the 8.2-m units of the Very Large Telescope (VLT) at the European Southern Observatory's (ESO) Cerro Paranal observatory in Chile was used to study the asteroid (2867) Steins. This object, a target of the European Space Agency (ESA) Rosetta mission, was observed with the Focal Reducer/Low Dispersion spectrograph (FORS) in polarimetric mode (*Fornasier et al.*, 2006b). The mode uses a half-wave phase retarder and a Wollaston prism as a beam splitter (*Appenzeller et al.*, 1998; *Bagnulo et al.*, 2011). In the following years, new VLT observations were devoted to studies of the potentially hazardous near-Earth asteroids (NEAs) (*Delbò et al.*, 2007; *De Luise et al.*, 2007), some selected main-belt asteroids (*Cellino et al.*, 2010, 2014), and Jupiter Trojans (*Belskaya et al.*, 2014). To start an observing program on spectropolarimetry of asteroids, *Bagnulo et al.* (2015) used FORS at VLT and the ISIS instrument of the 4.2-m William Herschel Telescope (WHT) of the Isaac Newton Group of Telescopes. In spite of the different instruments used at different observing sites, asteroid polarimetric data have always been found to be in very good mutual agreement.

A comprehensive review on various techniques and devices used in optical and near-infrared polarimetry is given by *Hough* (2005). Modern approaches to the design of

astronomical polarimeters and a list of currently available polarimeters at ground-based telescopes can be found in the review by *Keller et al.* (2015).

### 3. NEW FINDINGS FROM OBSERVATIONS

During the last decade, polarimetric observations of asteroids have become more frequent. Several observing campaigns have been carried out to characterize the polarimetric behavior of asteroids of different composition types (*Belskaya et al.*, 2003, 2005; *Fornasier et al.*, 2006a; *Gil-Hutton*, 2007; *Gil-Hutton et al.*, 2008, 2014; *Gil-Hutton and Cañada-Assandri*, 2011; *Cañada-Assandri et al.*, 2012). Many observing projects have been devoted to the study of specifically selected targets, including near-Earth asteroids (*Kiselev et al.*, 2002; *De Luise et al.*, 2007; *Delbò et al.*, 2007; *Belskaya et al.*, 2009b; *Masiero*, 2010), members of dynamical families (*Cellino et al.*, 2010), Trojans (*Belskaya et al.*, 2014), targets of space missions (*Cellino et al.*, 2005b; *Fornasier et al.*, 2006b; *Belskaya et al.*, 2010; *Hadamcik et al.*, 2011), and several individual objects (*Antonyuk and Kiselev*, 2012; *Bagnulo et al.*, 2010; *Cellino et al.*, 2006; *Masiero and Cellino*, 2009). Observations in order to investigate polarimetric behavior at very small phase angles were carried out by *Belskaya et al.* (2003), *Rosenbush et al.* (2005, 2009), and *Cellino et al.* (2005a). The latter paper aimed at providing an independent estimate of the albedos of small asteroids previously observed at thermal IR wavelengths by the Infrared Astronomical Satellite (IRAS). The wavelength dependence of asteroid polarization has been the subject of papers published by *Belskaya et al.* (2009a), *Gil-Hutton et al.* (2014), and *Bagnulo et al.* (2015).

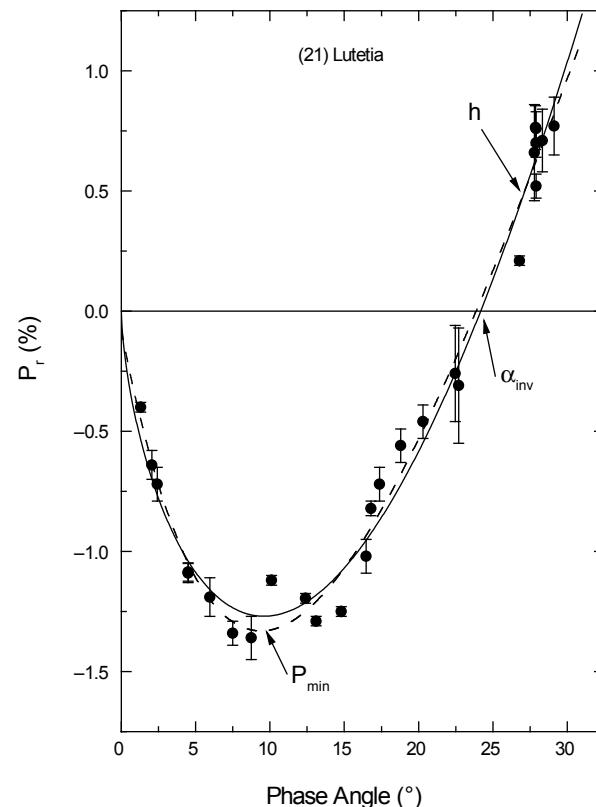

The number of asteroids for which polarimetric measurements are available reaches now  $\sim 350$ , almost  $3 \times$  the number at the time of the original *Asteroids* volume (*Dollfus and Zellner*, 1979). However, the number of asteroids with well-defined polarization phase curves did not increase substantially. For most asteroids, we have at our disposal measurements obtained at only few phase angles, which is not enough for an accurate determination of the main polarimetric parameters. To measure the depth and width of the polarization branch of an asteroid, observations at least at 5–6 different phase angles distributed from  $5^\circ$  to  $7^\circ$  to  $25^\circ$  to  $30^\circ$  are needed.

There are asteroids for which we have polarimetric observations obtained during several oppositions. For example, Fig. 1 shows a detailed polarization phase curve measured for the asteroid (21) Lutetia, a target of the Rosetta mission. The data were obtained during 10 apparitions in 1973–2011 by different authors (*Zellner and Gradie*, 1976; *Belskaya et al.*, 2010, and references therein; *Gil-Hutton et al.*, 2014). The scatter of the data for this asteroid may be a consequence of its surface heterogeneity (*Belskaya et al.*, 2010).

The behavior of the polarization phase curve is characterized by several parameters: the extreme value of the negative polarization branch  $P_{\min}$ , which occurred at the phase angle  $\alpha_{\min}$ ; the inversion angle  $\alpha_{\text{inv}}$  at which the polarization degree

changes its sign; and the polarimetric slope of the ascending branch  $h$  (Fig. 1). These parameters are typically derived by using the so-called trigonometric fit (*Lumme and Muinonen*, 1993) or the linear-exponential function (*Kaasalainen et al.*, 2003; *Muinonen et al.*, 2009). The trigonometric fit, using four free parameters (two of them can be fixed), provides a physically reasonable behavior of the polarization-phase dependence in a wide range of phase angles up to the polarization maximum  $P_{\max}$  at  $\alpha_{\max} \sim 100^\circ$  (see *Penttilä et al.*, 2005). The four-parameter linear-exponential function fits well the phase curve up to  $\alpha \sim 30^\circ$  and can be used for a joint fit of polarimetric and photometric phase curves (see *Muinonen et al.*, 2009). For a well-sampled phase curve, both fits give almost identical results (Fig. 1).

The polarimetric observations available are collected in the Asteroid Polarimetric Database (APD) at the Small Bodies Node of the Planetary Data System. The database has been compiled by *Lupishko and Vasiliev* (1997) and is updated annually (*Lupishko*, 2014). There are also other databases that include polarimetric data obtained in the specific papers (e.g., *Belskaya et al.*, 2009a,b; *Cellino et al.*, 2006; *Gil-Hutton et al.*, 2008). Below, we have summarized the most interesting recent findings on the polarimetric properties of asteroids.

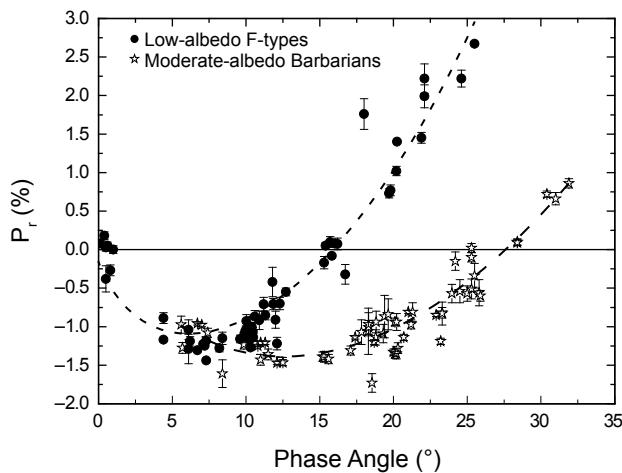

**Fig. 1.** Polarization phase-angle dependence of asteroid (21) Lutetia measured in 1973–2011 in the V-band (see text for references). The main polarimetric parameters  $P_{\min}$ ,  $\alpha_{\text{inv}}$ , and the polarimetric slope  $h$  are indicated by arrows. The solid line shows the trigonometric fit and the dashed line corresponds to the linear-exponential fit (see text).

### 3.1. Asteroids with Small Inversion Angles

In the first polarimetric survey of asteroids (Zellner and Gradie, 1976), the asteroid (704) Interamnia was found to have an unusually small inversion angle of about  $16^\circ$ . Small inversion angles typically indicate a bare rock surface (see Fig. 5). Dollfus and Zellner (1979) pointed out that it is unlikely that (704) Interamnia is the only dust-free asteroid, and assumed some peculiar surface composition of this asteroid. Belskaya *et al.* (2005) measured an even smaller inversion angle of about  $14^\circ$  for the asteroid (419) Aurelia. Both of these asteroids had been previously classified by Tholen (1989) as belonging to the rare F taxonomic class. In order to assess whether a small inversion angle could be a characteristic feature of F-class asteroids, observations of these asteroids were continued (Belskaya *et al.*, 2005; Fornasier *et al.*, 2006a; Gil-Hutton *et al.*, 2012, 2014). As a result, four more F-type asteroids, (213) Lilaea, (302) Clarissa, (325) Roberta, and (1021) Flammario, were found to have small inversion angles. The polarization phase curve of the above-mentioned asteroids is shown in Fig. 2. Their inversion angles do not exceed  $17^\circ$ .

Up to now, all known cases of asteroids exhibiting small inversion angles concern the F class. The most distinctive spectral feature of these asteroids, as compared to the other taxonomic classes, is the absence of UV absorption features at short wavelengths. More recent taxonomic classifications (Bus and Binzel, 2002; DeMeo *et al.*, 2009) use reflectance spectra covering only the visible and near-IR wavelengths and they can no longer identify a separate F class. Asteroids previously classified as F belong today mostly to the larger B or C classes. Gil-Hutton and Cañada-Assandri (2012) analyzed data obtained for 58 B- and C-type objects and found an indication of smaller inversion angles for several objects previously classified as F type.

**Fig. 2.** Extreme cases of asteroid polarization phase curves (see text for references). Data for the low-albedo F-type asteroids are shown by black circles. Polarization measurements of the moderate-albedo Barbarians are shown by asterisks. The dash and dotted lines display the fits using the trigonometric function (Lumme and Muinonen, 1993).

Unlike other very dark primitive asteroids, F-class objects are relatively abundant in the inner asteroid belt, a large fraction of them being associated with the Polana family (Cellino *et al.*, 2001; Milani *et al.*, 2014). At the same time, they may be also related to extinct cometary nuclei (Kolokolova and Jockers, 1997). Polarimetric observations of two cometary nuclei, 2P/Encke (Boehnhardt *et al.*, 2008) and 133P/Elst-Pizarro (Bagnulo *et al.*, 2010), also suggest a small inversion angle similar to the F-type asteroids.

Belskaya *et al.* (2005) proposed a possible interpretation of the particular polarimetric properties of the asteroid (419) Aurelia and the other F-class asteroids. It was shown that an optical homogeneity of asteroid regolith microstructure at scales on the order of visible light wavelengths may be responsible for relatively small values of the depth of the negative polarization branch and the inversion angle (Belskaya *et al.*, 2005). One of the feasible mechanisms can be the existence of carbon deposits on the regolith particles of F-class asteroids, making them optically more homogeneous than other classes of low-albedo asteroids. This assumption is in agreement with the almost flat spectra characterizing the F class.

Polarimetric observations can therefore be crucial in the identification of new F-type objects among asteroids recently classified as B class, and possibly to strengthen the preliminary indications of analogies with the polarimetric behavior of comets.

### 3.2. Asteroids with Large Inversion Angles

Polarimetric observations of the moderate-albedo asteroid (234) Barbara unexpectedly revealed considerable negative polarization  $P_r \sim -1.2\%$  at phase angles  $\alpha \geq 20^\circ$  (Cellino *et al.*, 2006). This result was surprising, because all other asteroids previously observed have zero or positive polarization at such large phase angles, which are close to the typical inversion angle of “normal” asteroids. Further observations of (234) Barbara confirmed a wide branch of negative polarization with an inversion angle  $\alpha_{inv} \sim 28^\circ$  (Gil-Hutton *et al.*, 2008; Masiero *et al.*, 2009). Apart from the large inversion angle, the polarization phase curve of asteroid (234) Barbara is characterized by a fairly deep branch of negative polarization (see Fig. 2). Cellino *et al.* (2006) suggested that such atypical polarimetric behavior for a moderate-albedo surface might be due to some unusual surface properties related to the rare Ld taxonomic classification of (234) Barbara (Bus and Binzel, 2002). Asteroids of the Ld class are characterized by a particularly reddish reflectance spectrum (Bus and Binzel, 2002), and had not been observed previously in polarimetry. Gil-Hutton *et al.* (2008) later found four more asteroids displaying the same Barbara-like polarimetric behavior. They are the L-class asteroids (172) Baucis, (236) Honoria, and (980) Anacostia, and the K-class asteroid (679) Pax. It was then also noticed that at least two asteroids with particular polarimetric behavior, Barbara and Anacostia, had in their spectra strong spinel features (Sunshine *et al.*, 2007). According to Burbine *et al.* (1992), the asteroids (980) Anacostia and (387) Aquitania,

which have quite similar orbits, share the property of being spinel-rich, suggesting that they could be fragments of the breakup of a spinel-rich parent body with affinities to carbonaceous CO3/CV3 chondrites. Subsequent observations of (387) Aquitania also revealed a Barbara-like polarimetric behavior, confirming the existence of a relation between the unusual mineralogical and polarimetric properties of these asteroids (*Masiero and Cellino*, 2009). *Gil-Hutton et al.* (2014) later found two more “Barbarians,” the K-type asteroid (402) Chloe and the L-type (729) Watsonia.

Among the eight asteroids with large inversion angles that were known at the beginning of 2014, at least two were members of the Watsonia family identified by *Novaković et al.* (2011). This fact raised the question of polarimetric properties of other Watsonia family members. *Cellino et al.* (2014) carried out observations of a sample of nine objects belonging to the Watsonia family and found that seven of them are characterized by polarization curves with large inversion angles. These authors concluded that the Watsonia family is a repository of Barbarians. This strengthens the hypothesis that the peculiar mineralogical composition of these objects should be responsible for their unusual polarization properties.

A common characteristic of the Barbarians is their classification as L, Ld, or K types according to taxonomic classifications based on visible wavelength data (*Bus and Binzel*, 2002). On the other hand, not all the asteroids belonging to these taxonomic classes show large inversion angles (e.g., *Gil-Hutton et al.*, 2014). Some misclassification due to similar spectroscopic properties in the visible may be present. This is confirmed by the fact that, if one looks at the more recent taxonomic classification by *DeMeo et al.* (2009), which is based on data that also includes the near-IR, all Barbarians currently known for which a DeMeo classification is available belong to the same class (L).

A possible interpretation of the peculiar polarimetric properties of Barbarians is related to the presence of spinel in calcium-aluminum-rich inclusions (CAIs) at their surfaces. Spinel is characterized by an unusually high refractive index, which might be related to the unusual polarimetric behavior of these objects (*Sunshine et al.*, 2007; *Gil-Hutton et al.*, 2008; *Masiero et al.*, 2009).

The search for new asteroids with large inversion angles continues. They can be easily identified by polarimetric observations at phase angles around 20°.

### 3.3. Polarization Behavior at Small Phase Angles

The interest in obtaining polarimetric observations at small phase angles is related to the understanding of the coherent-backscattering mechanism. This contributes to photometric and polarimetric phase dependences producing sharp features near opposition (see *Muinonen et al.*, 2002, for a review). The first pieces of evidence for the existence of polarization opposition peaks were found for high-albedo Galilean satellites of Jupiter by *Rosenbush et al.* (1997). After this discovery, extensive observations of the high-albedo

asteroids were made to search for a possible polarization opposition surge. *Rosenbush et al.* (2005) presented UBVRI polarimetric observations of the E-type asteroid (64) Angelina made in three apparitions with detailed coverage of small phase angles up to 0.4°. These authors claimed the discovery of a sharp peak of negative polarization superimposed on the regular branch. The peak has an amplitude of ~0.4% centered at a phase angle  $\alpha \sim 1.8^\circ$  (*Rosenbush et al.*, 2005). The authors found that the amplitude and position of the polarization peak was slightly different before and after opposition and at different apparitions. New observations by *Zaitsev et al.* (2014) revealed a secondary minimum at  $\alpha \sim 1.5^\circ$ . They underscored that further polarimetric observations of Angelina at  $\alpha \sim 3^\circ$ – $5^\circ$  are needed to reach a final conclusion on the shape of the phase dependence near opposition. *Rosenbush et al.* (2009) carried out observations of another high-albedo asteroid, (44) Nysa, at very small phase angles down to 0.4°. A polarization opposition effect with an amplitude of ~0.3% centered at  $\alpha \sim 0.8^\circ$  was found. *Rosenbush et al.* (2009) put together all polarimetric measurements for the E-type asteroids and concluded that a sharp secondary minimum is present at  $\alpha \sim 1^\circ$ .

Polarimetric measurements of the V-type asteroid (4) Vesta (*Mishchenko et al.*, 2010) and the S-type asteroid (20) Massalia (*Belskaya et al.*, 2003) did not reveal any sharp features at small phase angles.

We compare the polarization behavior at small phase angles for high- and moderate-albedo asteroids in Fig. 3. We plotted together all available measurements in the V and R bands having an accuracy of  $\sigma_p < 0.1\%$ . The moderate-albedo asteroids show a deeper negative branch down to very small phase angles. To confirm the existence of a secondary peak of negative polarization for high-albedo asteroids, more detailed and accurate measurements at  $\alpha \sim 1^\circ$ – $2^\circ$  seem to be required.

Among low-albedo asteroids, detailed observations at small phase angles were obtained for the F-type asteroid (1021) Flammario (*Fornasier et al.*, 2006a). The VRI observations at the phase-angle range of 0.1°–1° show zero or slightly positive polarization in all filters, both before and after opposition. *Fornasier et al.* (2006a) suggested a possible explanation related to the effect of surface anisotropy. Further observations of this asteroid are needed to conclude whether or not the measured peculiarity is real.

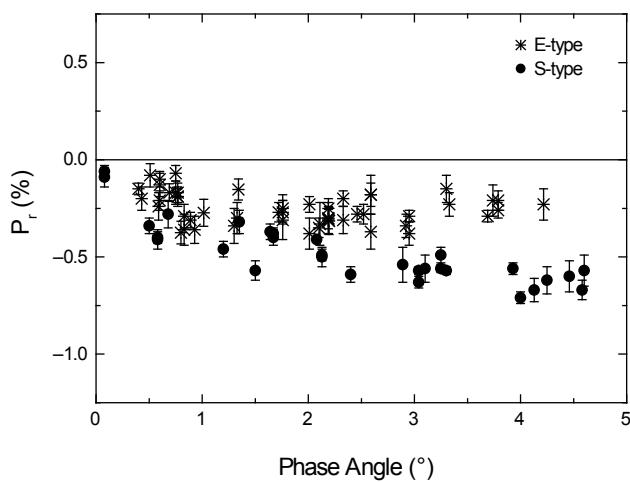

### 3.4. Spectral Dependence of Polarization Parameters

The first pioneering studies of the spectral dependence of linear polarization for the asteroids were based on broadband multi-color measurements. *Belskaya et al.* (2009a) analyzed the observations available in UBVRI colors for 52 main-belt asteroids. Within the accuracy of the measurements, the dependence of the degree of linear polarization upon wavelength in the spectral range of 0.37–0.83 μm was generally found to be rather weak and well described by a linear trend. It was also shown that moderate- and low-albedo asteroids exhibit opposite trends. This behavior, previously

found for several C- and S-type asteroids (*Belskaya et al.*, 1987; *Lupishko and Kiselev*, 1995), was confirmed with better statistics.

More recently, *Bagnulo et al.* (2015) have published the first example of full-fledged spectropolarimetric measurements of asteroids for a sample of 12 asteroids. The obtained results are in agreement with the *Belskaya et al.* (2009a) findings. Polarization data covering the spectral range of 0.39–0.93  $\mu\text{m}$  have a positive linear slope as a function of wavelength in the case of low-albedo asteroids, whereas moderate-albedo asteroids show a negative linear slope. We note that the values of polarization degree were considered with their signs, i.e., a *negative* spectropolarimetric slope means, for increasing wavelength, *more* polarization in the red in the negative branch and *less* polarization in the red in the positive branch. Conversely, if one considers the spectral behavior of the absolute value of  $P_r$ , the sign of the spectral gradients  $|\Delta P_r|/\Delta \lambda$  for the negative and positive branches is found to have opposite values. The latter approach had been previously adopted by *Lupishko and Kiselev* (1995), who discussed the inversion of the polarization spectral dependence for the S-class asteroids. Differences in the definition of the spectropolarimetric slopes, however, do not influence the interesting conclusion about the occurrence of opposite spectropolarimetric behavior for moderate- and low-albedo asteroids. For increasing wavelength, the negative branch of moderate-albedo asteroids becomes deeper, whereas the positive polarization becomes shallower. Low-albedo asteroids exhibit exactly an opposite behavior (*Belskaya et al.*, 2009a; *Bagnulo et al.*, 2015).

Several exceptions exist, however. Two moderate-albedo asteroids with large inversion angles, (234) Barbara and (599) Luisa, showed a shallower negative branch for increasing wavelength, while another Barbarian, (236) Honoria, has

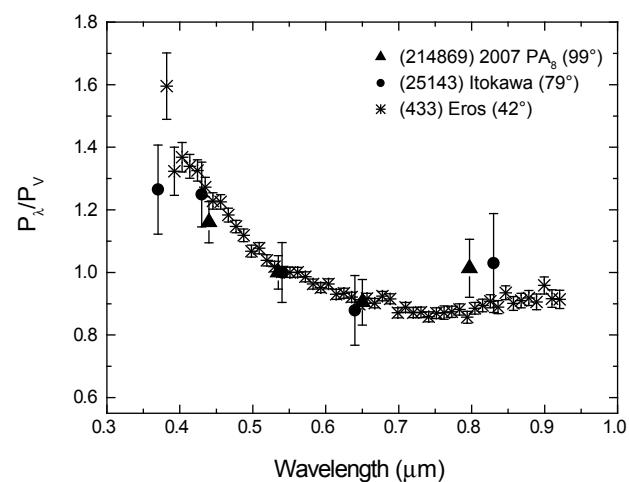

**Fig. 3.** Polarization dependence at small phase angles for the high-albedo E-type (*Zellner and Gradie*, 1976; *Rosenbush et al.*, 2005, 2009; *Zaitsev et al.*, 2014) and the moderate-albedo S-type asteroids (*Zellner and Gradie*, 1976; *Belskaya et al.*, 2003; *Fornasier et al.*, 2006a; *Gill-Hutton et al.*, 2014).

an opposite trend, typical for moderate-albedo asteroids (*Belskaya et al.*, 2009a; *Bagnulo et al.*, 2015). Among low-albedo asteroids, (87) Sylvia and (386) Siegena were mentioned as having atypical wavelength behavior (*Belskaya et al.*, 2009a). New and more accurate polarimetric measurements of these objects are needed to clarify the situation.

Note that the study of the spectral dependence of positive polarization for low-albedo asteroids is still based on a small amount of data. What seems reasonably certain is that the polarization spectra of Ceres and Pallas measured at  $\alpha \sim 22^\circ$ – $23^\circ$  are characterized by a similar increase of polarization degree with wavelength (*Bagnulo et al.*, 2015).

As for moderate-albedo asteroids, some spectral gradients of positive polarization have been reliably measured so far for several NEAs. The BVRI polarimetry of the Q-type NEA 214869 (2007 PA<sub>8</sub>) close to  $P_{\max}$  shows a nonlinear wavelength dependence of polarization (*Fornasier et al.*, 2015) that is similar to that of other moderate-albedo asteroids measured at large phase angles (Fig. 4). A similar nonlinear polarization spectrum was measured for the S-type asteroid (433) Eros at a phase angle of  $42^\circ$  (*Bagnulo et al.*, 2015). The spectropolarimetric behavior of these S- or Q-type NEAs shows an inverse correlation with the reflectance spectra in accordance with the Umov effect (*Umov*, 1905). A decrease of reflectance due to the 1- $\mu\text{m}$  absorption feature results in an increase of polarization degree at  $\lambda > 0.8 \mu\text{m}$ .

For the negative branch, the correlation between the spectropolarimetric spectrum and the spectral reflectance is more complex. *Bagnulo et al.* (2015) have shown that some asteroids with similar reflectance spectra exhibit totally different polarization spectra. As a rule, the negative polarization of S-type asteroids becomes stronger at longer wavelengths for increasing albedo, i.e., a higher albedo corresponds to a deeper  $|P_{\min}|$ . This contradicts the well-known

**Fig. 4.** Wavelength dependence of moderate-albedo NEAs (433) Eros (*Bagnulo et al.*, 2015), (25143) Itokawa (*Celilino et al.*, 2005b), and (214869) 2007 PA<sub>8</sub> (*Fornasier et al.*, 2015). The phase angle at which the dependence was measured is shown in parentheses.

inverse correlation of  $|P_{\min}|$  and albedo used for asteroid albedo estimations. Low-albedo asteroids tend to follow the more usual inverse correlation of  $|P_{\min}|$  and albedo.

More in general, it seems that asteroid spectropolarimetry promises to be a very important tool for the physical characterization of asteroids. The reason is that one single spectropolarimetric measurement is able to provide, at the same time, the information usually included separately in spectroscopic and polarimetric data, complemented with the dependence of polarization upon wavelength, another piece of information needed to classify asteroid behavior.

#### 4. ADVANCES IN THEORETICAL AND EXPERIMENTAL MODELING

##### 4.1. Theoretical Modeling

The understanding of the physical mechanisms responsible for the formation of the negative branch of polarization continues to improve. The role of the coherent-backscattering mechanism (CBM) was discussed in detail in *Asteroids III* by Muinonen et al. (2002). The CBM contributes both to the photometric and polarimetric phase dependences, producing sharp features near opposition. To explain broad negative branches, the contribution of single-particle scattering becomes important (e.g., Shkuratov et al., 1994, 2006; Lumme and Rahola, 1998). Recently, a standing-wave polarization mechanism (SWM) has been proposed for the negative linear polarization of single spherical and nonspherical particles (Muinonen et al., 2011). The SWM for negative polarization relies on the generation of forward- and backward-propagating internal waves within the single-scattering particles. Near the particle perimeter, these wave components form a standing wave that constitutes itself as an interference dial (Muinonen et al., 2011). For a linearly polarized incident wave, the internal standing wave, partially linearly polarized as the incident wave, tends to be stronger in the central plane perpendicular to the incident polarization. Due to an interference effect largely resembling that of the CBM, the backward-propagating wave component gives rise to negative polarization.

Several attempts were made to simulate the negative polarization of particulate surfaces. Computer modeling has been carried out by Shkuratov et al. (2002) and Stankevich et al. (2007), and applied to explain some systematic trends observed in laboratory measurements.

The successful application of the discrete dipole approximation (DDA) method to the interpretation of the polarization properties of cometary dust (e.g., Zubko et al., 2008; Lasue et al., 2009) is also noted. In particular, an analog of the Umov effect was found for single-particle scattering (Zubko et al., 2011).

Mishchenko et al. (2009) used numerically exact computer solutions of the Maxwell equations to simulate electromagnetic scattering by realistic models consisting of large numbers of randomly positioned, densely packed particles. They have shown that the negative polarization produced by

the coherent-backscattering effect is remarkably immune to packing-density effects. In this case, the negative polarization branch may become rather wide. The branch survives the increasing density, even if the characteristic distances between particles are on the order of the wavelength.

Petrov et al. (2011) developed Sh-matrix methods within the T-matrix formalism, which allows for the derivation of analytic solutions to the light scattering by nonspherical particles. This allows for a more efficient study of scattering by irregularly shaped particles.

Quantitative agreement was documented between the computations by the radiative-transfer coherent-backscattering method (RT-CB) (Muinonen, 2004) and the superposition T-matrix method (STMM) based on a direct computer solver of the Maxwell equations (Muinonen et al., 2012). The RT-CB method can make use of so-called phenomenological fundamental single scatterers (Muinonen and Videen, 2012). An extension of the RT-CB method to a realistic particulate model for an asteroid's surface is in progress.

##### 4.2. Laboratory Experiments

Laboratory measurements devoted to the interpretation of asteroid polarimetry were rather scarce last decade (e.g., Shkuratov et al., 2008). Measurements of possible meteorite analogs of the surfaces of asteroids (21) Lutetia and (2867) Steins, the targets of the Rosetta mission, were made by Hadamcik et al. (2010, 2011). An average size of regolith grains smaller than 50  $\mu\text{m}$  was suggested from the measurements.

The influence of particle size on the polarization phase curve was studied on particle-size separates of bright and absorbing powders (Ovcharenko et al., 2006; Shkuratov et al., 2008). They showed that the contributions of both the CBM and single-particle scatter are functions of particle size.

Several experiments were made to compare polarimetric properties of single particles and powdered surfaces (see Levasseur-Regourd et al., 2015, for a review). Shkuratov et al. (2007, 2008) showed that the negative polarization strengthened and the polarization degree at large phase angles increased with surface compression. The number density of the particles was found to have a major effect on the polarization maximum (Hadamcik et al., 2009).

Promising results were obtained when comparing laboratory measurements and results of numerical DDA simulations: Zubko et al. (2013) used experimentally measured refractive-index and size-distribution data for irregular feldspar particles to compute Mueller-matrix elements, obtaining highly consistent results.

Laboratory studies of structural analogs of asteroid regoliths remains in great need of further progress in interpreting polarimetric measurements of asteroids.

#### 5. POLARIMETRIC MEASUREMENTS AS A TOOL TO ASSESS SURFACE PROPERTIES

The interpretation of polarimetric observations of asteroids in terms of physical parameters is still not straightforward.

The main conclusions about asteroid surface properties as derived from polarimetric measurements are mostly based on empirical relationships. Particular importance has been paid to the relation between polarimetric parameters and albedo, and the analysis of similarities and differences in the polarization behavior of various objects.

### 5.1. Polarimetric Method of Asteroid Albedo Determination

Polarimetry is one of the best available techniques to derive the albedo from remote observations. An advantage is that an estimate of the albedo can be derived directly from polarimetric measurements without any need of ancillary information from other sources (*Bowell and Zellner*, 1974; *Zellner and Gradie*, 1976; *Zellner et al.*, 1977). This is in contrast with other possible methods of albedo determination, primarily from thermal radiometry, for which the accuracy is limited by the uncertainties in the adopted values of the absolute magnitude. In fact, a few single measurements of polarization degree at a phase angle within 7°–10° (near the extreme values of negative polarization) or even one single measurement at phase angles larger than 30° (in the positive branch of polarization) can be enough to conclude whether an asteroid has a low-, moderate-, or high-albedo surface. In order to determine a more precise value for the albedo (geometric albedo), the observations should cover at least four different phase angles to measure the polarimetric slope  $h$  with good accuracy. This number of observations is a minimum to reach a reliable result. This also constitutes a practical problem, due to the effort needed to observe the target in several observing runs, to allow the necessary change in the phase angle.

Another problem is the one of producing a reliable calibration of the empirical relationships “albedo–polarimetric slope” and “albedo– $P_{\min}$ ” used to determine the albedos of asteroids. Historically, these relations were derived from laboratory measurements of meteorites and then used to determine asteroid albedos (*Zellner and Gradie*, 1976).

Several attempts have been made since then to better calibrate the relationship using the albedos of asteroids available from radiometry and/or from stellar occultations (*Lupishko and Mohamed*, 1996; *Cellino et al.*, 1999, 2012; *Masiero et al.*, 2012). Most recently, *Cellino et al.* (2015b) performed a new, detailed analysis of the calibration problem of the relations between the geometric albedo and the polarization parameters of the asteroids.

In all the above mentioned papers, the authors derived their own values for the constant parameters  $C_1$  and  $C_2$  of the commonly adopted relationship between the geometric albedo  $A_g$  and polarimetric slope  $h$ , namely

$$\log(A_g) = C_1 \log(h) + C_2 \quad (1)$$

We have analyzed how adopting different published calibrations influences the derived values of albedo. Table 1 lists

the available sets of constants  $C_1$  and  $C_2$  found by different authors and the references to the corresponding papers. We also give the albedos calculated from equation (1) for three fixed values of the polarimetric slopes  $h$  corresponding to low-, moderate-, and high-albedo asteroids. For low- and moderate-albedo surfaces, the uncertainties in the polarimetric albedos due to different calibrations are comparable with the uncertainties caused by the errors in the measurements of the polarimetric slope  $h$ . A noticeable discrepancy appears in the case of high-albedo surfaces. Further investigation of the relationship of polarimetric slope and albedo for high-albedo asteroids is crucial to choose the best calibration.

The use of  $P_{\min}$  for albedo determination gives less-confident results. For example, in Fig. 2 the polarization phase curve of the F-type objects and that of the Barbarians show similar values of  $P_{\min}$  in spite of these objects having very different albedos. *Cellino et al.* (2015b) found large discrepancies between  $P_{\min}$ -derived albedos and those obtained from other data and recommend avoiding the use of  $P_{\min}$  for the albedo estimation.

There were also some attempts to find new polarimetric parameters that better correlate with albedo. *Masiero et al.* (2012) introduced a new polarimetric quantity  $p^*$  combining  $\log(h)$  and  $\log(P_{\min})$  in order to describe the maximum polarimetric variation when compared with the albedo and presented the albedo– $p^*$  relation. *Cellino et al.* (2015b) proposed using the difference in polarization degree at  $\alpha = 30^\circ$  and  $\alpha = 10^\circ$  as a new parameter. The comparison of albedos derived from different polarimetric parameters was generally in favor of the polarimetric slope  $h$ , mainly in cases when the coverage of the phase-polarization curve is not optimal. In these cases, a simple linear fit of observations around the inversion angle gives often reasonably accurate results (*Cellino et al.*, 2015b).

Over the last decade, numerous polarimetric measurements were carried out to determine albedos of particularly interesting asteroids, such as potentially hazardous near-Earth objects (*Belskaya et al.*, 2009b; *Fornasier et al.*, 2015; *Delbò et al.*, 2007; *De Luise et al.*, 2007) and targets of space missions (*Cellino et al.*, 2005b; *Fornasier et al.*, 2006b). In general, albedos derived from the polarimetric slope are consistent with the data of direct *in situ* measurements (e.g., *Fornasier et al.*, 2006b).

### 5.2. Regolith Properties Derived from Polarimetry

The relationship between the two parameters characterizing the negative polarization branch  $P_{\min}$  and  $\alpha_{\text{inv}}$  has long been considered as diagnostic of the surface texture (*Dollfus et al.*, 1989). According to laboratory measurements, the bare silicate rocks and fine-grained lunar samples occupy two distinct domains in the plot  $P_{\min}$  vs.  $\alpha_{\text{inv}}$ . The pulverized rocks and meteorites with grain sizes typically between 30 and 300  $\mu\text{m}$ , as well as asteroid data, lie generally in between these two domains. The general agreement of asteroid polarization phase curves with those of pulverized meteorites is considered as an indication of their similar texture.

TABLE 1. List of the constants  $C_1$  and  $C_2$  for the relationship between the geometric albedo and the polarimetric slope  $h$  used for asteroid albedo estimation.

Source of albedo data used for calibration	$C_1$	$C_2$	Albedo			References
			$h = 0.04$	$h = 0.10$	$h = 0.30$	
Meteorites	-1.00	-1.78	0.415	0.166	0.055	Bowell and Zellner (1974)
Meteorites	-0.92	-1.72	0.368	0.158	0.058	Zellner et al. (1977)
IRAS/	$-0.983 \pm 0.082$	$-1.731 \pm 0.066$	0.440	0.179	0.061	Lupishko and Mohamed (1996)
Occultations/ Spacebased						
IRAS	$-1.118 \pm 0.071$	$-1.779 \pm 0.062$	0.608	0.218	0.064	Cellino et al. (1999)
Occultations	$-0.970 \pm 0.071$	$-1.667 \pm 0.083$	0.489	0.201	0.069	Cellino et al. (2012)
WISE	$-1.207 \pm 0.067$	$-1.892 \pm 0.141$	0.624	0.207	0.055	Masiero et al. (2012)
Occultations	$-1.124 \pm 0.032$	$-1.789 \pm 0.025$	0.606	0.216	0.063	Cellino et al. (2015b)

An updated relationship between  $P_{\min}$  vs.  $\alpha_{\text{inv}}$  for asteroids is shown in Fig. 5. The domains for bare rocks and lunar fines as plotted by Dollfus et al. (1989) are also indicated. With new data, the range of inversion angles inherent for asteroid surfaces was found to be wider than previously considered. The F-class asteroids with small inversion angles occupy the domain for bare rocks, while Barbarians lie behind the domain for lunar fines. Asteroid (21) Lutetia, for which the composition is still under debate (see Barucci et al., 2012), belongs to the domain for lunar fines. The asteroids of the same composition class have a tendency to group in the plot of  $P_{\min}$  vs.  $\alpha_{\text{inv}}$ . This result suggests that a wide range of the inversion angles is most probably related to surface mineralogy rather than to variations of particle size of the regolith.

Penttilä et al. (2005) made a statistical analysis of the published polarimetric data of 100 asteroids in order to find relationships with Tholen's taxonomy (Tholen, 1984). They found groups among phase-polarization curves that agree with the published taxonomic classifications and concluded that polarimetry may provide a complementary approach for classification. Subsequent observations have confirmed that asteroids of the same taxonomic class exhibit a similar polarization phase behavior.

Fornasier et al. (2006a) showed that polarimetric values obtained for 36 asteroids of different classes are typically within the range of average polarization-phase curves of a corresponding taxonomic class. Only five asteroids in the dataset were outside the typical values of their classes, which may be due to either an erroneous taxonomic classification or their particular surface properties.

Gil-Hutton and Cañada-Assandri (2011) carried out polarimetric measurements for 56 S-, L-, Ld-, and K-type asteroids and found clear differences between their mean polarization phase curves. Polarimetry of 58 B- and C-type objects was presented by Gil-Hutton and Cañada-Assandri (2012). They found that Ch- and C-type objects show deeper negative branches than Cb or B types. Cañada-Assandri et al. (2012) observed 33 X-type objects and demonstrated clear differences in the average phase-polarization curve for objects classified as M and P type by Tholen (1984).

A large polarimetric survey of 129 main-belt asteroids has shown that the obtained data well agree with the average polarization phase curves of the corresponding types (Gil-Hutton et al., 2014).

The fact that the polarimetric properties of asteroids belonging to the same taxonomic classes are essentially identical suggests that they have similar regolith microtextures. Two extreme cases of inversion angles can be explained by optically homogeneous regolith microstructure in the case of

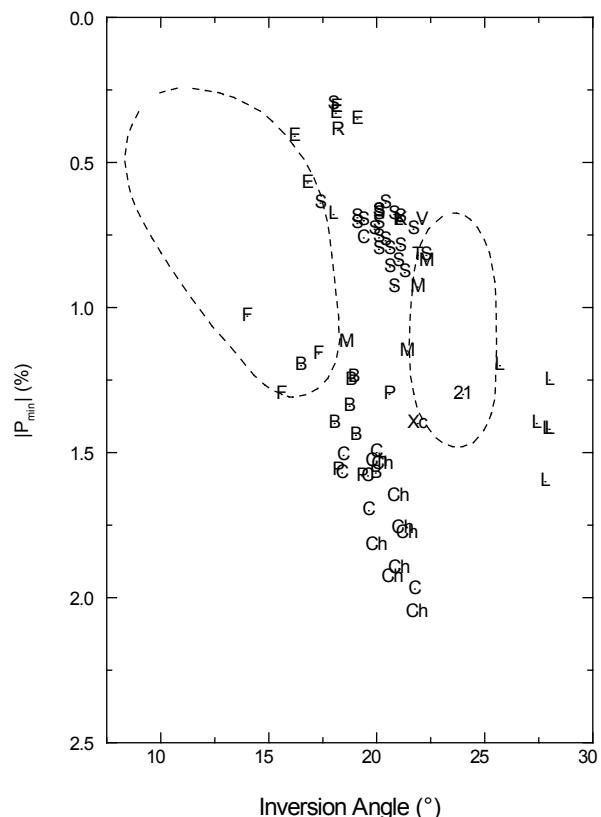

Fig. 5. Relationship between  $P_{\min}$  vs.  $\alpha_{\text{inv}}$  for asteroids of different taxonomic types (shown by letters). The domains for bare rocks and lunar fines as indicated by Dollfus et al. (1989) are also shown.

small  $\alpha_{\text{inv}}$  (Belskaya *et al.*, 2005), and heterogeneous regolith formed by a mixture of components with highly different optical properties in the case of large  $\alpha_{\text{inv}}$  (Gil-Hutton *et al.*, 2008). To understand interrelations of the surface mineralogy and texture, more laboratory and numerical modeling is needed.

### 5.3. Application to Study Near-Earth Asteroids

Observations of NEAs provide the unique possibility of investigating polarization phase dependence at large phase angles close to polarization maximum.

Recent polarimetric observations of the NEA (23187) 2000 PN<sub>9</sub> were made at the largest phase angle  $\alpha = 115^\circ$  ever observed in asteroid polarimetry (Belskaya *et al.*, 2009b). The value of maximum polarization was estimated to be  $P_{\text{max}} \sim 7.7\%$  at  $\alpha_{\text{max}} \sim 103^\circ$ , which is close to the previous estimations for the moderate-albedo NEAs. The Q-type NEA 214869 (2007 PA<sub>8</sub>) showed smaller positive polarization with  $P_{\text{max}} \sim 6\%$  at  $\alpha_{\text{max}} \sim 100^\circ$  in the V band (Fornasier *et al.*, 2015). The polarimetric properties of the asteroid 214869 (2007 PA<sub>8</sub>) are very close to those of the asteroid (25143) Itokawa (Cellino *et al.*, 2005b), suggesting possible similarity of their surface properties.

Two E-type asteroids measured at large phase angles (Kiselev *et al.*, 2002; De Luise *et al.*, 2007) provided a preliminary estimation of  $P_{\text{max}} \sim 2.3\%$  at  $\alpha_{\text{max}} \sim 80^\circ$  for a high-albedo object.

For low-albedo asteroids, no value of  $P_{\text{max}}$  has been measured so far. The single observation at large phase angle for (2100) Ra-Shalom gave  $P \sim 11\%$  at  $\alpha_{\text{max}} \sim 60^\circ$  (Kiselev *et al.*, 1999).

Large differences in the polarization degree for high-, moderate-, and low-albedo asteroids provide a unique way to select primitive low-albedo NEAs by a single polarimetric measurement at  $\alpha > 40^\circ$ . Estimations of albedo of potentially hazardous NEAs are another important application of polarimetric observations. Using instruments like the ESO 8-m VLT telescope, it is possible to obtain albedos and sizes of hazardous objects, as demonstrated by the recent observations of (99942) Apophis (Delbò *et al.*, 2007).

## 6. CONCLUSIONS AND FUTURE WORK

Extensive observational campaigns in the last decade considerably increased the number of asteroids with published polarimetric measurements. These campaigns led to the discovery of asteroids with peculiar polarimetric properties, characterized by narrow negative polarization branches with small inversion angles and wide negative branches with large inversion angles. Further observations have shown that these properties are related to surface mineralogy. All asteroids showing small inversion angles belong to the F-class asteroids, which currently are no longer identified as a separate class. Asteroids with large inversion angles, called Barbarians, seem to belong to the

L class identified by DeMeo *et al.* (2009), using both visible and near-IR spectral data. A possible interpretation of their peculiar polarimetric properties is the presence of spinel in CAIs in their surfaces. These are cases in which even a single polarimetric measurement at a suitable phase angle can be sufficient to provide a classification, something that is not always possible based on spectroscopic data at visible wavelengths. Polarimetric measurements can be an effective tool for asteroid taxonomy.

Traditional application of polarimetry to determine asteroid albedos is especially efficient in the study of NEAs. Polarimetry has been successfully used to estimate the size and albedo of potentially hazardous NEAs. Even a single polarimetric measurement at large phase angles can provide a prompt assessment of an asteroid's geometric albedo.

In the coming years the use of new polarimeters based on CCD detectors will extend available data to increasingly smaller objects and will allow the study of different groups that are important for the understanding of the physical evolution of the asteroid belt. Polarimetric observations of several asteroid family members will shed some light on their surface properties and will also be used to detect interlopers (Milani *et al.*, 2014). On the other hand, the knowledge of the polarization phase curve and polarimetric parameters of different taxonomic classes not yet studied will provide information about the relation between polarimetry and taxonomic classification. Finally, the analysis of larger numbers of spectropolarimetric observations will be used as a tool to reach more robust conclusions about the relation between polarimetric parameters and mineralogy.

In the theoretical modeling of asteroid polarimetry, there are remarkable future prospects for a rigorous, numerical multiple-scattering model where the limitations of the far-field interactions in the RT-CB method will be removed. Prior to this advance, it is plausible that an approximate RT-CB method will be extended to depolarizing, nonspherical single scatterers. Such an advance will allow for the ensemble-averaged, either experimentally measured or numerically computed, scattering matrices to be fully utilized in the interpretation of asteroid polarimetry.

Great progress in polarimetric instrumentation significantly expands the opportunities for polarimetric observations of asteroids. With the improvement of interpretation models and theory, we will enter a new era of extensive application of the polarimetric technique to the study of asteroids.

---

Radar is a very powerful technique for characterizing near-Earth and main-belt asteroids and for improving their orbits. This results from radar's ability to spatially resolve objects that often cannot be resolved at comparable resolutions by other groundbased techniques. Radar has revealed binary and contact binary objects, at least two triple systems, non-principal-axis rotators, objects whose radar reflectivity and circular polarization ratio have longitudinal variation, irregularly shaped near-Earth asteroids, objects with metallic compositions, objects with rubble-pile structures, and detailed radar images of main-belt asteroids that reveal complicated surfaces and substantial topographic relief. This chapter concentrates on the most significant advances in the field since publication of the radar chapter by Ostro *et al.* (2002) in *Asteroids III*. Detailed descriptions of asteroid radar observing techniques and terminology have appeared in Ostro (1993) and Ostro *et al.* (2002) (*Asteroids III*), so we refer readers to those papers for background information. This chapter emphasizes the first ground-truth tests of asteroid shape models by spacecraft encounters, population trends among near-Earth and main-belt asteroids, results for selected objects, new observing techniques, improved capabilities at radar telescopes, and improvements in three-dimensional shape modeling. We conclude with a discussion of future prospects.

## 1. INTRODUCTION

Planetary radar astronomy is an active form of observation in which the observer illuminates the target with radio waves having known properties and measures the reflected signal in order to investigate the physical properties of the target and to improve its orbit. Radar observations can occur during the day, in cloudy weather, during rain, and in a real sense represent a laboratory experiment on objects at distances of up to hundreds of millions of kilometers.

The world's most sensitive facilities for radar observations of asteroids are the Arecibo Observatory and the Goldstone Solar System Radar. Arecibo has a diameter of 305 m and is the world's largest operational single-dish radio telescope. Arecibo's S-band system operates at a frequency of 2380 MHz ( $\lambda = 12.6$  cm) and has a transmitter power of 900 kW. The dish is built into a sinkhole and cannot move; to point, the transmitters and receivers are suspended above

the dish on azimuth and elevation rails that permit tracking of objects 360° in azimuth and within 20° of zenith. Arecibo is located in Puerto Rico at a latitude of +18°, so it is able to observe objects at declinations from -1° to +38° and see approximately one-third of the sky. Due to its pointing restrictions, Arecibo can track a given object for a maximum of 2.9 h/day. The highest range resolution currently available at Arecibo is 7.5 m/pixel.

The Goldstone Solar System Radar is located on the DSS-14 antenna at the National Aeronautics and Space Administration's (NASA) Goldstone Deep Space Communications Complex. DSS-14, hereafter referred to as "Goldstone," is part of the Deep Space Network (DSN). Goldstone has a diameter of 70 m, operates at a transmitter frequency of 8560 MHz ( $\lambda = 3.5$  cm), and has a transmitter power of 450 kW. Goldstone is fully steerable and can track objects north of -35°, providing coverage for ~80% of the sky. The finest range resolution available at Goldstone is 3.75 m/pixel.

Due to its higher transmitter frequency, Goldstone can provide  $3.6\times$  finer Doppler resolution than Arecibo in high signal-to-noise ratio (SNR) situations, which can be helpful for resolving small and/or slowly rotating objects.

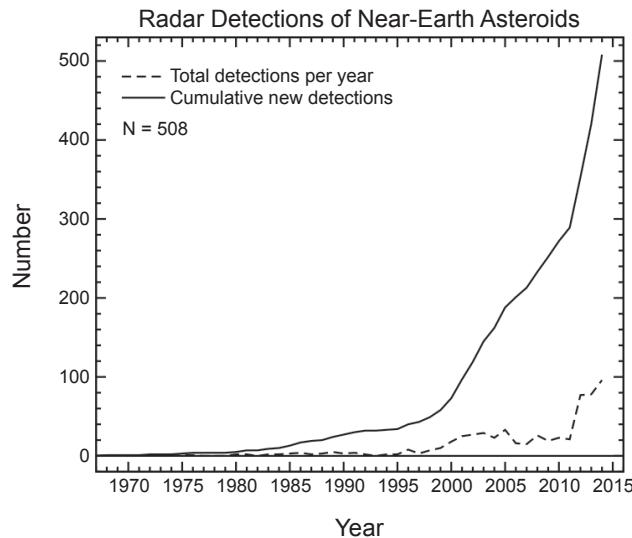

The capabilities of Arecibo and Goldstone are complementary: Arecibo is about  $20\times$  more sensitive and can detect objects to twice the distance, but Goldstone can track objects for several times longer, much farther north and south, and achieve higher resolutions in range and Doppler frequency. Arecibo is designed as an astronomical observatory and is easier to use and schedule on short notice. The primary mission at Goldstone is spacecraft communication, and the facility is currently available for astronomical observations for  $<10\%$  of the time. Target-of-opportunity observations are possible at Goldstone but more challenging to schedule than targets identified well in advance. For many of the best targets, both observatories are utilized to maximize the return on scientific investment. Due to the time it takes equipment to switch from transmitting to receiving, Arecibo can observe objects as close as 0.008 AU and Goldstone can observe objects as close as 0.005 AU. For closer objects, the 34-m DSS-13 antenna is often used to receive echoes from Goldstone transmissions, although that bistatic configuration reduces the SNRs by a factor of  $\sim 6$ . The 100-m Green Bank Telescope is also available for bistatic observations using both Arecibo and Goldstone to transmit.

In practice, due to its greater sensitivity, Arecibo can detect significantly more near-Earth asteroids (NEAs) than is possible at Goldstone despite Arecibo's restricted pointing capabilities. The principal reason is that many near-Earth objects traverse Arecibo's declination window when they are still close enough for Arecibo to detect. The fraction of NEAs observable by Goldstone that are too far north or south for Arecibo to detect is  $\sim 5\%$  (S. P. Naidu, personal communication).

Radar astrometry can produce dramatic improvements in asteroid orbits for recently discovered objects due to radar's high fractional precision of up to 1 part in  $10^8$ . For example, for a single opposition object, including radar astrometry in the orbit solution typically increases the interval of Earth encounter statistical predictability by a factor of 5 from 80 to 400 years, on average, compared to a solution based only on optical measurements (*Ostro and Giorgini, 2004*). The effects of radar astrometry on asteroid orbit determination have been discussed in several papers; for a detailed summary see *Ostro and Giorgini (2004)*.

## 2. RECENT RADAR DETECTION HISTORY

The number of NEAs observed with radar has increased dramatically since publication of *Asteroids III*, from 120 at the end of 2002 to 508 at the end of 2014 (Fig. 1 and tabulated online at <http://echo.jpl.nasa.gov/asteroids/PDS.asteroid.radar.history.html>). This is due largely to a six-fold increase in the number of NEA discoveries. During the decade after completion of the upgrade at Arecibo in the late 1990s, the average number of NEA radar detections was 20–30

**Fig. 1.** Number of NEA radar detections through the end of 2014. The increase in cumulative detections in 1999–2000 was caused in part by a surge of discoveries by LINEAR and by the order-of-magnitude increase in sensitivity at Arecibo after the upgrade. The increase in 2012 was the result of increased funding for Arecibo and greater access to telescope time at Arecibo and Goldstone.

annually. This jumped by a factor of  $\sim 3$  in 2012 following increased NASA funding at Arecibo (and to a lesser extent at Goldstone) and due to greater access to telescope time for targets known well in advance. Many weak targets that had previously been ignored are now being observed. The minimum SNR threshold adopted for scheduling an asteroid for radar observations is typically  $\sim 30/\text{day}$  at Goldstone and  $\sim 15/\text{day}$  at Arecibo, although there are many instances where observations are attempted for weaker targets.

Obtaining time for target-of-opportunity observations at Goldstone has long been much more cumbersome than at Arecibo. At Arecibo, submission of an urgent proposal can lead to scheduling observations within one day. At Goldstone it is necessary to coordinate radiation clearance with more than 25 government organizations whose airspace surrounds DSS-14; this process used to take up to several days, but recent improvements have shrunk this to  $<2$  days. It is also possible to observe objects on very short notice without radiation clearance by reducing the transmitter power to 110 kW. Many targets of opportunity have been observed recently at both observatories by redirecting time previously scheduled for other asteroids. Radar delay-Doppler astrometry is used to update the orbit solution during the observations and is posted online shortly after the experiment is complete at <http://ssd.jpl.nasa.gov/?radar>.

### 2.1. Technological Developments

**2.1.1. Arecibo.** One of the most significant developments at Arecibo has been an upgrade in the highest resolu-

tion available for delay-Doppler imaging. Shortly after the upgrade in 1999, the highest range resolution was 15 m/pixel by taking data with the Caltech Baseband Recorder (CBR), equipment originally designed for observing pulsars. However, the CBR was complicated to use, it did not permit real-time monitoring of the data (so the user did not know if there were echoes or problems until much later), and it didn't utilize the full bandwidth available from Arecibo's klystron amplifiers. In 2004, the "Portable Fast Sampler" (PFS) data-taking system designed and built by J. L. Margot became fully operational and provided range resolutions up to 7.5 m/pixel. The PFS is much more straightforward to use, can write data directly to disk rather than using striped tape drives, permits the user to check the data in near-real time, and has been upgraded, cloned, and installed at Goldstone and Green Bank. The 7.5-m resolution is close to the theoretical limit of  $\sim 6$  m imposed by the bandwidth of Arecibo's klystrons. A factor of 2 in range resolution yields pronounced differences in the detail visible in delay-Doppler radar images, and nearly all the strongest SNR targets observed at Arecibo now use 7.5-m resolution.

**2.1.2. Goldstone.** The most important improvement at Goldstone during the last decade has been the development of finer-resolution delay-Doppler imaging using chirp waveforms. From 1992 to 2010, the finest range resolution at Goldstone was 18.75 m achieved by using binary phase-coded waveforms. Although Goldstone's klystron amplifiers could be modulated at higher frequencies and in principle obtain higher resolutions, 18.75 m (with the frequency side lobes of binary phase-coded waveforms) is the finest resolution possible without violating Goldstone's frequency license. To achieve higher resolution without violating the license, linear frequency modulation (also known as chirping) was implemented (Slade et al., 2011). The chirp system improved the resolution at Goldstone by a factor of 5 from 18.75 m to 3.75 m, a resolution twice as fine as the highest resolution available at Arecibo. This illustrates another way in which the capabilities of Arecibo and Goldstone are complementary. The first asteroid observed with a range resolution of 3.75 m was 2010 AL<sub>30</sub> (Slade et al., 2010), an object  $\sim 30$  m in diameter that approached within 0.00086 AU (0.3 lunar distances) in January 2010.

A five-fold improvement in resolution reveals considerably more detail than was previously possible and has yielded dramatic images of several objects a few hundred meters in diameter (or larger), such as (308635) 2005 YU<sub>55</sub>, (214869) 2007 PA<sub>8</sub>, (4179) Toutatis, 2014 HQ<sub>124</sub>, and (357439) 2004 BL<sub>86</sub>. For example, numerous impact craters and boulders are visible on the surface of 2005 YU<sub>55</sub> (Fig. 2). In addition, a new digital receiver system has been acquired that can obtain dual-polarization delay-Doppler images at resolutions as fine as 1.25 m/pixel, 3 $\times$  finer than Goldstone can transmit, in preparation for possible use of higher-resolution waveforms in the future.

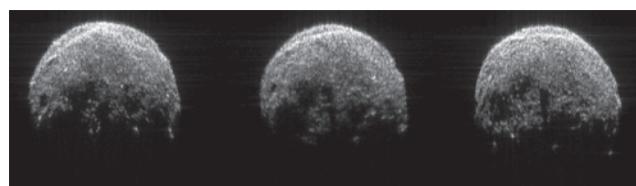

With the new chirp/digital receiver system, it is now possible to spatially resolve NEAs  $\sim 30$  m in diameter and estimate their three-dimensional shapes. The chirp imaging system

also enables finer precision ranging astrometry, particularly for tiny objects, with uncertainties of  $\sim 10$  m.

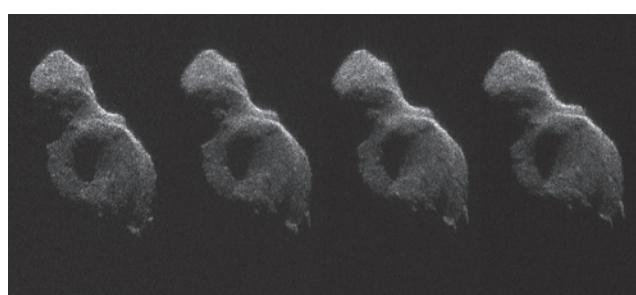

Clones of the new digital receiver equipment were installed at Arecibo and Green Bank in 2014. Using Goldstone to transmit, Arecibo can now acquire images with a resolution of 3.75 m, which is twice as fine as Arecibo can achieve monostatically. The new equipment was successfully tested at Arecibo with observations of NEA 2014 HQ<sub>124</sub> (Fig. 3) in June 2014 and at Green Bank with observations of 2005 YQ<sub>96</sub> and 2004 BL<sub>86</sub> in January 2015. When used in bistatic mode with Goldstone transmitting and Arecibo receiving, the SNRs are about 5 $\times$  stronger relative to those obtainable with monostatic observations at Goldstone. Reception at Green Bank increases the SNRs by a factor of  $\sim 2$  relative to monostatic observations due to Green Bank's larger diameter (100 m) and the doubling of the integration time.

## 2.2. Radar Speckle Tracking

Development of the radar speckle technique for estimation of asteroid spin vectors (Busch et al., 2010) is a major new capability since publication of *Asteroids III*. When illuminated with a monochromatic coherent uncoded radar waveform [continuous-wave (CW) observations], each point on a target reradiates with a random phase determined by its distance from the transmitter and the radar scattering properties of the surface. These wavefronts combine, producing a

**Fig. 2.** Bistatic Goldstone DSS-14/DSS-13 radar images of near-Earth asteroid 2005 YU<sub>55</sub> obtained on November 9, 2011. Range increases down and Doppler frequency increases to the left, so rotation is clockwise. Range resolution is 3.75 m/row, but the data were double sampled, so each row corresponds to 1.875 m.

**Fig. 3.** Bistatic Goldstone-Arecibo images of near-Earth asteroid 2014 HQ<sub>124</sub> obtained on June 8, 2014. Each pixel has dimensions of 1.875 m  $\times$  0.00625 Hz.

pattern of constructive and destructive interference that project onto Earth as high- and low-intensity splotches known as radar speckles. The speckles have a characteristic length scale of  $L_{\text{speckle}} = D\lambda/d$ , where  $D$  is the distance to the target,  $d$  is its diameter, and  $\lambda$  is the radar wavelength. For NEA radar targets,  $L_{\text{speckle}}$  is usually  $>100$  km and  $<10,000$  km.

As the target rotates, the speckle pattern moves in the same direction as the target's surface. By tracking the speckle motion, it is possible to estimate the pole direction, sense of rotation, and rotation rate (Margot *et al.*, 2007, 2012). For objects with unknown spin states, the antennas must be separated by less than the speckle scale (Busch *et al.*, 2010). Near-Earth asteroids can be observed with speckle tracking by transmitting from Arecibo or Goldstone and receiving with elements of the Very Long Baseline Array (VLBA) or Very Large Array (VLA).

The current discovery rate of NEAs is  $\sim 1500$  per year, of which  $\sim 5$ – $10$  are suitable for speckle tracking. This technique has been applied to a number of NEAs and has resolved spin-state ambiguities for (341843) 2008 EV<sub>5</sub> (Busch *et al.*, 2011) and 2005 YU<sub>55</sub> (Busch *et al.*, 2012).

### 2.3. Shape Modeling Improvements

The three-dimensional shape reconstruction software was originally written by R. S. Hudson (Hudson, 1993), who used it to produce detailed shape models of contact binary (4769) Castalia (Hudson and Ostro, 1994), non-principal-axis rotator (4179) Toutatis (Hudson and Ostro, 1995; Hudson *et al.*, 2003), angular asteroid (6489) Golevka (Hudson *et al.*, 2000), and less-detailed models of several other NEAs.

When *Asteroids III* was published in 2002, the software was capable of handling 24 parameters describing the spin, shape, and reflectivity of asteroids, and 11 types of penalties designed to guide the optimization routine. Since then, C. Magri has overseen most of the development and maintenance of the software and documentation (Magri *et al.*, 2007b), with contributions from others starting in 2005 when the software was released more widely. The software is now more capable and easier to use. A number of graphical capabilities and penalty functions have been added, and the software can now handle a greater variety of input formats, coding schemes, and sampling modes. The modeling of photometric properties has also been significantly expanded. Ovoid shapes are now supported in addition to the original ellipsoid, spherical harmonic, and vertex shape representations. The user can also specify pixel masks to vignette one component of a binary asteroid when modeling the other component (Ostro *et al.*, 2006) or to assign weights to different parts of an image (Nolan *et al.*, 2013). The software can handle time-variable spin rates and spin impulses. The former was instrumental in establishing the first Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) detection (Taylor *et al.*, 2007), and the latter is important in representing spin-state changes during close planetary encounters (Takahashi *et al.*, 2013). A libration model has also been incorporated to properly represent the dynamics of asteroid satellites (Naidu and

Margot, 2015). The current version allows for 243 adjustable parameters and 24 penalties to the objective function. This makes it a rather specialized tool with a substantial learning curve, but also an invaluable asset that has transformed the depth and breadth of asteroid radar data analysis.

## 3. SCIENCE RESULTS SINCE ASTEROIDS III

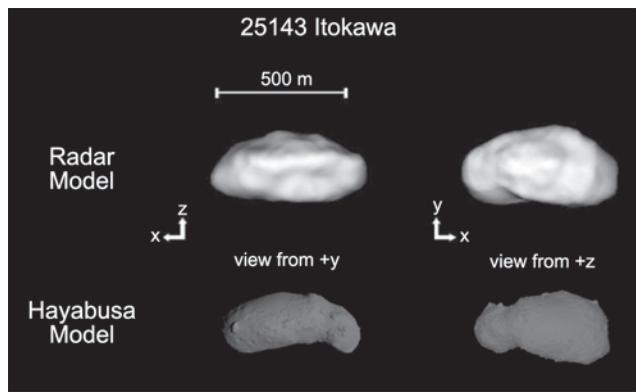

### 3.1. Ground-Truth of Radar Shape Models by Spacecraft Missions: (25143) Itokawa and (4179) Toutatis

**3.1.1. (25143) Itokawa.** Itokawa was the first NEA visited by a spacecraft for which a three-dimensional model from inversion of radar images was also available. Ostro *et al.* (2004) reported radar observations and a physical model from extensive imaging in 2001, and Ostro *et al.* (2005) incorporated additional radar images obtained in 2004 to estimate improved models.

The radar observations provided repeated coverage over a restricted range of longitudes in Itokawa's northern hemisphere in 2001 and sparse coverage of other longitudes on three days in 2004. Due to the nearly 12-h rotation period, radar images obtained in 2001 sampled very similar orientations day after day, although two weeks of sky motion ultimately extended the rotational coverage somewhat (see Fig. 1 of Ostro *et al.*, 2005). The asteroid's pole direction and sky positions in 2001 precluded seeing the bend between Itokawa's "head" and "body." In 2004, the sky positions were very different, and the concavity between the components was conspicuous. Unfortunately, in 2004 radar imaging occurred on far fewer days than in 2001, so a significant fraction of the surface was never seen at high resolution, and this propagated into limitations for the shape model. The highest range resolutions in 2001 and 2004 were 15 m/pixel at Arecibo and 19 m/pixel at Goldstone.

In 2005, the Hayabusa spacecraft began an extended encounter with Itokawa (Saito *et al.*, 2006; see also the chapters by Yoshikawa *et al.* and Scheeres *et al.* in this volume). The Hayabusa images reveal zeroth-order agreement with the Ostro *et al.* (2005) smooth model's shape and dimensions, but the spacecraft data also revealed obvious differences. Figure 4 compares the three-dimensional models estimated from the radar and spacecraft images. The Ostro *et al.* radar model has principal axes within 10% of 594  $\times$  320  $\times$  288 m. The dimensions reported by Saito *et al.* (2006) were 535  $\times$  294  $\times$  209 m with uncertainties of  $\sim 1$  m. Thus, within their stated uncertainties, the long and intermediate axes are consistent but the short axis is not. The mismatch of the short axis is probably a consequence of significant gaps in latitude coverage in the radar images. The subradar latitudes during radar imaging were never within 45° of the poles and they occurred over a relatively narrow range of longitudes.

Ostro *et al.*'s (2005) smooth model shows a bend between the head and body but it underestimated the depth of the neck, a discrepancy noted in the paper. In practice, during the modeling process it is often difficult to fit every feature

**Fig. 4.** Two principal axis views of the (25143) Itokawa models estimated from inversion of radar images [top row, adapted from Ostro et al. (2005)] and from Hayabusa spacecraft images [bottom row, adapted from Gaskell et al. (2008)]. The renderings are shown at the same orientations and approximately to scale. The lower hemisphere in the renderings on the left was not imaged by radar.

visible in the images with the shape reconstruction algorithm currently in use. For example, the fits to the narrow end were not as tapered as indicated by the data from 2001 even though various approaches were attempted to improve them. The bend between the head and the body in the synthetic images reported by Ostro et al. is not as deep as it appears in the radar images. The shape modeling started with a single-component; in retrospect, the modeling could have produced better fits had it started with two overlapping ellipsoids (S. J. Ostro, personal communication), an approach that was not in use in 2005. For example, Magri et al. (2011) started modeling deeply bifurcated contact binary (8567) 1996 HW<sub>1</sub> with overlapping ellipsoids and obtained excellent fits. The radar model of Itokawa also has an equatorial ridge that is not present on the asteroid; this was noted by Ostro et al. (2005), and is probably an artifact due to the combination of penalties against rough or concave surfaces, and also due to the *Shape* software's default vertex adjustment order from south to north in a spiral pattern. The effects of the order of vertex adjustment were explored by modeling 2008 EV<sub>5</sub> by Busch et al. (2011), who found that when the adjustment pattern was randomized, the sharpness of the equatorial ridge was reduced.

Boulders are ubiquitous in spacecraft images of Itokawa, but were any visible in the radar data? Hints of small-scale topography at the resolution limit are visible in Arecibo images near the neck in an area where Hayabusa images show several decameter-scale boulders, but the resolution in the radar images was insufficient to make statements about the origin of the radar features. Yoshinodai, the largest boulder, was not visible due to gaps in the radar latitude and longitude coverage. Inspection of the 2001 radar images shows a cluster of radar-bright pixels corresponding to a ridge several tens of meters in extent in the spacecraft images of

the northern hemisphere between the “head” and the broad smooth region known as Sagamihara.

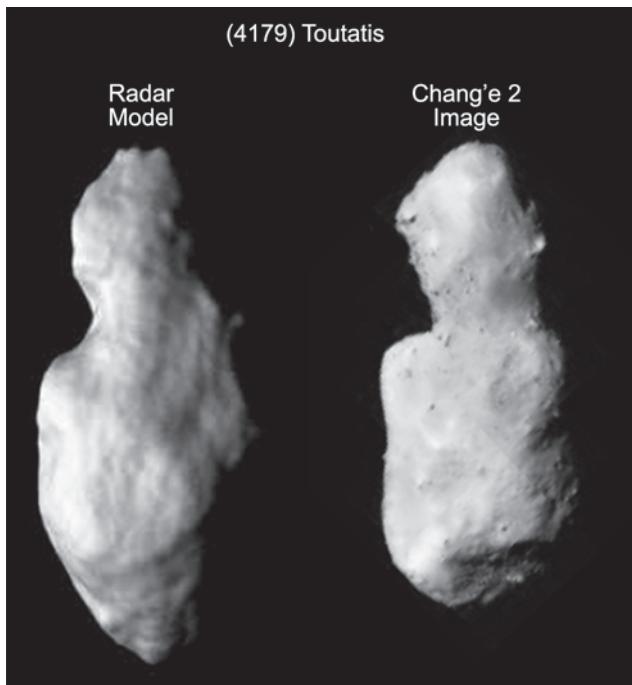

**3.1.2. (4179) Toutatis.** Toutatis was imaged with radar during close Earth approaches in 1992, 1996, 2000, 2004, 2008, and 2012. Hudson and Ostro (1995) estimated the first three-dimensional model of Toutatis using the 1992 images with a resolution of 75 m/pixel; Hudson et al. (2003) estimated a high-resolution model utilizing images from 1992 and 1996 with resolutions as fine as 18.75 m/pixel. The Hudson et al. (2003) high-resolution model is among the most detailed published to date.

Toutatis is the second asteroid imaged in detail by radar that has also been visited by a spacecraft, and it therefore provides an important “ground-truth” test of the shape modeling process (see also the chapter by Barucci et al. in this volume). The Chang'e-2 spacecraft flew by Toutatis on December 13, 2012, and acquired a series of images at resolutions as high as ~2 m/pixel. Due to the asteroid's slow rotation and the spacecraft's velocity, the Chang'e-2 images show only one side.

Huang et al. (2013) and Zou et al. (2014) describe images obtained by the spacecraft and compare them with the Hudson et al. (2003) model. The Chang'e-2 images match the asteroid's orientation as predicted by the radar-derived spin state model (Takahashi et al., 2013), and show many of the features in the radar-derived Toutatis shape model presented in Hudson et al. (2003): the large and small lobes of the asteroid, the neck between them, and ridgelines and depressions on both lobes (Fig. 5). The spacecraft images yield estimates of the asteroid's dimensions that are consistent within their stated uncertainties: Hudson and Ostro (1995) reported major axes within 0.1 km of 4.60 × 2.29 × 1.92 km; Huang et al. (2013) estimated “Toutatis’ maximum physical length and width” to be within 10% of 4.75 × 1.95 km.

However, the Chang'e-2 images also show mismatches that reflect limitations of early radar shape modeling techniques and of the 1992 and 1996 Toutatis radar data. The most pronounced differences appear in the model's large end, which is more tapered than in spacecraft images, and the region between the two lobes, which is more angular in the Chang'e-2 images. The differences at the wide end originate primarily because previous radar observations did not have detailed coverage of that region. Although Toutatis was observed with radar in 2000, 2004, and 2008, those observations were restricted to no more than four days during each apparition and did not achieve thorough coverage due to the asteroid's slow rotation.

The true structure of the neck between the small and large components is more angular than in the Hudson et al. (2003) shape model. This is partly an artifact of the fitting procedure: The Hudson et al. shape model was rendered as a single surface, with a penalty function incorporated in the shape inversion that favored smooth shapes to prevent fitting noise. In this case, that procedure smoothed over the real structure. Better results could have been obtained by using a two-component shape model, one for each of the two lobes, and by having higher-resolution radar data.

**Fig. 5.** Comparison between the *Hudson et al.* (2003) radar-derived shape model of (4179) Toutatis and a representative image obtained by the Chang'e-2 spacecraft (adapted from *Huang et al.*, 2013). The orientations and scales are approximate and were estimated by eye. Illumination directions are similar.

*Hudson et al.* (2003) adopted a conservative modeling approach and stated “In penalizing relief in our shape reconstruction, we chose to suppress features rather than to risk showing features that might not be present on Toutatis.” Although the match between the *Hudson et al.* shape model and Toutatis’ shape as seen by Chang’e-2 is not perfect, it validates the use of radar shape modeling in understanding asteroid shapes and spin states.

During the 2012 encounter, Toutatis was imaged with radar at resolutions up to 3.75 m/pixel, the highest-resolution radar images ever obtained for this object. The images placed tens of thousands of pixels on the asteroid, covered the wide end more extensively than previously, and revealed a number of small radar-bright spots that Busch et al. (in preparation) linked with boulders in the Chang’e-2 images.

Propagation of Toutatis’ spin vector from 1992 to 1996 and 2000 showed orientation differences that were within the uncertainties of the *Hudson and Ostro* (1995) spin state, but images obtained in 2004 and 2008 clearly revealed discrepancies that were much larger. *Takahashi et al.* (2013) fit the images using an updated model for the shape and spin state that incorporated radar images obtained through 2008 and integrations that explicitly included gravitational perturbations experienced by Toutatis throughout its heliocentric orbit. They were able to successfully reproduce the orientation during each apparition imaged by radar. They found that the spin state changed during each flyby, with

the most pronounced changes occurring during the closest encounter within 0.01 AU ( $\sim$ 4 lunar distances) in 2004. This is one of the first instances where changes to a NEA’s spin state during close Earth flybys have been detected. Similar changes are likely to become evident for an increasing number of NEAs as future radar observations occur; for example, *Scheeres et al.* (2005) predicted that spin-state changes should be obvious with (99942) Apophis after its approach within 5.1 Earth radii in 2029.

### 3.2. Main-Belt Asteroids

Many main-belt asteroids (MBAs) have been observed with radar since publication of *Asteroids III*, but less work has been done with this population because far fewer MBAs are suitable for detailed imaging and the SNRs of the best targets are much lower than they are for NEAs. Most MBAs observed recently have been CW detections at moderate to weak SNRs and all have been at Arecibo. However, a number of MBAs have been imaged, most notably (4) Vesta, (5) Astraea, (7) Iris, (12) Victoria, (216) Kleopatra, and (654) Zelinda. In principle, Arecibo is so sensitive that several MBAs could be detected with radar on any night of the year.

*Magri et al.* (2007a) presented detailed statistical analyses of the radar albedo and circular polarization ratio at 12.6 cm wavelength of 84 MBAs, 55 of which were observed by radar for the first time. Some conclusions from an earlier study (with a smaller sample size) by *Magri et al.* (1999) were strengthened: M asteroids have higher mean radar albedos and a wider range of albedos than other MBAs, suggesting that both metal-rich and metal-poor M-class objects exist; C- and S-class MBAs have indistinguishable radar albedo distributions; and the F, G, P, and D classes are not as radar-bright as C and S objects (but a convincing statistical test requires larger sample sizes). In contrast with earlier work, *Magri et al.* (2007a) found that S-class MBAs have higher circular polarization ratios at 12.6 cm wavelength than other MBAs, indicating greater near-surface structural complexity at decimeter scales.

*Shepard et al.* (2008a, 2011) report that circular polarization ratios at 12.6 cm wavelength for E-class MBAs (44) Nysa, (64) Angelina, and (434) Hungaria are significantly higher than for most other taxonomic classes but somewhat lower than the polarization ratios reported among E-class NEAs (*Benner et al.*, 2008). The E-class MBAs are up to several tens of kilometers in diameter, so the difference in the circular polarization ratios relative to those seen among NEAs suggests that the circular polarization ratio has an inverse gravitational dependence.

*Shepard et al.* (2008a, 2010, 2011, 2015) estimated radar albedos for most of the X- and M-class MBAs that are detectable at Arecibo. This indicated high radar albedos for (16) Psyche, (216) Kleopatra, (758) Mancunia, and (785) Zwetana, suggesting that they are almost certainly metallic; established evidence for wide variations in radar albedo as a function of rotation on (16) Psyche, (129) Antigone, (135) Hertha, (758) Mancunia, and (785) Zwetana;

suggested deep concavities on numerous objects; and showed that more than 60% of M-class asteroids with 3- $\mu\text{m}$  hydration features reported from infrared spectroscopic observations (*Rivkin et al.*, 2000) have high radar albedos that are consistent with largely metallic surfaces. The presence of hydration features associated with these M-class asteroids is puzzling; *Shepard et al.* (2015) suggest that these may be the results of material delivered via impacts. Variations in the radar albedos also suggest compositional and/or structural complexity on large scales (*Shepard et al.*, 2015).

**3.2.1. (21) Lutetia.** *Shepard et al.* (2008a) reported delay-Doppler images of Lutetia prior to the Rosetta flyby in 2010. The images viewed Lutetia along the polar axis and were not sufficient for three-dimensional shape estimation, but they suggested a polar dimension of  $84 \pm 12$  km that was consistent with later observations by the Rosetta spacecraft (*Sierks et al.*, 2011; see also the chapter by Barucci et al. in this volume).

**3.2.2. (7) Iris.** Arecibo radar images of Iris obtained in November 2006 reveal a topographically complex object whose gross shape is approximately ellipsoidal with equatorial dimensions within 15% of  $253 \times 228$  km (*Ostro et al.*, 2010). The most prominent features are three  $\sim 50$ -km-diameter concavities almost equally spaced in longitude around the south pole that are probably impact craters.

**3.2.3. (216) Kleopatra.** Kleopatra has been observed at Arecibo in 1999 (*Ostro et al.*, 2000), 2008, and 2013. The 2008 and 2013 delay-Doppler images confirm the “dogbone” shape reported by *Ostro et al.* (2000) but hint that the radar albedo may be somewhat lower than previously reported. The shape reported by *Ostro et al.* (2000) has been confirmed by adaptive optics imaging reported by *Descamps et al.* (2011), who also discovered that Kleopatra has two small moons. The SNRs of the radar observations spatially resolve the primary but are not strong enough to reveal echoes from the satellites. Additional information about Kleopatra appears in the chapter by Scheeres et al. in this volume.

### 3.3. Yarkovsky Effect Detections Enabled by Radar Astrometry

The Yarkovsky effect is a key mechanism for the delivery of NEAs from the main belt to the near-Earth region and it has been the subject of extensive theoretical investigations (*Bottke et al.*, 2002, 2006). A description of the Yarkovsky effect appears in the chapter by Vokrouhlický et al. in this volume, so here we will concentrate on the role that radar can play in its detection and the implications it has for constraining the physical properties of NEAs.

Radar observations of NEAs provide important opportunities to measure the Yarkovsky orbital drift. This effect has been detected with Arecibo radar data for (6489) Golevka (*Chesley et al.*, 2003) and is the dominant source of uncertainty in some NEA trajectory predictions (*Giorgini et al.*, 2002; *Farnocchia et al.*, 2013a,b) for bodies smaller than  $\sim 2$  km. The Yarkovsky effect acts on the semimajor axis linearly with time and the mean anomaly quadratically

with time as a function of an object’s spin, shape, thermal inertia, other material properties, and orbit. For asteroids of known sizes and spins, a measurement of the Yarkovsky drift rate can be interpreted in terms of bulk density and thermal inertia (*Chesley et al.*, 2003; *Nugent et al.*, 2012). If independent measurements of the thermal inertia exist, then it is possible to estimate the bulk density of the object (*Chesley et al.*, 2014) and thus constrain its internal structure. Although the Yarkovsky drift can be estimated in some cases with optical astrometry alone (*Nugent et al.*, 2012; *Farnocchia et al.*, 2013a), the uncertainties associated with these orbital drift determinations are typically reduced by an order of magnitude when radar data are included.

*Giorgini et al.* (2002) established the long-term coupling between the orbital evolution of (29075) 1950 DA (and NEAs in general) and physical properties such as spin state, shape, thermal inertia, and bulk density through the action of the Yarkovsky effect. The Yarkovsky effect is a major source of uncertainty for the future motion of Apophis (*Giorgini et al.*, 2008) and Bennu (*Chesley et al.*, 2014) and can lead to resonant returns and potential Earth impacts via deflection through keyholes.

*Vokrouhlický et al.* (2000) predicted that the Yarkovsky effect could be detected for several NEAs with future radar ranging measurements. This was confirmed by *Chesley et al.* (2003) for Golevka through a combination of Arecibo and Goldstone radar astrometry obtained in 1991, 1995, and 2003, and utilization of the three-dimensional model published by *Hudson et al.* (2000). This yielded a bulk density of  $2.7 \text{ g cm}^{-3}$  and was the first detection of the Yarkovsky effect for a solar system object. Predictions for detecting the Yarkovsky effect for other NEAs appeared in *Vokrouhlický et al.* (2005a,b). In general, three radar detections spread out over at least several years are necessary, although due to the dependence on the mass, a longer baseline may be required for more massive objects and a shorter baseline could suffice for smaller ones.

*Chesley et al.* (2014) report a Yarkovsky effect detection for (101955) Bennu based on a weak ranging detection at Arecibo in 2011 coupled with radar astrometry obtained in 1999 and 2005 (*Nolan et al.*, 2013). The thermal inertia was already available (*Emery et al.*, 2013), enabling direct estimation of the asteroid’s mass and bulk density, information that is invaluable for the Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) mission that will arrive at Bennu in 2018.

*Vokrouhlický et al.* (2005b) described binary NEAs for which detection of the Yarkovsky effect could soon be possible. Masses of binary systems can be estimated by fitting range-Doppler measurements between the components of binary system and application of Kepler’s third law (*Margot et al.*, 2002), so a Yarkovsky effect detection enables estimating the mass from an independent technique (although one that often requires numerous assumptions and is less robust than direct fitting of the mutual orbit of a binary system). The first binary where both approaches provided mass estimates is (1862) Apollo, whose bulk density estimated from

the orbit of  $\sim 2.6 \text{ g cm}^{-3}$  (T. Ford, personal communication) is consistent (to within the uncertainties) with the value of  $2.86^{+0.48}_{-0.68} \text{ g cm}^{-3}$  estimated by *Rozitis et al.* (2013) from the Yarkovsky effect detection (*Farnocchia et al.*, 2013a).

To facilitate future Yarkovsky effect detections, NEAs previously detected by radar are now observed at every opportunity when the SNRs are expected to be strong enough for ranging measurements. During the coming decade, this could increase the number of NEA mass and bulk density estimates by a factor of several. Among these is (99942) Apophis, which will approach within 0.113 AU in 2021, when radar astrometry is likely to yield a strong Yarkovsky effect detection and estimates of the asteroid's shape, mass, and density (*Giorgini et al.*, 2008; *Farnocchia and Chesley*, 2014).

### 3.4. Radar Detection of the YORP Effect

**3.4.1. (54509) YORP.** The YORP effect is a torque on the spin state of an asteroid due to the absorption and anisotropic reemission of sunlight (*Rubincam*, 2000; see also the chapter by Vokrouhlický et al. in this volume). The first direct evidence of the YORP effect came from combined radar and optical observations of asteroid (54509) YORP (*Taylor et al.*, 2007; *Lowry et al.*, 2007), and optical observations of (1862) Apollo (*Kaasalainen et al.*, 2007).

By virtue of its nearly 1:1 orbital resonance with Earth and a moderate heliocentric eccentricity, (54509) YORP made annual close approaches to Earth from 2001 to 2005. In 2001, Goldstone images and optical light curves established a rapid rotation period of 12.2 minutes. Additional light curves were obtained annually, as were radar observations at Arecibo in 2004 and 2005. Under the assumption of an unchanging spin state, neither the radar images from 2001 and 2004 nor the light curves from 2001 to 2005 could be linked self-consistently. Combining the radar-derived spin-axis orientation with the optical data showed clear evidence for a discrete change in the sidereal spin period from year to year (*Lowry et al.*, 2007), and applying the three-dimensional shape model from inversion of the radar images revealed that a continuously increasing correction to the rotational phase was required to simultaneously fit the light curves over multiple years (*Taylor et al.*, 2007). Both methods revealed a change in spin rate of  $(2.0 \pm 0.2) \times 10^{-4} \text{ deg d}^{-2}$ , amounting to more than a  $200^\circ$  of drift in rotation phase when trying to link light curves obtained over four years. The observation of YORP accelerations on the rotations of objects spanning from 100-m-sized (54509) YORP to multi-kilometer NEA (1620) Geographos (*Durech et al.*, 2008) suggests that the YORP effect is capable of altering the spin of most NEAs. Furthermore, the YORP effect is mass dependent, and if detected, can provide a useful constraint on an asteroid's mass (*Capek and Vokrouhlický*, 2004).

**3.4.2. (99942) Apophis.** When discovered in December of 2004, Apophis was briefly estimated to have a 2.7% chance of impacting Earth in 2029. Additional optical measurements quickly showed there was no impact risk at that time. However, there will be an extremely close approach

to the Earth in 2029, estimated to be a 1-in-800-year event for an object of that size.

Arecibo subsequently detected Apophis at distances of 0.192–0.268 AU in 2005 and 2006, with CW echo power spectra and ranging (*Giorgini et al.*, 2008). The first radar echoes acquired on January 27, 2005, were  $4.8\sigma$  off the frequency predicted by the optical-only solution. Including the radar measurements in a new orbit solution revealed a 1.4-arcsec systematic bias in the prediscovery optical measurements and moved the April 13, 2029, encounter prediction 4.4 Earth radii closer to Earth while reducing the uncertainty in Apophis' location during the encounter by 98%. This was a  $5\sigma$  trajectory correction.

The new radar-corrected orbit had better predictability through the 2029 encounter, but degraded rapidly thereafter. This was due to the new solution's deeper entry into Earth's gravity field in 2029, an approach 45% closer than predicted prior to the debiasing enabled by radar observations. The steeper gravity gradient differentially pulls on and elongates the statistical uncertainty space to a greater extent than the more distant uncorrected preradar encounter.

Echo power spectra, ranging measurements, and coarse-resolution images of Apophis were obtained at Goldstone and Arecibo from December 2012 through March 2013. The images and echo bandwidths suggest an elongated object but are insufficient for estimation of a detailed three-dimensional model. There had been some potential for the Yarkovsky effect to be detected if Apophis was on the low-mass side of what was possible, with a spin pole perpendicular to its orbit plane, in concert with favorable thermal properties. However, the new radar astrometry excluded that extreme combination of properties, showing no significant evidence of Yarkovsky effect motion over 2004–2013 [as predicted by *Farnocchia et al.* (2013b)], and effectively ruled out the remaining impact potential in 2036. Reliable orbit prediction is now possible into the 2060s but the orbital uncertainties grow rapidly afterward.

### 3.5. Near-Earth Asteroid Population Trends

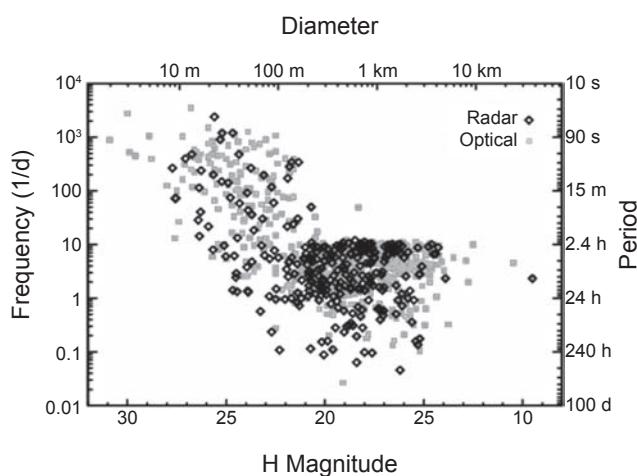

**3.5.1. Overview of the near-Earth asteroid shape and spin distributions.** Radar observations of NEAs have revealed a heterogeneous population with a wide range of shapes and spin characteristics. Near-Earth asteroids detected by radar range over roughly 4 orders of magnitude in size from meter-scale objects 2006 RH<sub>120</sub> and 2013 EC<sub>20</sub> to the largest NEA, (1036) Ganymed, at over 30 km in effective diameter. Their rotation periods span at least 4 orders of magnitude as well, from 16 seconds to more than one week. The radar-determined shapes of NEAs are similarly diverse, from simple spheroids and ellipsoids to multiple-component (binary and triple) systems to double-lobed contact binaries and extremely irregular angular bodies.

*Taylor et al.* (2012) examined the shape and spin distributions of the NEA population observed with the Arecibo radar system since 1998. They found that radar-detected NEAs with diameters larger than  $\sim 200$  m (with a sample size of over 100 objects) are not dominated by a single category of

shape. A radar-observed multiplicity fraction of  $\sim 17\%$  among NEAs with  $H < 21$  is in agreement with optical observations (Pravec et al., 2006; see also the chapter by Margot et al. in this volume), while, perhaps surprisingly, contact binaries account for a similar fraction at  $\sim 14\%$ , roughly 50% larger than reported in earlier estimates (Benner et al., 2006). At smaller sizes, binaries and contact binaries are much less common, with only three binaries and one contact binary known with  $H > 21$  and none with  $H > 22$ . Furthermore, only about one in four objects with  $H > 21$  are assigned basic shapes due to the difficulty in obtaining sufficient resolution in radar images. Those with shapes assigned often appear irregular either with angular shapes or highly specular reflections from facets.

The spin distribution of NEAs estimated from radar observations closely matches the spin distribution determined from optical light curves (Fig. 6; see the chapter by Scheeres et al. in this volume for a different version of this figure). Light curves are biased against small, slowly rotating bodies because of their inherent faintness, which often limits their observability and hence the opportunity to confidently record an entire rotation period on the scale of many tens of hours. Radar observations detect an apparent spin rate based on the instantaneous echo bandwidth, which does not require one to observe an entire rotation. Thus, radar should detect a small, slowly rotating body as a narrow echo.

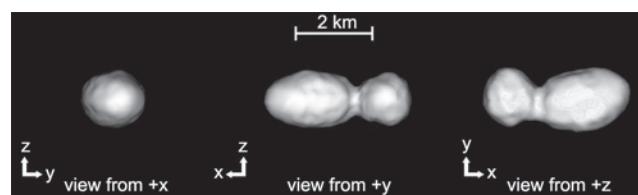

The distinct change in the shape and spin distributions of the NEA population at  $H = 21$  or 22 (100- to 200-m diameters) may indicate fundamental structural changes at this scale.

**Fig. 6.** Spin-rate distribution of near-Earth asteroids as determined by optical and radar techniques (Taylor et al., 2012). Optical data (gray squares) are periods from the Warner lightcurve database [Warner et al. (2009), September 2014 update] with quality factors  $U \geq 2$ ; radar data (black diamonds) are estimated from echo bandwidths observed at Arecibo. There is broad agreement between the two techniques despite different observational biases, including the lack of slowly rotating small bodies. Diameters are computed from absolute magnitudes by assuming an optical albedo of 0.2.

**3.5.2. Abundance of contact binary near-Earth asteroids.** Radar imaging since completion of the upgrade at Arecibo in 1999 revealed more than 30 NEAs that are deeply bifurcated (Benner et al., 2006; Brozovic et al., 2010; Magri et al., 2011). Benner et al. (2006) found that at least  $\sim 10\%$  of NEAs  $> 200$  m in diameter are candidate contact binaries, where a contact binary is defined as “an asteroid consisting of two lobes that are in contact, [and] have a bimodal mass distribution, that may once have been separate.” By this definition, objects such as Itokawa and Toutatis that have two components with substantial size differences, and thus lack bimodal mass distributions, were not classified as contact binaries. The definition of a contact binary is necessarily subjective, and due to considerable subsequent research on the formation and evolution of Itokawa and radar imaging of hundreds of additional NEAs, we now relax the definition to include objects that are obviously bifurcated, have components that can be significantly different in size (with size ratios of at least 4:1), and mass distributions that aren’t bimodal. With this revised definition, the fraction of candidate contact binaries imaged by radar has grown to  $\sim 14\%$  (Taylor et al., 2012). Given that true binaries comprise  $\sim 16\%$  of the NEA population above  $\sim 200$  m in diameter (Margot et al., 2002), this implies that the abundances of contact binaries and true binaries are comparable and that these objects together constitute  $\sim 30\%$  of the NEA population  $> 200$  m in diameter. Figure 7 shows an example: the three-dimensional model of 1996 HW<sub>1</sub>, which was imaged at Arecibo in 2008 and is one of the most deeply bifurcated NEAs observed to date (Magri et al., 2011).

These contact binary objects display considerable dynamic range in long axis lengths, spectral classes, and spin states. The largest is (192642) 1999 RD<sub>32</sub>, with a long axis of  $\sim 6$  km, and the smallest is 2013 JR<sub>28</sub>, with a long axis of  $\sim 100$  m. The fastest rotator is (4769) Castalia with a rotation period of 4 h, and the slowest, 2002 FC and 2004 RF<sub>84</sub>, have unknown rotation periods of days to weeks. None of the contact binaries rotate as fast as the rapidly spinning primaries of most NEA binaries and triples (see the chapter by Margot et al. in this volume). Some of the contact binaries rotate at rates close to where they could separate if spun up slightly (Benner et al., 2006; Scheeres, 2007). A significant (but not yet quantified) fraction are non-principal-axis rotators.

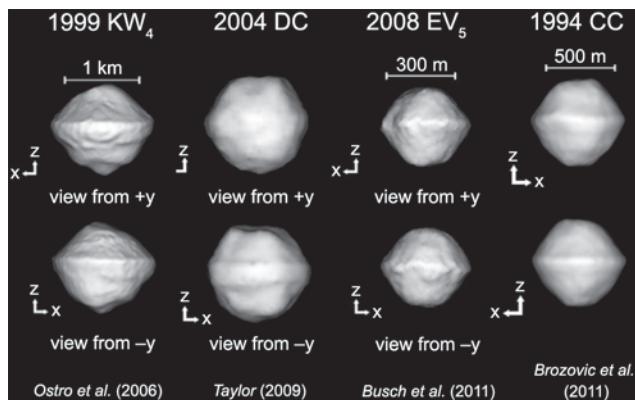

**Fig. 7.** Principal axis views of the 1996 HW<sub>1</sub> shape model (adapted from Magri et al., 2011). This is one of the most bifurcated NEAs modeled to date using delay-Doppler radar images.

How did such objects form and why are they so abundant? Plausible formation mechanisms are by low-velocity collisions; collapse of true binaries through tidal friction or as a result of orbital perturbations during close planetary encounters; by spinup due to YORP; or by partial disruption during close planetary flybys. Combinations of the factors above may be necessary to explain the slowest rotators.

**3.5.3. Binary near-Earth asteroids.** Binary asteroids are a field of vigorous research and are treated in considerable detail in the chapter by Margot et al. in this volume. In this chapter we mention them only to illustrate points that also apply to broader trends within the NEA population.

**3.5.4. Equatorial ridges.** Evidence for equatorial bulges appears in radar images for many rapidly rotating NEAs  $>200$  m in diameter, some relatively slow rotators, and for most of the primaries in binary and triple NEA systems. The first clear case was the primary of binary (66391) 1999 KW<sub>4</sub> (Ostro et al., 2006), which exhibited a “double exposure” appearance at its leading edge that corresponded to the sharp edge of its ridge. Bulges have since been seen in models for (311066) 2004 DC (Taylor, 2009), 2008 EV<sub>5</sub> (Busch et al., 2011), (136617) 1994 CC (Brozovic et al., 2011), 2005 YU<sub>55</sub> (Busch et al., 2012), the primary of (185851) 2000 DP<sub>107</sub> (Naidu et al., 2015), and in radar images of numerous other NEAs for which shape models are not yet available. Figure 8 shows renderings of shape models for selected objects with bulges. The ridges are thought to form via YORP-induced spinup acting on an object with a rubble-pile internal structure (Harris et al., 2009; Walsh et al., 2008; see also the chapter by Scheeres et al. in this volume). Although no formal estimate of their abundance is available, radar observations and three-dimensional modeling indicate that NEAs with equatorial ridges are relatively common. In more detail, the delay-Doppler signature of objects with oblate vs. spheroidal shapes are discussed by Busch et al. (2011) and applied to 2008 EV<sub>5</sub>.

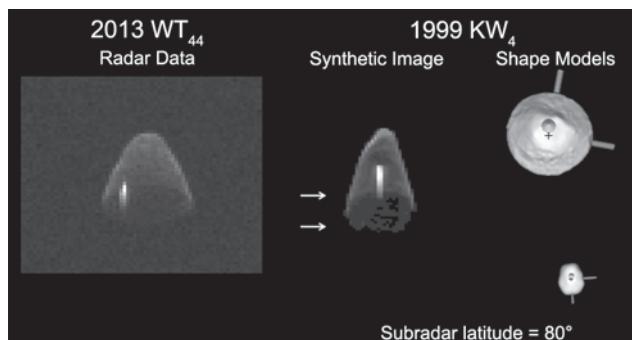

In addition to the appearance of shape models, direct evidence for oblate shapes comes from images of 2013 WT<sub>44</sub>, which was observed at a subradar latitude close to a pole.

**Fig. 8.** Model renderings of four NEAs with evidence for oblate shapes. Each model is viewed along the + and - y-axes.

Figure 9 compares the radar images of 2013 WT<sub>44</sub> with a high-latitude view of the 1999 KW<sub>4</sub> model (Ostro et al., 2006) to illustrate the appearance of the equatorial ridge from a nearly pole-on perspective. The 2013 WT<sub>44</sub> images show a flat polar region, a roughly cone-shaped hemisphere, and a “doubly curved” trailing edge region that shows the entire circumference of an equatorial ridge tilted relative to the radar line-of-sight.

**3.5.5. Radar evidence for impact craters.** Features suggesting impact craters have been seen on numerous NEAs imaged by radar starting with (4179) Toutatis in 1992 (Ostro et al., 1995; see also Hudson et al., 2003). The candidate craters generally take the form of circular to ellipsoidal radar-dark features from tens of meters to more than 2 km in extent. Interpretation of radar-dark features is hampered by the counterintuitive nature of delay-Doppler images, the resolution, SNRs, and rotational coverage of the data. Deep concavities are visible along the leading edges of other objects, but do not appear as radar-dark regions. Concavities are also evident in some shape models and may represent craters but their origins are not clear. Candidate craters appear in radar images of many objects such as (4183) Cuno, (33342) 1998 WT<sub>24</sub> (Busch et al., 2008), (53319) 1999 JM<sub>8</sub> (Benner et al., 2002), and (185851) 2000 DP<sub>107</sub> (Naidu et al., 2015). Table 1 lists NEAs imaged by radar that show evidence for impact craters. Figure 10 shows Arecibo images of (136849) 1998 CS<sub>1</sub>, which has a number of radar-dark features suggesting impact craters, and Fig. 2 shows images of 2005 YU<sub>55</sub>, which has several small ellipsoidal radar-dark regions and a small concavity on its leading edge. Craters are conspicuously absent in radar images of many other NEAs, perhaps because such features are not present, due to limited viewing geometry, or perhaps because the SNRs and resolution are insufficient.

**Fig. 9.** Comparison between observations of binary NEA 2013 WT<sub>44</sub> and a synthetic radar image of binary 1999 KW<sub>4</sub> viewed at a high subradar latitude. *Left:* Goldstone delay-Doppler image of 2013 WT<sub>44</sub> obtained on March 20, 2014. Resolution = 18.75 m  $\times$  0.5 Hz. *Middle:* Synthetic radar image of 1999 KW<sub>4</sub> generated using the geometry of the models shown on the right. In the synthetic image, upper and lower arrows point to echoes from the near and far edges of the equatorial bulge.

TABLE 1. NEAs with radar-detected craters.

Asteroid	H
(1580) Betulia	14.5
(4179) Toutatis	15.3
(4183) Cuno	14.4
(33342) 1998 WT <sub>24</sub>	17.9
(52760) 1998 ML <sub>14</sub>	17.5
(53319) 1999 JM <sub>8</sub>	15.2
(136849) 1998 CS <sub>1</sub>	17.6
(185851) 2000 DP <sub>107</sub>	18.2
(304330) 2006 SX <sub>217</sub>	18.9
(308635) 2005 YU <sub>55</sub>	21.9
(388188) 2006 DP <sub>14</sub>	18.9
2010 JL <sub>33</sub>	17.7

**3.5.6. Radar evidence for boulders on near-Earth asteroid surfaces.** Delay-Doppler radar observations of numerous NEAs have revealed many small clusters of radar-bright pixels in some of the highest SNR images obtained at Arecibo and Goldstone. Many of the spots persist as the asteroids rotate, so the bright pixels are not receiver noise, self noise, or artifacts. Clusters of bright pixels appear primarily in high-resolution radar images with resolutions of 4–19 m/pixel and suggest that these are features a few tens of meters in extent or smaller. Many spots appear near the trailing edges of the images and are uprange from radar shadows, implying that the source for some of the features is small-scale topography. Figures 2 and 3 show images of 2005 YU<sub>55</sub> and 2014 HQ<sub>124</sub>, NEAs that have conspicuous and widespread radar-bright spots. To date, small groups of bright pixels have been seen on at least 14 NEAs, establishing that these features are relatively common.

Benner et al. (2014a) suggest that the bright pixels are echoes from surface and near-surface boulders, which have also been seen on each of the three NEAs imaged at close range by spacecraft: (433) Eros [Near Earth Asteroid Rendezvous (NEAR)], (25143) Itokawa (Hayabusa), and (4179) Toutatis (Chang'e-2). These asteroids have also been imaged by radar, but the SNRs and/or resolutions were insufficient to reveal boulders with Eros and Itokawa. However,

radar images of Toutatis obtained in 2012 reveal spots that can be linked with boulders in the Chang'e-2 spacecraft images. Of the objects with evidence for boulders, 1999 RD<sub>32</sub> is the largest, with a long axis of ~6 km, and 2014 BR<sub>57</sub> is the smallest, with a diameter of about 80 m.

**3.5.7. Circular polarization ratio correlations with spectral class.** Benner et al. (2008) conducted a survey of more than 200 NEAs detected by radar and found distinct correlations between their circular polarization ratios (abbreviated as “SC/OC”) and some spectral classes. E- and V-class NEAs have high SC/OC values, a trend that is mirrored among the handful of E-class MBAs that have also been detected to date by radar (Shepard et al., 2008b, 2011). In contrast, SQ-class and optically dark NEAs show circular polarization ratios that vary from ~0.1 to ~0.5 but otherwise show no obvious trends. Fifty-six percent of the NEAs in which SC/OC > 0.5 in the sample have unknown spectral classes, and if all of them turn out to be E- or V-class objects, that implies that EV-class NEAs are much more abundant in the near-Earth population than has been previously realized. Since the study by Benner et al. (2008) was published, the sample of NEAs observed by radar has more than doubled and the pattern of high SC/OC values among E- and V-class objects has persisted (Springmann et al., 2013).

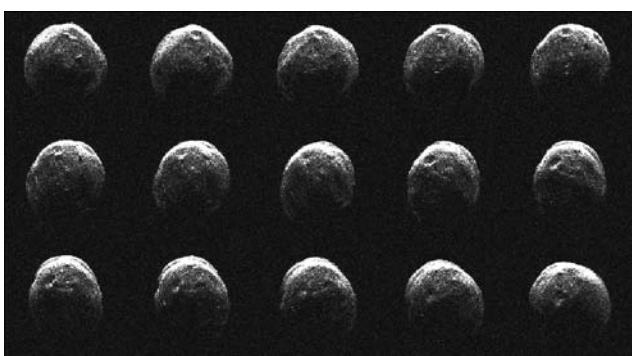

How are we to understand these correlations? Benner et al. (2008) speculated that this could possibly “be due to the intrinsic mechanical properties of different mineralogical assemblages but also may reflect very different formation ages and collisional histories.” The fact that the trend of high SC/OC appears to remain across a wide range of diameters, including inner MBAs up to several tens of kilometers in diameter, suggests that there is at least a component due to composition.

Virkki et al. (2014) modeled the effects of electric permittivity and the size of surface structure on asteroid radar circular polarization ratios and radar albedos. They find that obtaining SC/OC > 1 at 3.5 and 13 cm wavelengths requires a high refractive index ( $n > 2$ ), which may explain the high polarization ratios observed among basaltic V-class objects because basalt has a relatively high refractive index. In general, SC/OC > 0.5 occurs from surfaces with scatterers from one to a few times larger than the radar wavelength, although this is also a function of the refractive index and thus composition. Fundamentally, though, asteroid surfaces with high SC/OC are still not well understood.

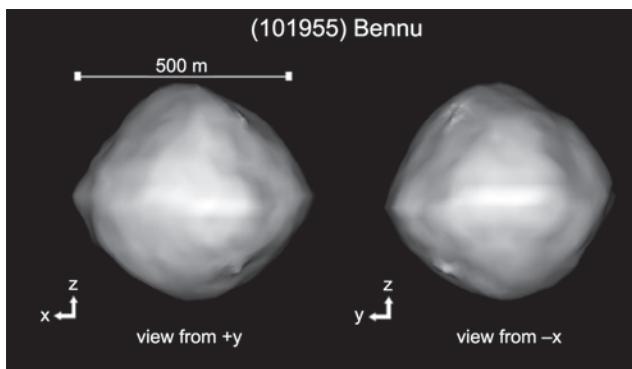

## 4. RESULTS FOR SELECTED ASTEROIDS

### 4.1. (101955) Bennu

Nolan et al. (2013) estimated the shape of Bennu based on Arecibo and Goldstone imaging in 1999 and 2005 (Fig. 11). Bennu is an optically dark spheroid with major axes of 565 × 535 × 508 m, a sidereal rotation period of 4.3 h, a modest equatorial ridge, evidence for a relatively large boulder in the southern hemisphere, and broad-scale near-surface roughness features.

**Fig. 10.** Arecibo images of (136849) 1998 CS<sub>1</sub> obtained on January 18, 2009. Resolution is 7.5 m × 0.09 Hz. Rotation is counterclockwise.

**Fig. 11.** Renderings of the three-dimensional model of (101955) Bennu (adapted from Nolan *et al.*, 2013) viewed along the x- and y-axes.

Bennu is the target of the OSIRIS-REx mission, which will provide a stringent test for the shape-modeling process when the spacecraft arrives in October 2018.

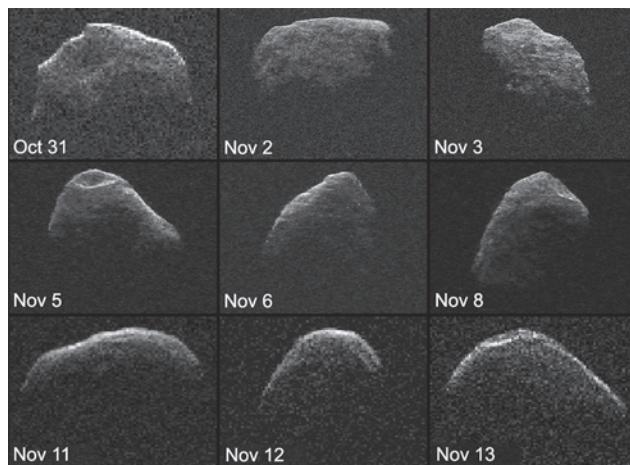

Chesley *et al.* (2014) report detection of the Yarkovsky effect for Bennu through radar astrometry obtained in 1999, 2005, and 2011 and optical astrometry from 1999 to 2013. This yields estimates of the mass and bulk density that are invaluable for planning the OSIRIS-REx mission. The density,  $\rho = 1.3 \text{ kg m}^{-3}$ , implies a macroporosity of  $\sim 40\%$  and suggests a rubble-pile internal structure. Bennu has one of the highest impact probabilities known, and, due to frequent close Earth encounters, will probably require orbital monitoring indefinitely (Milani *et al.*, 2009).

#### 4.2. (4660) Nereus

Nereus had been identified as a potential spacecraft target since its discovery because of the low  $\Delta V$  required for a rendezvous. Nereus was an early target for the NEAR mission and the original target for the Hayabusa mission. Arecibo and Goldstone images of Nereus obtained in 2002 enabled Brozovic *et al.* (2009) to reconstruct a three-dimensional model, which resembles an ellipsoid with principal axis dimensions  $X = 510 \pm 20 \text{ m}$ ,  $Y = 330 \pm 20 \text{ m}$ , and  $Z = 241^{+80}_{-10} \text{ m}$ , and features two prominent facets.

#### 4.3. (214869) 2007 PA<sub>8</sub>

Goldstone imaged 2007 PA<sub>8</sub> on 16 days in 2012. The images achieved range resolutions as fine as 3.75 m, placed thousands of pixels on the asteroid, and revealed an elongated, asymmetric object (Fig. 12) (Brozovic *et al.*, in preparation). The surface has angularities, facets, and a concavity  $> 200 \text{ m}$  in diameter. Shape modeling yields an effective diameter of  $1.35 \pm 0.05 \text{ km}$ , and elongation (long/intermediate axis ratio) = 1.4. The modeling revealed that 2007 PA<sub>8</sub> is a non-principal-axis rotator in short-axis mode with an average period of precession by the long axis around the angular momentum vector of  $4.26 \pm 0.02 \text{ d}$  and an oscillatory period

**Fig. 12.** Images of (214869) 2007 PA<sub>8</sub> obtained at Goldstone during October–November 2012. Range resolutions are 18.75 m on October 31 and November 11–13; 7.5 m on November 2, 3, and 8; and 3.75 m on November 5 and 6. The highest resolutions were obtained on dates when the asteroid was closest to Earth and the signal-to-noise ratios were strongest. Each panel has the same delay-Doppler dimensions.

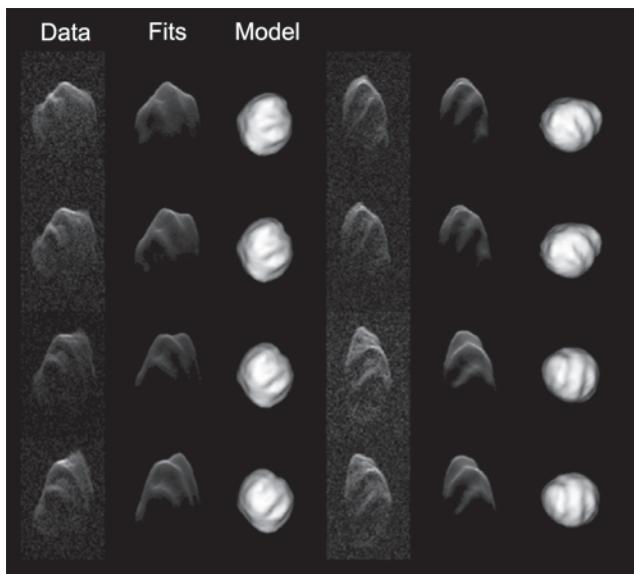

around the long axis of  $20.55 \pm 3.75 \text{ d}$ . The amplitude of rolling around the long axis is  $42 \pm 7^\circ$ . 2007 PA<sub>8</sub> is the second confirmed short-axis mode non-principal-axis rotator found in the NEA population, after Apophis (Pravec *et al.*, 2014).

#### 4.4. (162421) 2000 ET<sub>70</sub>

Arecibo images of 2000 ET<sub>70</sub> place thousands of pixels on the object (Fig. 13) (Naidu *et al.*, 2013). The three-dimensional physical model has dimensions of  $2.6 \times 2.2 \times 2.1 \text{ km}$ , a retrograde spin state with a 9-h period, and an unusually low optical albedo of  $\sim 2\%$ . The northern hemisphere has dramatic ridges oriented approximately perpendicular to the long axis, but the southern hemisphere is much more rounded, a global shape dichotomy that is uncommon among NEAs imaged by radar to date.

#### 4.5. (308635) 2005 YU<sub>55</sub>

2005 YU<sub>55</sub> approached within 0.0022 AU (0.85 lunar distances) in November 2011, the closest approach of a known asteroid  $> 300 \text{ m}$  in diameter since 1982 (2012 TY<sub>52</sub>) and until 2028 (2001 WN<sub>5</sub>). This provided an extraordinary opportunity for radar imaging, and extensive observations were obtained at Goldstone, Arecibo, the Green Bank Telescope, and elements of the VLBA over two weeks (Busch *et al.*, 2012). The SNRs were among the highest ever obtained for any NEA and resulted in radar images with resolutions as fine as 3.75 m in range (Fig. 2). The images reveal a rounded object whose surface has many small radar-bright spots, suggesting numerous boulders, and radar-dark regions that may be impact craters. Modeling indicates that the shape

**Fig. 13.** Selected Arecibo images, fits, and plane-of-sky views of the 2000 ET<sub>70</sub> shape model (Naidu et al., 2013).

is close to spheroidal with maximum dimensions of  $360 \pm 40$  m in all directions. The shape has a ridge roughly parallel to the equator that resembles ridges seen on other rapidly rotating spheroidal NEAs imaged by radar, but unlike those other objects, 2005 YU<sub>55</sub> is a relatively slow rotator with a period of  $\sim 19$  h.

#### 4.6. 2014 HQ<sub>124</sub>

Bistatic Goldstone-Arecibo X-band images of 2014 HQ<sub>124</sub> achieve a resolution of  $3.75$  m  $\times$   $0.00625$  Hz (Fig. 3) and provide some of the most detailed radar views obtained for any near-Earth object (Benner et al., 2014b). 2014 HQ<sub>124</sub> is a slowly rotating object that is elongated, bifurcated, and angular with a long axis of at least 400 m. The larger lobe has a narrow, sinuous,  $\sim 100$ -m-long radar-dark feature that may be a scarp or perhaps a fault. These observations were the first test of new data-taking equipment at Arecibo that can acquire images at 3.75 m resolution using transmissions from Goldstone. Radar astrometry increased the interval of reliable Earth encounter predictability by a factor of 2 to  $\sim 900$  years.

#### 4.7. (341843) 2008 EV<sub>5</sub>

Busch et al. (2011) observed 2008 EV<sub>5</sub> with Arecibo, Goldstone, and the VLBA during the asteroid's passage within 0.022 AU in December 2008. Radar speckle tracking indicates retrograde rotation; this is the first NEA where that technique was used successfully. The object has a diameter of  $400 \pm 50$  m, a prominent ridge parallel to its equator, and a concavity about 150 m in diameter (Fig. 8). The concavity may be an impact crater; if so, then its ejecta may have produced some of the numerous boulders that are suggested by radar bright spots near the south pole. This object was

the target for the proposed European Space Agency's Marco Polo-R mission and is a leading candidate for NASA's proposed Asteroid Redirect Mission.

#### 4.8. (33342) 1998 WT<sub>24</sub>

1998 WT<sub>24</sub> approached within five lunar distances (0.0125 AU) in December 2001, when it was the strongest asteroid radar target ever observed up to that point. This asteroid was observed extensively at Goldstone and Arecibo and yielded a detailed three-dimensional model (Busch et al., 2008). The images show a rounded object with a conspicuous radar-bright spot several pixels in extent that persists over multiple rotations. The asteroid has a diameter of  $415 \pm 40$  m and the shape is dominated by three large basins that may be impact craters.

#### 4.9. (29075) 1950 DA

1950 DA is a type case highlighting the importance of radar astrometry and shape modeling for predicting asteroid trajectories and the interaction between orbits, shapes, and spin states due to the Yarkovsky effect.

1950 DA was discovered in 1950, lost until 2000, and then observed extensively at Arecibo and Goldstone during a close approach in March 2001. Radar astrometry indicated that 1950 DA will approach Earth in 2880, and the outcome of this approach depends on the magnitude and direction of the Yarkovsky acceleration. Due to the uncertainties in unmeasured physical parameters, Giorgini et al. (2002) included uncertainties in the Earth impact probability by expressing it as an interval, concluding that "the maximum probability of impact is best expressed as being between 0 and 0.33%."

Shape modeling by Busch et al. (2007) generated two pole solutions and two corresponding shapes: one that is roughly spheroidal and  $\sim 1.2$  km in diameter, and a second that is oblate,  $\sim 1.2$  km from pole to pole, and  $\sim 1.6$  km across at the equator (Busch et al., 2007). The data were insufficient to determine if 1950 DA spins prograde or retrograde, producing an ambiguity in the asteroid's future trajectory and thus in the impact probability.

Farnocchia and Chesley (2014) utilized additional optical astrometry, and remeasured radar astrometry from 2001 and new radar ranging from Arecibo in 2012 to further improve the orbit. The main source of uncertainty remains the Yarkovsky effect, which was detected at the  $\sim 5\sigma$  level. Utilizing a statistical model of the Yarkovsky effect, they found that, due to the sign of the orbital drift, prograde rotation is ruled out. This appears to be the first time that a pole direction ambiguity has been resolved by detection of the Yarkovsky effect, which was predicted by Busch et al. (2007).

Rozitis et al. (2014) adopted the retrograde shape model from Busch et al. (2007) and used thermal modeling of Wide-field Infrared Survey Explorer (WISE) spacecraft data to estimate 1950 DA's thermal inertia and bulk density. They state that the asteroid's rapid spin (2.1 h) implies a need

for cohesive forces to prevent rotational breakup. *Rozitis et al.*'s (2014) work hinges on the  $5\sigma$  Yarkovsky effect detection reported by *Farnocchia and Chesley* (2014) and on the retrograde shape model without regard to the uncertainties in that model. However, more recently, *Hirabayashi and Scheeres* (2015) find that cohesion is necessary over a much wider range of densities, indicating that a change in density estimate will not substantively impact the main conclusions of *Rozitis et al.* (2014) (see the chapter by Scheeres et al. in this volume).

Future radar and optical astrometry can refine estimates of 1950 DA's Yarkovsky effect drift, improve estimates of the asteroid's future trajectory, and improve estimates of its bulk density and constraints on its internal structure. The next opportunity for radar observations of 1950 DA is in 2032, when an extensive imaging campaign at Arecibo and Goldstone could provide higher-resolution images than were obtained in 2001.

#### 4.10. (1580) Betulia

*Magri et al.* (2007b) modeled the shape and spin state of Betulia using Arecibo data obtained in 2002 and light curves obtained in 1976 and 1989. They obtain a model that resembles the *Kaasalainen et al.* (2004) convex-definite shape reconstructed from light curves but is dominated by a prominent concavity in the southern hemisphere. Betulia has an effective diameter of  $5.39 \pm 0.54$  km and a shape that is roughly triangular when viewed along its polar axis.

#### 4.11. (100085) 1992 UY<sub>4</sub>

Goldstone and Arecibo radar images of 1992 UY<sub>4</sub> obtained in 2005 reveal a lumpy, modestly asymmetric, 2-km-diameter object. The surface is characterized by gently undulating topography with many modest concavities. Numerous fine-scale, radar-bright features are evident at the trailing edges and limbs; one of the most prominent has a visible extent of about 100 m and juts out abruptly from the approaching limb, suggesting a large block similar to the boulder Yoshinodai seen on (25143) Itokawa by the Hayabusa spacecraft (*Saito et al.*, 2006).

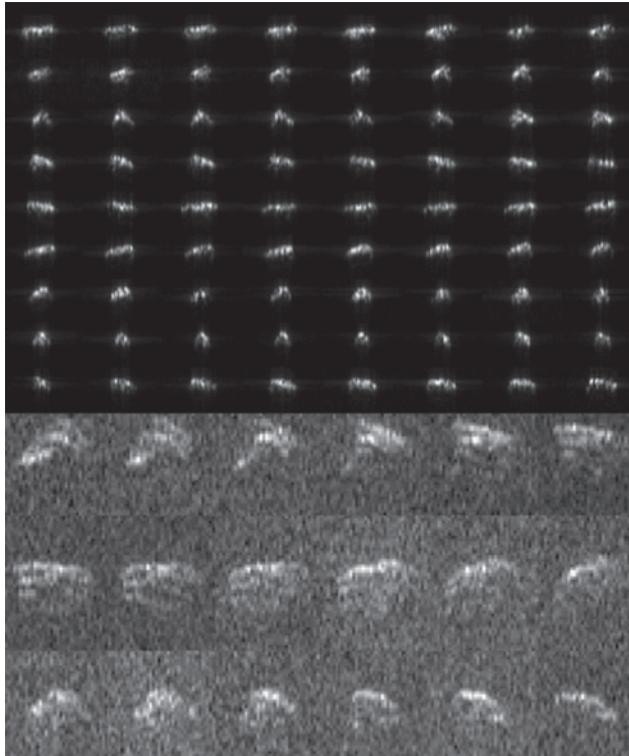

#### 4.12. Tiny Near-Earth Asteroids

Near-Earth asteroids with diameters  $<140$  m (corresponding to  $H > 22$ ) comprise approximately one-fourth of all NEAs observed with radar. The fraction of such objects observed by radar has increased  $\sim 50\%$  since publication of *Asteroids III* because more of these objects are being discovered with sufficient advance notice to schedule radar observations, due to greater access to telescope time, and due to more rapid response protocols. Several have been observed within one lunar distance, and one, 2006 RH<sub>120</sub>, was a temporarily captured satellite of Earth. A further motivation has been acute interest since 2011 in tiny NEAs that could be targets for human missions. To that end, as many

objects on the NASA Near-Earth Object Human Spaceflight Accessible Targets Study list (NHATS) (<http://neo.jpl.nasa.gov/nhats/>) are observed with radar as possible even if the SNRs are very weak.

Due to development of the 3.75-m resolution imaging system at Goldstone, it has become possible to obtain delay-Doppler images that can spatially resolve NEAs as small as  $\sim 30$  m in diameter. This opens up a new capability to investigate the physical properties of a much smaller subset of the NEA population than was previously possible. The first object imaged at 4-m resolution was 2010 AL<sub>30</sub> (*Slade et al.*, 2010). More recently, several NEAs such as (367943) Duende (2012 DA<sub>14</sub>), 2013 ET, and 2014 BR<sub>57</sub> have been imaged, revealing a suite of irregular to spheroidal shapes (Fig. 14).

Ranging astrometry from tiny NEAs can yield orbits with sufficient precision to detect nongravitational perturbations from solar radiation pressure. If detected, this perturbation yields an estimate of the area/mass ratio. To date, solar radiation pressure perturbations have been detected in the

**Fig. 14.** Goldstone images of two NEAs that are less than 100 m in diameter. *Top:* (367943) Duende (2012 DA<sub>14</sub>) imaged on February 16, 2013. Duende has major axes of  $\sim 40 \times 20$  m, an angular shape, and is a non-principal-axis rotator (*Moskovitz et al.*, 2013). *Bottom:* 2013 ET images from March 10, 2013. 2013 ET appears structurally complex, has a long axis of at least 40 m, and has alternating radar-dark and radar-bright regions. In each collage, the range resolution is 3.75 m, but the data were double sampled, so each row corresponds to 1.875 m.

motion of one NEA observed by radar: 2006 RH<sub>120</sub> in 2007 (P. W. Chodas, personal communication).

## 5. THE FUTURE

The future for asteroid radar observations is potentially very bright if capabilities at least equal to those currently available at Arecibo and Goldstone are maintained. As the number of NEAs discovered has grown rapidly in the last decade, so too have the number of short-term targets of opportunity and targets known well in advance. This trend will only continue as existing surveys upgrade and as new surveys begin.

The Large Synoptic Survey Telescope (LSST) could yield vastly more NEA discoveries when it begins routine operations in the 2020s, and with it could come a dramatic increase in radar targets. Due to its sensitivity, it seems likely that many NEAs larger than a few tens of meters in diameter found by LSST will be discovered months or even years before they will be detectable by radar.

The number of NEAs observed annually with radar is a fraction of what could be done if a dedicated radar facility were available. Schedules and equipment problems continue to be obstacles for observing on short notice but are less cumbersome than only a few years ago. The net effect is that roughly one-third of NEAs that are potentially detectable with radar are actually being observed.

Arecibo could observe many more asteroids if additional telescope time and funding were available. The observatory is already operating the S-band radar at close to the legal limit imposed by local air pollution laws, and a significant increase would require new, lower-emission generators. Due to its extraordinary sensitivity, though, the most effective way to increase the number of NEA radar detections is to augment the number of observations at Arecibo.

Demand at Goldstone for spacecraft communications is expected to diminish over the next several years as existing spacecraft cease operations and as future spacecraft switch to NASA's 34-m antennas for tracking. This could provide an opportunity to observe significantly more asteroids. Although most requests at Goldstone to observe NEAs known well in advance are scheduled, obtaining time on short notice remains challenging because schedules for flight projects are arranged many weeks in advance, and changing schedules on short notice has effects that ripple through the DSN.

### 5.1. Other Radar Facilities

Are there other existing radar facilities that could be utilized to observe NEAs? The 70-m Evpatoria antenna in Crimea has conducted bistatic NEA radar observations utilizing radio telescopes at Effelsberg (Germany), Medicina (Italy), and Irbene (Latvia) as receivers. Evpatoria has also acted as a receiver for Goldstone X-band transmissions of (6489) Golevka (Zaitsev et al., 1997), 1998 WT<sub>24</sub> (Di Martino et al., 2004), and 2004 XP<sub>14</sub> and could be used for monostatic observations of very close targets if the system

were modernized (B. Shustov, personal communication). Installation of a high-power planetary radar was considered for the new 64-m Sardinia Radio Telescope (Saba et al., 2005) but was not implemented due to the cost.

In February 2013, J. Vierinen (personal communication) detected radar echoes from (367943) Duende with the European Incoherent Scatter Scientific Association (EISCAT) facility near Tromso, Norway; this was the first time EISCAT was used for asteroid observations. Nechaeva et al. (2013) observed Duende by using Evpatoria to transmit and Irbene and Medicina to receive. The 37-m X-band and 46-m ultra-high-frequency (UHF) antennas at Haystack Observatory also detected Duende (P. Erickson and M. Hecht, personal communication). Radar observations of Duende were scheduled at the 35-m Tracking and Imaging Radar (TIRA) facility in Germany, but those observations were canceled due to logistical problems (D. Koschny, personal communication). Although orders of magnitude less sensitive than Goldstone, these facilities could detect a modest number of near-Earth objects annually during very close flybys.

### 5.2. Future Radar Capabilities

A new radar facility began operations in January 2015 on the 34-m DSS-13 antenna at the Goldstone Deep Space Communications Complex. DSS-13 is an experimental test bed that has been equipped with an 80-kW klystron that transmits at C-band (7190 MHz, 4.2 cm). The klystron has a bandwidth of 80 MHz and can achieve a range resolution of up to 1.875 m/pixel, which is twice as fine as the highest resolution at the 70-m DSS-14 Goldstone antenna and four times finer than at Arecibo. DSS-13 is not equipped to receive its own radar echoes, so reception must occur at another facility such as Green Bank, Arecibo, or the 34-m DSS-28 antenna at Goldstone. Bistatic DSS-13/Arecibo and DSS-13/Green Bank observations are significantly less sensitive than observations at DSS-14, but for very strong targets such as 2005 YU<sub>55</sub>, (367943) Duende, and 2014 HQ<sub>124</sub>, where the SNR is not a limiting factor, DSS-13 would have been ideal. The new radar at DSS-13 is in its commissioning phase and routine operations are planned by the end of 2015.

The 70-m DSS-43 antenna at the Canberra Deep Space Communication Complex in Australia and the 64-m Parkes Radio Telescope could in principle be configured as a bistatic radar system using an existing S-band transmitter on DSS-43 that can radiate 400 kW. This bistatic system might achieve SNRs perhaps ~4% as strong as those at Goldstone and could enable radar observations of very close NEAs at southern declinations that are inaccessible to Goldstone and Arecibo. Proof-of-concept tests are planned in late 2015. Farther into the future, one of the 34-m DSN antennas at Canberra could be equipped with an 80-kW, 80-MHz klystron and transmitter identical to the system at DSS-13 (Davarian, 2011).

Another concept in the early stages of development is the Ka-Band Objects Observations and Monitoring (KaBOOM) phased-array radar test bed at the Kennedy Space Center (<http://www.nasa.gov/directorates/heo/scan/engineering/>

technology/*KaBOOM.html*). KaBOOM is a three-element array with antennas 12 m in diameter. The effective radiated power of an array of transmitters is proportional to  $N^2$ , where  $N$  is the number of array elements (Davarian, 2011), so in principle it is possible use a large number of small antennas radiating low power ( $\sim 5$  kW) to achieve much higher sensitivity than with a single, large dish. The engineering challenges are formidable and it is not yet known if this technique is feasible.

### 5.3. Greater Automation

Observing NEAs with radar remains a labor-intensive process that requires at least three people at the observatory to operate the telescope and transmitter, adjust cables, take data, make key decisions, and update ephemerides. At Arecibo it is still necessary to switch cables and adjust voltage gains when changing setups, a process that in principle could be automated with one electronics box. In the future, one can envision a situation with a nightly queue where the telescope automatically moves from target to target, where software automatically processes the data to determine when a detection has occurred, estimates and reports range-Doppler corrections to the ephemerides, and then slews to the next target. Imaging of high-SNR targets would require more direct human control to maximize the scientific return, but weaker targets could be observed in the automated manner described above.

### 5.4. Shape Modeling

The shape models discussed above demonstrate a clear need for improvements to the shape-modeling procedure. A better estimation algorithm that can fit topographically rugged objects is particularly desirable because features are often visible in radar images that the fits do not adequately reproduce. It would be helpful if a straightforward method of manually adjusting specific vertices on a model were possible in order to fit fine-scale features. Coupled estimation of the shapes and orbits of binaries would also be helpful.

Although increasing computer speed is useful, the limiting factor for estimating three-dimensional models is actually the ability of the user to assess the fits. Experience has shown that the human eye is more reliable than the  $\chi^2$  statistic for assessing the quality of fits, but this requires time-consuming visual inspection of many images.

Another impediment for augmenting the number of asteroid shape models is the paucity of NEA pole directions. Knowledge of the pole direction dramatically shrinks the time to estimate three-dimensional shapes. Otherwise, pole estimation requires a lengthy grid search may that not yield a unique solution. Radar speckle observations can provide pole directions for the subset of targets with very strong SNRs, and increasing the number of days of radar observations to extend sky motion can help, but the biggest contribution will probably come from obtaining more light curves. Light curves can often provide pole directions when

radar observations cannot, but obtaining light curves can be a major logistical challenge and they are often not available for many NEAs observed by radar.

## 6. SUMMARY

The number of NEAs being observed annually with radar is approaching 100, but that is still only a fraction of the number that could be observed if telescope time, funding, personnel, equipment problems, and the ability to respond to targets of opportunity very rapidly were not issues.

Asteroid radar astronomy has made dramatic strides forward since publication of *Asteroids III*; the field is growing, and it has considerable scientific potential. New discoveries occur frequently, imaging resolutions are approaching the realm of planetary geology, and radar observations have become important in ways that were never imagined only a decade ago.

**Acknowledgments.** We thank D. J. Scheeres and an anonymous reviewer for comments that improved this manuscript. Part of this work was performed at the Jet Propulsion Laboratory, California Institute of Technology, under contract with the National Aeronautics and Space Administration (NASA). ---

In the past decade, hundreds of asteroid shape models have been derived using the lightcurve inversion method. At the same time, a new framework of three-dimensional shape modeling based on the combined analysis of widely different data sources — such as optical lightcurves, disk-resolved images, stellar occultation timings, mid-infrared thermal radiometry, optical interferometry, and radar delay-Doppler data — has been developed. This multi-data approach allows the determination of most of the physical and surface properties of asteroids in a single, coherent inversion, with spectacular results. We review the main results of asteroid lightcurve inversion and also recent advances in multi-data modeling. We show that models based on remote sensing data were confirmed by spacecraft encounters with asteroids, and we discuss how the multiplication of highly detailed three-dimensional models will help to refine our general knowledge of the asteroid population. The physical and surface properties of asteroids, i.e., their spin, three-dimensional shape, density, thermal inertia, and surface roughness, are among the least known of all asteroid properties. Apart from the albedo and diameter, we have access to the whole picture for only a few hundreds of asteroids. These quantities are nevertheless very important to understand, as they affect the nongravitational Yarkovsky effect responsible for meteorite delivery to Earth, as well as the bulk composition and internal structure of asteroids.

## 1. INTRODUCTION

The determination of asteroid physical properties is an essential part of the complex process of revealing the nature of the asteroid population. In many cases, this process starts with obtaining observational data, continues with creating a model of the asteroid (i.e., its size, three-dimensional shape, and spin state, in the first approximation), and ends with interpreting new facts based on the model or a set of these. In this sense, modeling is a crucial mid-step between observations and theory. Results based on individual well-studied asteroids can be generalized to other members of the population. On the other hand, a statistically large sample of asteroids with known properties can reveal physical effects that play an important role for the whole population.

In this chapter, we will build on the content of the *Asteroids III* chapter by Kaasalainen *et al.* (2002a) about asteroid models reconstructed from *disk-integrated* photometry. Although visual photometry still remains the most important data source of the modeling, the main progress in this field

since *Asteroids III* has been the addition of *complementary data sources*. Many of these data sources are *disk-resolved*, thus containing much more information than disk-integrated data. This shift in paradigm — using photometry not alone but simultaneously with complementary data — was mentioned in the last paragraph of the *Asteroids III* chapter as “perhaps the most interesting future prospect,” and we are now at this stage. In the following, we will review all data types suitable for inversion, their sources, uncertainties, and how they can be used in modeling.

When describing the methods of data inversion and the results obtained by these methods, it is also important to emphasize caveats, ambiguities, and possible sources of errors. Although the description of what can be obtained from different data sources is exciting, the knowledge of what cannot, i.e., the limitations of our datasets, is of the same importance. Omitting this may lead to overinterpretation of results.

This chapter is structured as follows. First, we review the main principles of the multimodal inverse problem in

section 2. Then, in section 3, we discuss each data type and their contribution to model characteristics and details, and we describe some extensions of the predominant model. In section 4, we discuss the main results based on lightcurve inversion and multimodal asteroid reconstruction. We conclude with prospects for the future in section 5.

## 2. THEORETICAL ASPECTS OF INVERSION AND DATA FUSION

Asteroid physical model reconstruction from multimodal data is, by its very nature, a mathematical inverse problem. It is ill-posed; i.e., the uniqueness and stability properties of the solution are usually not very good unless the data are supported by a number of prior constraints. Furthermore, it is not sufficient just to fit some model to the data numerically and try to probe the solution space with some scheme. Although there are more approaches to the problem of asteroid shape reconstruction, they are usually dealing with only one data type and we mention them in the next section. Here, we describe the problem in a general way in the framework of *generalized projections*: Our data are various one- or two-dimensional projection types of a three-dimensional model, and understanding the fundamental mathematical properties of the inverse projection mapping is essential. This includes a number of theorems on uniqueness, information content, and stability properties (Kaasalainen and Lamberg, 2006; Kaasalainen, 2011; Viikinkoski and Kaasalainen, 2014).

Let the projection point  $\xi_0$  in the image plane (plane-of-sky or range-Doppler) of the point  $\mathbf{x}_0$  on the body be mapped by the matrix  $\mathbf{A}$ :  $\xi_0 = \mathbf{Ax}_0$ . Define the set  $I(\xi)$  for any  $\xi$  as

$$I(\xi) = \{\mathbf{x} | g(\xi, \mathbf{x}; R, t) h(\mathbf{x}; M, R, t) = 1\} \quad (1)$$

where we have explicitly shown the time  $t$  and the adjustable parameters:  $M$  for the shape and  $R$  for the rotation. The projection point function  $g(\xi; \mathbf{x}) = 1$  if  $\mathbf{A}(R, t)\mathbf{x} = \xi$ , and  $g = 0$  otherwise. The ray-tracing function  $h = 1$  if  $\mathbf{x}$  is visible (for occultation, thermal, and radar data), or visible and illuminated (for disk-resolved imaging and photometry in the optical); otherwise  $h = 0$ . The set  $I(\xi)$  is numerable and finite. The number of elements in  $I(\xi)$  is at most one for plane-of-sky projections (each point on the projection corresponds to at most one point of the asteroid's surface); for range-Doppler, it can be more (more points on an asteroid's surface can have the same distance to the observer and the same relative radial velocity). Generalized projections, i.e., all the data modes presented in section 3, can now be presented as scalar values  $p(\xi)$  in the image field  $\Omega$

$$p(\xi; t) = \int_{\Omega} f(\xi, \eta) \sum_{x \in I(\eta)} S(x; M, R, L, t) d\eta \quad (2)$$

where  $L$  denotes the luminosity parameters (for scattering or thermal properties), and the luminosity function is denoted by  $S$ . The function  $f$  is the point-spread, pixellation,

or other transfer function of the image field. For interferometry, it is typically the Fourier transform kernel. In fact, the reconstruction process works efficiently by taking the Fourier transform of any image type rather than using the original pixels (Viikinkoski and Kaasalainen, 2014). For lightcurves,  $f = 1$  [and  $\xi$  is irrelevant,  $p(\xi)$  is constant]. The surface albedo is usually assumed to be constant, although its variegation can be included in  $S$  by the parameters  $L$  if there are high-quality disk-resolved data. In the case of lightcurves only, we can get an indication of non-uniform albedo and compensate for this with a (non-unique) spot model (Kaasalainen *et al.*, 2001).

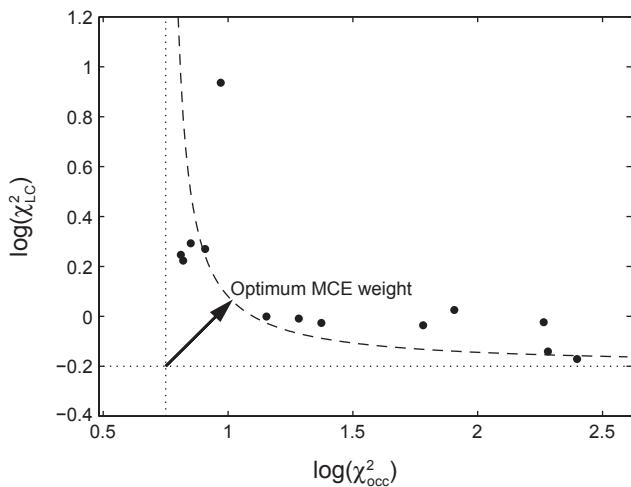

The multimodal inverse problem can be expressed as follows. Let us choose as goodness-of-fit measures some functions  $\delta_i$ ,  $i = 1, \dots, n$ , of  $n$  data modalities. Typically,  $\delta$  is the usual  $\chi^2$ -fit form between  $p_{\text{model}}$  and  $p_{\text{obs}}$ . Our task is to construct a joint  $\delta_{\text{tot}}$  with weighting for each data mode

$$\delta_{\text{tot}}(P, D) = \delta_1(P, D_1) + \sum_{i=2}^n \lambda_{i-1} \delta_i(P, D_i), \quad D = \{D_i\} \quad (3)$$

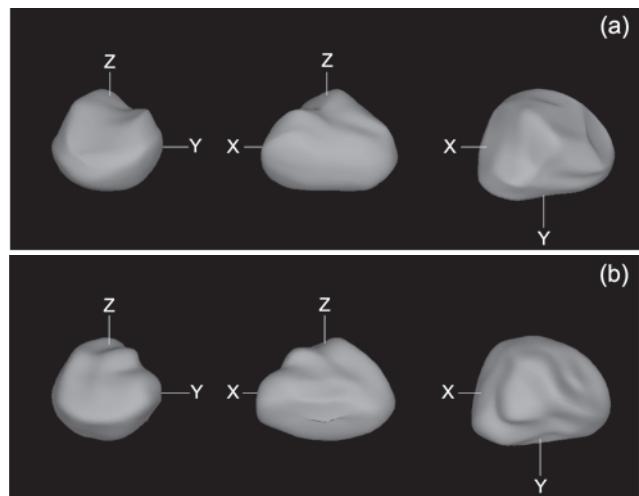

where  $D_i$  denotes the data from the source  $i$ ,  $\lambda_{i-1}$  is the weight of the source  $i$ , and  $P = \{M, R, L\}$  is the set of model parameter values. The best-fit result is obtained by minimizing  $\delta_{\text{tot}}$  with nonlinear techniques, typically Levenberg-Marquardt for efficient convergence. Regularization functions  $r(P)$  can be added to the sum; these constrain, for instance, the smoothness of the surface to suppress large variations at small scales, the deviation from principal-axis rotation to force the model to rotate around the shortest inertia axis (assuming uniform density), or the gravitational slope, etc. (Kaasalainen and Viikinkoski, 2012).

The modality (and regularization) weights  $\lambda_i$  are determined using the maximum compatibility estimate (MCE) principle (Kaasalainen, 2011; Kaasalainen and Viikinkoski, 2012). This yields well-defined unique values that are, in essence, the best compromise between the different datasets that often tend to draw the solution in different directions. Moreover, MCE values of weighting parameters are objective, not dependent on the user's choice, although their values are usually close to those determined subjectively based on experience. Plotting various choices of weights typically results in an L-shaped curve shown in Fig. 1; the best solution is at the corner of the curve. In this way, the reconstruction from complementary data sources is possible even if no single data mode is sufficient for modeling alone.

For practical computations, the surface is rendered as a polyhedron, and  $S$  and  $h$  are computed accordingly with ray-tracing (Kaasalainen *et al.*, 2001). Rather than using each vertex as a free parameter, the surface can be represented in a more compact form with spherical harmonics series (for starlike or octantoid shapes) or subdivision control points (Kaasalainen and Viikinkoski, 2012; Viikinkoski *et al.*, 2015). These *shape supports* are essential for convergence: They allow flexible modifications of the surface with a moderate number of parameters while not getting stuck in local minima

**Fig. 1.** The level of fit for lightcurves and occultation data for different weighting between the two data types. The optimum weight is around the “corner” of the L-curve. Each dot corresponds to an inversion with a different weight  $\lambda$ .

**Fig. 2.** Model of (41) Daphne reconstructed from lightcurves and adaptive-optics images using (a) subdivision surfaces and (b) octantoids. The general shape remains stable, even if small-scale features slightly change.

or overemphasizing the role of regularization functions when searching for the best-fit solution. Each shape support has its own characteristic way of representing global and local features. For example, the octantoid parameterization

$$\mathbf{x}(\theta, \varphi) = \begin{cases} x(\theta, \varphi) = e^{a(\theta, \varphi)} \sin \theta \cos \varphi \\ y(\theta, \varphi) = e^{a(\theta, \varphi)+b(\theta, \varphi)} \sin \theta \sin \varphi \\ z(\theta, \varphi) = e^{a(\theta, \varphi)+c(\theta, \varphi)} \cos \theta \end{cases} \quad (4)$$

where  $a$ ,  $b$ , and  $c$  are linear combinations of the (real) spherical harmonic functions  $Y_l^m(\theta, \varphi)$ , with coefficients  $\{a_{lm}\}$ ,  $\{b_{lm}\}$ , and  $\{c_{lm}\}$ , respectively, are easy to regularize globally while retaining the ability to produce local details. The coordinates  $(\theta, \varphi)$ ,  $0 \leq \theta \leq \pi$ ,  $0 \leq \varphi < 2\pi$ , parameterize the surface on the unit sphere  $S^2$  but do not represent any physical directions such as polar coordinates.

This inverse problem is a typical example of a case where model and systematic errors dominate over random measurement errors. Thus the stability and error estimation of the solution are best examined by using different model types (Fig. 2). In the case of shape, for example, the reliability of the features on the solution can be checked by comparing the results obtained with two or more shape supports [star-like, octantoid, subdivision (Viikinkoski et al., 2015)]. This yields better estimates than, e.g., Markov chain Monte Carlo sequences that only investigate random error effects within a single model type.

A particular feature of the model reconstruction from disk-resolved data is that the result is dominated by the target image boundaries rather than the pixel brightness distribution within the target image. This is because the information is contained in the pixel contrast, which is the largest on the

boundary (occultations are special cases of this as they are samples of the boundary contour). This is very advantageous when considering the effect of model errors in luminosity properties (scattering or thermal models): It is sufficient to have a reasonable model, and the result is not sensitive to the parameters  $L$ . Thus, for example, Atacama Large Millimeter Array (ALMA) data can be used for efficient reconstruction even with a very approximate semi-analytical Fourier-series thermal model — more detailed models have hardly any effect on the shape solution (section 3.5) (Viikinkoski and Kaasalainen, 2014; Viikinkoski et al., 2015).

### 3. DATA AND MODELING

We describe all data types that can be used, the various ways of collecting data and their accuracy, the typical number of asteroids for which data exist, and expectations for the future. We also discuss a typical result of inversion — the resolution of the model and how many targets can be modeled (Table 1).

#### 3.1. Photometry

Disk-integrated photometry is, and will always be, the most abundant source of data, because it is available for essentially every single known asteroid. Because asteroid brightness periodically changes with its rotation, frequency analysis of asteroid lightcurves provides asteroid rotation periods — the basic physical property derivable from time-resolved photometry. The regularly updated Asteroid Lightcurve Database of Warner et al. (2009) (available at <http://www.minorplanet.info/lightcurvedatabase.html>) now contains rotation periods and other physical parameters for almost 7000 objects, about half of which have a rotation

TABLE 1. List of observation techniques and derivable physical properties.

Technique	Period	Spin	Size	Shape	Thermal Inertia	Number of Models		
						Asteroids III	Asteroids IV	Asteroids V
Photometry	X	X		X		30	500	$10^4$
Images		X	X	X		5	50	$10^2$
Occultation		X	X	X		$5^*$	50	$10^2$
Radar	X	X	X	X		10	30	$10^2$
Radiometry			X		X	$10^*$	20	$10^4$
Interferometry		X	X	X		$5^\dagger$	<10	$10^2$
Flyby	X	X	X	X	X	6	10	<15

\*Ellipsoidal models.

†HST/FGS.

The “X” indicates which physical properties are derivable from which technique. The number of models available at the time of the *Asteroids III* book (Asteroids III) and now (Asteroids IV) is only approximate. The Asteroids V column is an order-of-magnitude estimate for the next decade.

period that is secure and unambiguous. The role of amateur astronomers in this field is traditionally strong, and growing even stronger with increasing levels of their technical and software equipment. Hundreds of asteroid lightcurves are published quarterly in the *Minor Planet Bulletin*; most of them are then archived in the Asteroid Light Curve Database at the Minor Planet Center site ([http://www.minorplanetcenter.net/light\\_curve2/light\\_curve.php](http://www.minorplanetcenter.net/light_curve2/light_curve.php)) in the ALCDEF standard (Warner et al., 2011). The efficiency of lightcurve production can be increased by dedicated wide-field photometric surveys (e.g., Masiero et al., 2009; Polishook et al., 2012), although the period determination from undersampled lightcurves is often ambiguous (Harris et al., 2012).

For period determination, a single lightcurve covering the full rotation is sufficient. However, a set of such lightcurves observed at different geometries (asteroid illuminated and seen from various directions) is needed to reconstruct the shape and spin state of an asteroid. The *lightcurve inversion* method of Kaasalainen and Torppa (2001) and Kaasalainen et al. (2001) was already reviewed in *Asteroids III* (Kaasalainen et al., 2002a). Since then, the method has been widely used and hundreds of asteroid models have been derived. They are publicly available at the Database of Asteroid Models from Inversion Techniques (DAMIT) (<http://astro.troja.mff.cuni.cz/projects/asteroids3D>). The reliability of the method was proved by comparing its results with independent data such as laboratory asteroid models (Kaasalainen et al., 2005), adaptive-optics (AO) images (Marchis et al., 2006), stellar occultations (Durech et al., 2011), or spacecraft images of asteroids (2867) Šteins (Keller et al., 2010) and (433) Eros (Kaasalainen et al., 2002a).

From disk-integrated photometry alone, only a global shape without any small-scale details can be derived. Because the reflectivity of the surface is not known, the models are not scaled and the information about the size has to come from complementary data. To avoid overinterpretation and artifacts of the modeling, the shapes are usually represented by a *convex* model. This allows working not in the obvious

radius parameter space but instead in the Gaussian image space (describing a convex body by the curvature of its surface). This is less intuitive, but it makes the inverse problem less vulnerable to errors of data and model because of the Minkowski stability (Lamberg and Kaasalainen, 2001): Even if the areas of individual surface facets may change significantly for slightly different datasets, the global convex shape changes very little.

From the practical point of view, we are interested in finding a *unique solution* for the inverse problem. To guarantee this, observations covering a sufficiently wide range of viewing and illumination geometries are needed. For a typical main-belt asteroid, this means observations during several apparitions. For a close-approaching near-Earth asteroid, several months could be sufficient. For more distant objects, we can in principle observe changing lightcurve amplitude because of changing aspect, but this would take many decades. Nevertheless, transneptunian objects (TNOs) and Centaurs can be never observed from Earth at geometry significantly different from opposition, which is not sufficient to reconstruct a unique convex model (Russell, 1906). If the lightcurves observed in various filters are different, there is some spectral/color variegation over the surface, and a crude color map can be reconstructed (Nathues et al., 2005).

A typical outcome of lightcurve inversion is a convex shape model that describes the global characteristics of the real asteroid. It is also easy to obtain nonconvex versions with the general inversion procedures (see section 2), but then one should produce several solutions with various model types and parameters, and be very cautious about the results (Viikinkoski et al., 2015). In general, disk-integrated photometry contains very little information about nonconvexities unless they are very pronounced or observed at very high phase angles where shadowing effects play an important role (Durech and Kaasalainen, 2003). Nonconvex models seldom fit lightcurves better than convex ones simply because the latter typically already fit the data down to noise level. This sets the resolution limit of photometry (see discussion in

Kaasalainen et al., 2001, 2002a; Viikinkoski et al., 2015, and references therein).

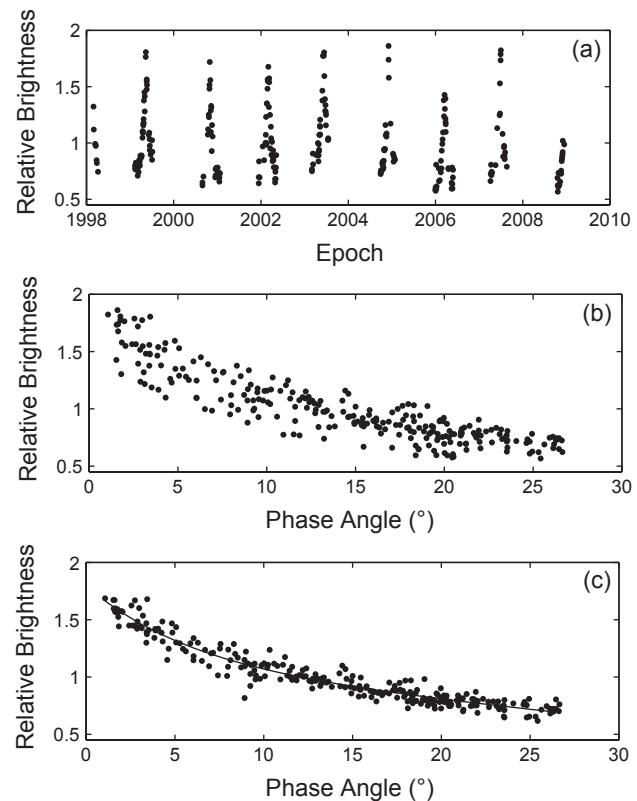

The relative accuracy of the sidereal rotation period determined from lightcurves is on the order of  $10^{-5}$  or better, depending mainly on the time span of observations. The direction of the spin axis can be determined with an accuracy from a couple of degrees for the models based on many decades of observations with many dense lightcurves, to more than  $20^\circ$  for models based on limited and noisy data. For asteroids orbiting in the ecliptic plane, the geometry for an Earth-based observer is limited to that plane. Then the disk-integrated brightness of a body with surface described by radius vector  $(x, y, z)$  and pole direction  $(\lambda, \beta)$  in ecliptic coordinates is the same as for a body  $(x, y, -z)$  with the spin axis direction  $(\lambda + 180^\circ, \beta)$  (Kaasalainen and Lamberg, 2006). That is why for a typical main-belt asteroid, there are usually two equally good mirror shape solutions with about the same pole latitude and pole longitude difference of about  $180^\circ$ . This ambiguity can be removed with disk-resolved plane-of-sky projections (e.g., images, stellar occultations; see sections 3.2 and 3.4).

Apart from “classical” lightcurves where the sampling of brightness variations is dense with respect to the rotation period, there are also data that are *sparse in time*. Such datasets typically consist of only a single to a few brightness measurements per night. Provided the whole sparse dataset is internally calibrated, it can be used the same way as a standard lightcurve that would be extremely long and very sparsely sampled (Kaasalainen, 2004). These data are routinely provided by all-sky astrometric surveys with various — usually poor — photometric quality. Current surveys provide data of accuracy scarcely better than 0.1 mag. Given a typical lightcurve amplitude of 0.3 mag, the signal is often drowned in noise and systematic errors. This leads to many physically acceptable models fitting the data to the noise level (Durech et al., 2005). However, the total amount of data is huge and it has been shown that at least for some asteroids, models can be successfully derived from these data or from their combination with dense lightcurves (Durech et al., 2009; Hanuš et al., 2011).

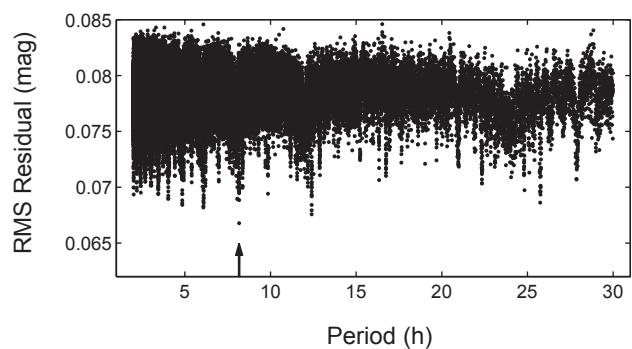

As an example, we show sparse photometry for asteroid (21) Lutetia from the U.S. Naval Observatory (260 points covering 10 years) in Fig. 3 and the period search results in Fig. 4. The best-fit model based on this dataset has the same rotation period and a similar spin-axis direction as the models based on much larger and multiple datasets (Fig. 6).

When using noisy sparse data or only a limited number of data points, a simple shape model of a triaxial ellipsoid is usually sufficient to model the data and to derive the correct period and spin vector orientation (Cellino et al., 2009; Cellino and Dell’Oro, 2012; Carbognani et al., 2012). The advantage of this approach is that the shape is described by only two parameters (axes ratios) and the scanning of the period parameter space is much faster than with general shapes.

The ongoing [Panoramic Survey Telescope and Rapid Response System (Pan-STARRS), Catalina, Gaia] and future [Asteroid Terrestrial-impact Last Alert System (ATLAS),

**Fig. 3.** Sparse-in-time photometry of (21) Lutetia obtained at the U.S. Naval Observatory plotted as a function of (a) time and (b) phase angle. The brightness was reduced to the unit distance from Earth and the Sun. The scatter in the phase plot is caused by the intrinsic noise of the data and the rotational and aspect effects. (c) Residuals for the best-fit model (Fig. 6) plotted over the phase curve (solid curve).

**Fig. 4.** Period search for (21) Lutetia. Each point represents a local minimum in the parameter space to which the optimization algorithm converged. The lowest RMS residual (arrow) corresponds to the best-fit model shown in Fig. 6.

Large Synoptic Survey Telescope (LSST)] surveys will provide new data every night for essentially every known asteroid. Using this data for automated lightcurve inversion with well-mastered treatment of systematic effects,

recognition of the best-fit models, definition of uniqueness of the solution, etc., is the main challenge for the future lightcurve inversion.

### 3.2. Remote Sensing Disk-Resolved Images

The most direct way to obtain information on the shape of an asteroid is to take pictures of it. The apparent shape as visible on the plane of the sky is delimited by the limb and the terminator, and multiple views obtained while the target rotates can fully characterize its three-dimensional shape. However, to resolve the small angular diameter ( $<0.5''$ ) sustained by asteroids, large facilities are required.

In the 1980s, speckle imaging or speckle interferometry provided “the first glimpses of an asteroid’s surface” [i.e., (4) Vesta by *Drummond et al.* (1988)]. This technique is based on the analysis of the speckle pattern in the images of astronomical sources obtained through large telescopes at high magnification power and very short integration time. The aim is to overcome the blurring effects due to the astronomical seeing and to attain diffraction-limited resolution images. Speckle interferometry has been commonly used to study the size, shapes, and surface features of the largest asteroids (*Drummond et al.*, 1985, 1988; *Ragazzoni et al.*, 2000; *Cellino et al.*, 2003). With the launch of the Hubble Space Telescope (HST) in orbit and the first light of the large (10-m class) groundbased telescopes equipped with AO-fed cameras [e.g., W. M. Keck, European Southern Observatory (ESO) Very Large Telescope (VLT), Geminis, Subaru], the importance of speckle interferometry has decreased.

The critical issue in direct imaging is of course the angular resolution. Any image is the result of the convolution of the object on the plane of the sky with the instrument response, the point spread function (PSF). In space, the PSF is stable and corresponds to the diffraction pattern of the telescope. From the ground, the atmospheric turbulence constantly deforms the PSF and blurs the images, hence the need for real-time correction of the PSF by AO. The technical challenges of sending a large telescope to space and of building deformable mirrors explain why the first disk-resolved images in the 1990s were still limited in resolution and only the largest asteroids — (1) Ceres, (2) Pallas, and (4) Vesta — have been imaged. In the decade since *Asteroids III*, numerous studies have been based on direct imaging of asteroids (e.g., *Thomas et al.*, 2005; *Carry et al.*, 2008; *Descamps et al.*, 2008; *Schmidt et al.*, 2009; *Marchis et al.*, 2013).

Both from space or with AO on the ground, however, the contrast and angular resolution can be improved by deconvolution of the image by the PSF. This is particularly true for images acquired from the ground with residuals from nonperfect AO correction. Deconvolution is an ill-posed problem, but robust algorithms adapted to planetary images are available (*Conan et al.*, 2000; *Mugnier et al.*, 2004; *Hom et al.*, 2007) and have been validated on-sky (*Witasse et al.*, 2006). It is nevertheless the most critical part of the post-processing, as an incorrect deconvolution can introduce a systematic error on the apparent size. An example of an

AO image and the reconstructed shape model for asteroid (41) Daphne is shown in Fig. 5.

Current facilities deliver an angular resolution of about 30 to 50 milliarcseconds (mas), depending on the wavelength. The apparent shape can therefore be measured for asteroids with an apparent diameter larger than  $\approx 80$ –100 mas, i.e., a couple of hundred targets. Simulations and observations of known targets such as the satellites of Saturn (*Marchis et al.*, 2006; *Drummond et al.*, 2009; *Carry*, 2009) have shown that a precision of a few milliarcseconds can be derived on the two-dimensional profile on the plane of the sky, corresponding to only a few kilometers for main-belt asteroids. With upcoming large telescopes (30+ m, such as the Thirty Meter Telescope or the European Extremely Large Telescope), the angular resolution will be improved by a factor of 3–4, providing more than 500 targets. Second-generation instruments with extreme AO foreseen on these telescopes should allow the observation of about 7000 asteroids, with sizes of only a few kilometers (*Merline et al.*, 2013).

Using disk-resolved images, giant craters have been discovered (*Thomas et al.*, 1997; *Conrad et al.*, 2007), ambiguity in spin solutions have been solved (*Marchis et al.*, 2006; *Carry et al.*, 2010a), albedo maps have been constructed (*Li et al.*, 2006; *Carry et al.*, 2008), convex three-dimensional shape models from lightcurves have been set to scale (*Hanuš et al.*, 2013a), and full three-dimensional shape models have been determined (*Carry et al.*, 2010b; *Descamps et al.*, 2011).

### 3.3. Flybys

Asteroid imaging and mapping *in situ* is essentially an extreme example of disk-resolved images. The modeling in such cases is more a cartographic than an inverse problem as the data are abundant, directly usable (containing identification points on the surface, etc.), and high-resolution (there is no ill-posedness). However, asteroid flybys, during which roughly half the target is likely to remain unseen (not visible and illuminated), pose a special problem: how to see the dark side. The principle here is to use the high-resolution map of the nearside, constructed with a number

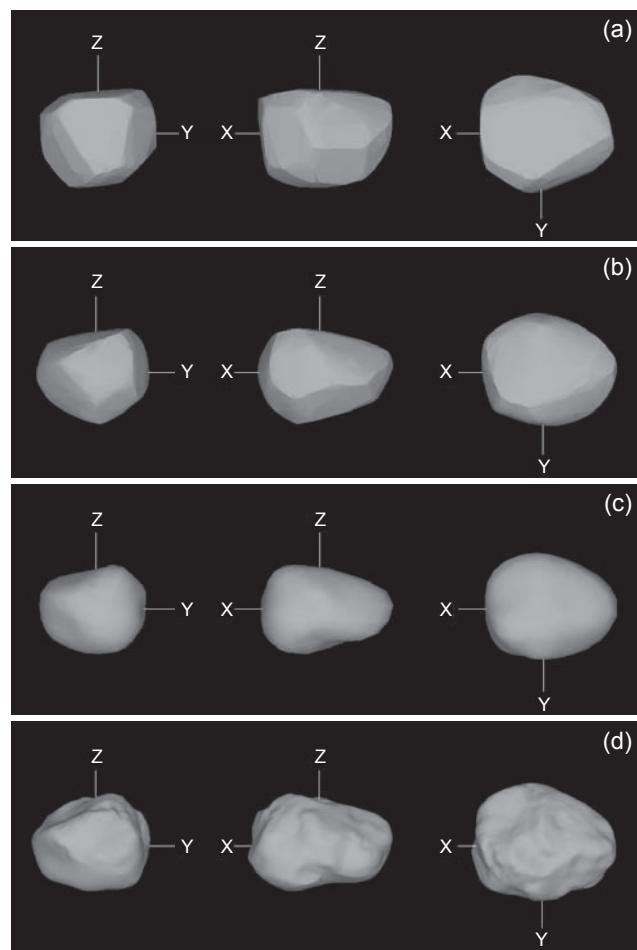

**Fig. 5. (a)** Deconvoluted adaptive optics image of asteroid (41) Daphne; **(b)** corresponding image of the reconstructed model (projection of the octantoid model from Fig. 2). The model is shown under artificial illumination that enhances its three-dimensional shape and is different from the simple light-scattering model used for the inversion. The AO image has resolution of 10 mas/pixel. The model was reconstructed from 14 AO images obtained with the ESO VLT and several lightcurves.

of methods of photoclinometry, photogrammetry, and image fitting (Preusker et al., 2012; Gaskell et al., 2008; Jorda et al., 2012), as a constraint in the otherwise same multi-mode inverse problem as with groundbased observations. The procedure is described in Kaasalainen and Viikinkoski (2012); with it, reconstructions of the dark side, such as those of (2867) Šteins (Keller et al., 2010) or (21) Lutetia (Sierks et al., 2011) (see also Fig. 6), are more detailed than from, e.g., lightcurves alone. This is because half the target is accurately reconstructed, with practically no error margin, and therefore the fluctuation margin of the darkside is considerably smaller as well.

### 3.4. Stellar Occultations

The observation of a stellar occultation consists in recording the duration of the disappearance of a star behind the asteroid. Knowing the apparent motion of the asteroid on the plane of the sky, obtained from its ephemeris, this duration can be converted in a physical length on the disk

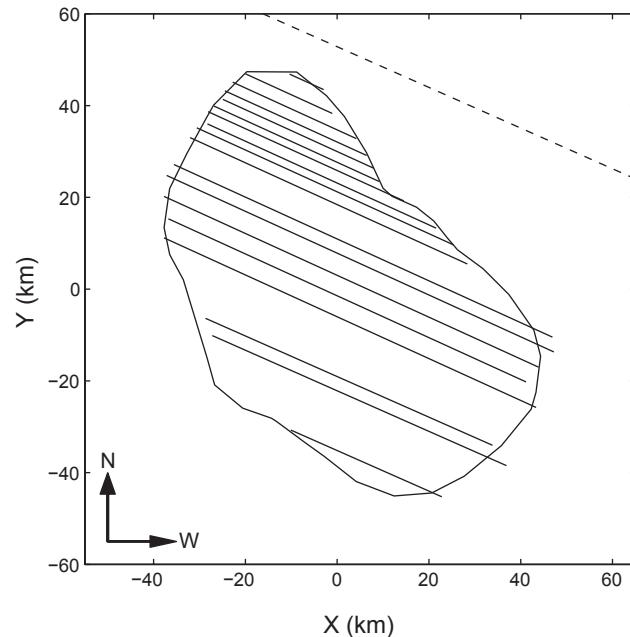

**Fig. 6.** Different shape models for (21) Lutetia derived from different sets of data. The level of detail increases with more data: **(a)** sparse photometry (section 3.1), **(b)** dense lightcurves (Torppa et al., 2003), **(c)** lightcurves and AO (Carry et al., 2010b), and **(d)** Rosetta flyby (Sierks et al., 2011).

of the asteroid, called a chord. Provided several observers record the same event from different locations on Earth, the two-dimensional profile of the asteroid is drawn on the plane of the sky (Millis and Dunham, 1989). The main difference with disk-resolved imaging resides in the profile, made by only the limb for occultations, and the limb + terminator for imaging. Both techniques provide the two-dimensional profile of the target as projected on the plane of the sky at the epoch of observations (Fig. 7).

Disk-resolved imaging and stellar occultation are, however, radically different in terms of facilities, data processing, potential targets, reproducibility, and achievable precision. For stellar occultations, the properties of the occulted star generally matter more than the actual target: the asteroid. If the occulted star is bright enough, its occultation, even by a very small asteroid, can be detected with small-aperture telescopes. This is of course the main advantage of stellar occultations, where the apparent size and shape of potentially any asteroid can be measured. Moreover, this technique can also be successfully used for distant TNOs, which have angular sizes too small to be resolved by imaging (Sicardy et al., 2011). In practice, however, a given asteroid will seldomly occult bright stars. Measurements are thus hard, if not impossible, to reproduce.

Stellar occultations are nevertheless extremely valuable. The accuracy of the timing is dictated by time-series

**Fig. 7.** An example of a well-covered occultation that provides almost an “image” of the projected asteroid (135) Hertha (Timerson et al., 2009). The model of Hertha based on its lightcurves and occultation data is overplotted. The dashed line is a negative observation constraining the northern part of the model’s projection. Formal timing uncertainties are between 0.02 and 0.2 s, corresponding to 0.12–1.2 km in the projection, which is below the resolution of the model. The RMS of the fit is 1.9 km.

photometry, and can therefore be extremely precise. An uncertainty of 50 ms in timings converts into only a 300-m uncertainty in the length of the chord, typical for a main-belt asteroid (at 1.5 AU from Earth with an apparent motion of  $10''/h$ ). The main source of uncertainty is, however, the absolute timing of each chord, required to align them on the plane of the sky. Occultations observed by the naked eye suffered from the fact that the absolute timing was poor. Since a decade ago, thanks to the availability of low-cost positioning and timing systems [e.g., the Global Positioning System (GPS)], stellar occultations are becoming more and more valuable.

The main contributors to the field are currently amateur astronomers: For a given event, observers have to move to set themselves on the predicted occultation path on Earth. Small-aperture ( $<20$  cm) mobile stations are therefore ideal for recording stellar occultations. Because of the uncertainties of the star and asteroid positions on sky, there is generally an uncertainty of a few tens of kilometers in the location of the occultation path on Earth, requiring observers to spread over a large area to cover the event. This usually prohibits dense coverage of the asteroid profile. When only a couple of chords are available, the event provides limited information on the size, and little if any on the shape. Current occultation predictions of sufficient accuracy concern only stars in the Hipparcos catalog and large (at least tens of kilometers) asteroids. With the upcoming publication of the European Space Agency (ESA) Gaia stellar catalog and update of asteroid orbits, this uncertainty about position is expected to drop significantly, making future occultations easier to predict, and therefore observe (Tanga and Delbo, 2007).

Overall, stellar occultations can provide precise measurements of the size and shape of an asteroid, as projected on the plane of the sky. However, events are rare for a given target. Occultations are therefore very valuable in combined datasets, e.g., to set scale to otherwise dimensionless three-dimensional shape models (e.g., Ďurech *et al.*, 2011; Hanuš *et al.*, 2011). From almost 2500 occultations compiled by Dunham *et al.* (2014), there are about 160 “good” ones that allow a reliable determination of an asteroid’s size and about 40 “excellent” ones that show details regarding an asteroid’s profile.

### 3.5. Interferometry

Inferometry is another technique that can be used to overcome the limitations of small angular sizes of asteroids, in order to measure their sizes, shapes, and the possible presence of satellites. An astronomical interferometer coherently combines (i.e., conserving phase information) the light from two or more apertures of the same telescope or of distinct telescopes spaced by a distance  $B$ . The spatial resolution (in radians) is on the order of  $\lambda/B$  where  $\lambda$  is the wavelength.

In the following, we give a basic introduction to interferometry of asteroids. Further details can be found in the following works: Jankov (2010) and Matter *et al.* (2013) for a broad introduction to astronomical optical interferometry,

methods and instrumentation; Delbo *et al.* (2009) for a description of the techniques, and the models for deriving the size and basic shape proprieties of asteroids from the ESO Very Large Telescope Interferometer (VLTI) MID-infrared Interferometric instrument (MIDI) data; Carry *et al.* (2015) for an extension of the technique of Delbo *et al.* (2009) to the determination of the sizes and the separation of binary asteroids; and Matter *et al.* (2011) for a description and the extension of a thermophysical model to the analysis of interferometric data of asteroids with the aim of obtaining surface properties such as the thermal inertia.

Interferometers measure the coherence function of the source, also called the interferometric visibility, which is given by the ratio between the correlated and total flux. The correlated flux is the amount of flux in the interferometric fringes. More precisely, the correlated flux is the Fourier transform of the brightness distribution of the source measured on the interferometer’s baseline projected on the plane of the sky (e.g., see Delbo *et al.*, 2009, and references therein).

The Fine Guidance Sensors (FGS) onboard the Hubble Space Telescope (HST) are optical white-light shearing interferometers (Nelan *et al.*, 1998) that combine the light from distinct apertures of the HST primary mirror and have been used to measure the size and basic shape properties of asteroids (Hestroffer *et al.*, 2002; Tanga *et al.*, 2003). HST/FGS data have clearly demonstrated the bi-lobed nature of some bodies such as (216) Kleopatra (Tanga *et al.*, 2001) and (624) Hektor (Tanga *et al.*, 2003), but were not able to detect the presence of the little moons orbiting these asteroids (Descamps *et al.*, 2011; Marchis *et al.*, 2014), due to the large-magnitude difference between the asteroids and their respective moons. Despite the impressive angular resolution of a few milliarcseconds, corresponding to a few kilometers at a distance of 1.2–1.5 AU, a clear limitation of HST/FGS asteroid studies is the bright limiting magnitude of the instrument of about  $V \sim 13\text{--}14$  mag (Tanga *et al.*, 2003). A recapitulation of the HST/FGS asteroids results can be found in Dotto *et al.* (2002).

Groundbased interferometry is limited to observation of bright targets because of the requirement to take exposures shorter than the atmospheric coherence time of a few milliseconds. The limiting magnitudes of groundbased long-baseline interferometers and the intrinsic low surface brightness of asteroids have prevented the use of these instruments for the studies of small solar system bodies until the availability of the VLTI.

Interferometry in the mid-infrared was proven to be also very sensitive to the global shape of asteroids as well as their surface characteristics (Matter *et al.*, 2011, 2013). In particular, since observations are typically carried out in the thermal infrared (8–13  $\mu\text{m}$ ), MIDI data are sensitive to the surface temperature distribution, which is strongly affected by the value of the thermal inertia (see the chapter by Delbo *et al.* in this volume).

Figure 8 shows the visibility and the total flux as a function of the angular diameter of an asteroid at 2.5 AU from the Sun and at 1.5 AU from Earth, where 1 mas roughly

corresponds to 1 km on the asteroid. Note that main-belt asteroids smaller than  $\sim 20$  km cannot be easily observed with MIDI at the VLTI. There are about 1000 known asteroids  $< 20$  km in diameter, implying that interferometry is potentially an interesting technique for shape modeling. On the other hand, as interferometry in the thermal infrared is sensitive to the spatial distribution of the temperature on the asteroid surface, this technique can be used to determine thermophysical properties of asteroids when the body shapes are known, as demonstrated by Matter *et al.* (2011, 2013).

Each VLTI baseline can only be used one at a time with MIDI. MIDI will likely be decommissioned in the near future, to be replaced after 2016 by the Multi AperTure mid-Infrared SpectroScopic Experiment (MATISSE). This instrument will combine up to four unit telescopes (UTs) or auxiliary telescopes (ATs), allowing six simultaneous baselines. This feature will enable measurement of the spatial distribution of the infrared flux along different directions. MATISSE will also measure closure phase relations and thus offer an efficient capability for image reconstruction. In ad-

dition to the N band, the MATISSE will also operate in the L and M bands. Unfortunately, MATISSE is not expected to be any more sensitive than MIDI.

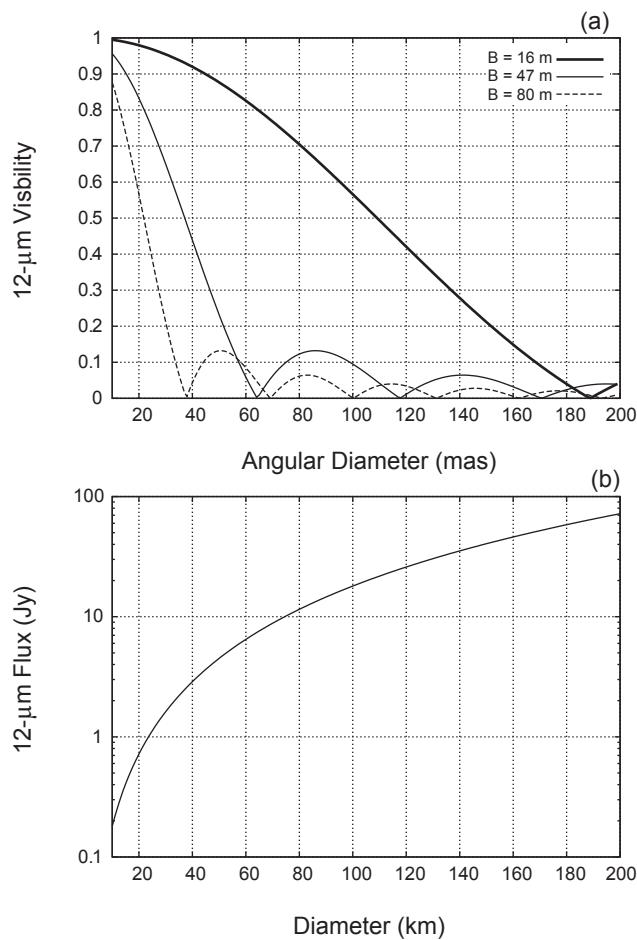

Another second-generation instrument at the VLTI, GRAVITY, will combine the light from all four UTs, offering further improvements in spatial resolution compared to MIDI and MATISSE (although with more a more stringent  $V \leq 11$  limiting magnitude). It will provide near-infrared AO-assisted precision narrow-angle ( $\sim 4''$ ) astrometry at the 10  $\mu\text{as}$  level in the K band (2.2  $\mu\text{m}$ ). Both the reference star and the science object have to lie within the  $\sim 4''$  field of view. In imaging mode, GRAVITY can achieve a resolution of  $\sim 3$  mas in the near-IR (Eisenhauer *et al.*, 2008). The imaging mode can be used to precisely measure the sizes and the orbits of the satellites of large asteroids, the latter with  $V \leq 11$  mag.

AMBER is the current near-infrared focal instrument of the VLTI. It operates in the J, H, and K bands (i.e., from 1.0 to 2.4  $\mu\text{m}$ ). The AMBER limiting magnitude for asteroid observations is  $V \sim 9$  mag. There are only a handful of asteroids brighter than this limit. These bodies are also the largest ones with angular extensions generally  $> 100$  mas, implying a very low visibility in the J-H-K with the UT baselines. Although the photometric flux of these few asteroids is such that  $H < 7.5$  mag, their correlated magnitudes due to the low visibilities are much higher than 7.5 mag, preventing their fringe detection and tracking in the near-IR.

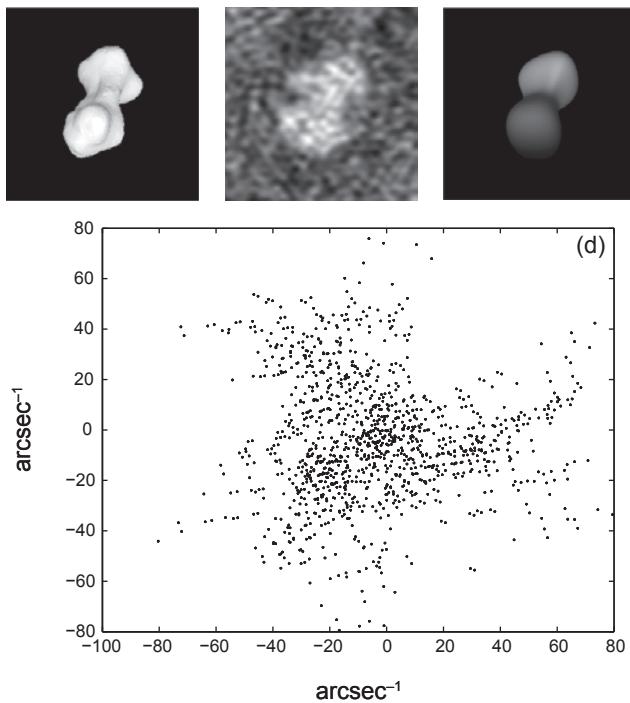

However, one of the most interesting instruments for asteroid groundbased interferometry is the Large Binocular Telescope Interferometer (LBTI). It consists of two 8.4-m telescopes mounted side by side in a single mount, with a 14.4-m center-to-center spacing. This configuration offers a unique capability for interferometry of a Fizeau beam combination. This offers a wide field of view ( $\sim 10\text{--}20''$ ) and low thermal background. For example, the LINC-NIRVANA instrument can — in principle — be able to resolve binary asteroids whose components are separated  $> 20$  mas. This will allow splitting many binary asteroids.

Another important source of interferometric data in the near future is ALMA. It will provide resolution  $\sim 5$  mas at 0.3 mm and a dense mesh of baselines, thus enabling “imaging” of hundreds of asteroids in the main belt (Busch, 2009). A useful feature of the multimodal inversion is that the raw ALMA (and any other interferometric) data can be used directly as the original Fourier transform: There is no need to reconstruct the image estimate. Furthermore, the reconstruction of the overall shape is insensitive to inaccuracies and uncertainties in the thermal model used because the model is determined mainly by the boundary of the projection; the distribution of brightness inside the boundary is much less important (Viikinkoski and Kaasalainen, 2014; Viikinkoski *et al.*, 2015). An example of inversion of simulated ALMA data is shown in Fig. 9.

Long-baseline interferometry can also represent a novel approach to determine the masses and the densities of asteroids in a range of sizes and distances never studied before. In particular, modern interferometers such as the VLTI, LBTI, and Magdalena Ridge Observatory Interferometer can

**Fig. 8.** (a) Visibility and (b) total flux for an asteroid at 2.5 AU from the Sun and 1.5 AU from Earth as a function of its diameter for different values of the baseline. The MIDI limiting correlated flux (flux times visibility) is 0.5–1 Jy and 10–20 Jy for the UTs and ATs respectively. Similar limiting fluxes are expected for MATISSE. See text for further details.

**Fig. 9.** Simulated infrared flux from an asteroid **(a)** radar shape model of Kleopatra by Ostro *et al.* (2000) and **(b)** a “dirty image” with atmospheric noise, obtained by transforming the incompletely sampled frequency plane **[(d)]**, 6000 points, 50 antennas]. The smallest resolvable detail is approximately 10 mas. Provided enough observations at different geometries are available (here eight observation runs were used), a shape model **[(c)]** can be constructed directly from the raw interferometric data.

spatially resolve binary asteroids discovered by photometric lightcurves in the main belt (Carry *et al.*, 2015). The separation of the components of these systems is too narrow for traditional observational techniques such as AO used with 10-m-class telescopes.

### 3.6. Direct Size Measurement with Gaia

The ESA Gaia mission, whose operations started in 2014, will provide accurate astrometry and photometry of asteroids. Photometric data can be used the same way as sparse photometry from groundbased observatories (section 3.1). The potential of Gaia-like data was demonstrated by Cellino *et al.* (2009) on data from the Hipparcos satellite. Apart from disk-integrated brightness, Gaia will provide also direct measurements of asteroid sizes, in a way very similar to interferometry. Being designed as an astrometry mission at the microarcsecond level, the PSF of Gaia is accurately known and stable. Deviations of the PSF from that of a point-like source can thus be measured and used to estimate the apparent size of asteroids.

Owing to the amount of sources observed by Gaia, the satellite does not download images to Earth, but only

one-dimensional flux profiles, corresponding to small two-dimensional windows centered on targets, stacked along one direction, similar to interferometry in that respect. Interpretation of this one-dimensional profile relies therefore on the *a priori* knowledge of the two-dimensional flux distribution on the plane of the sky. In the creation of the Gaia catalog, this will be done iteratively, starting from simple spheres at zero phase angle to finally the spin and triaxial ellipsoid solutions determined otherwise from Gaia photometry (Mignard *et al.*, 2007; Cellino *et al.*, 2007).

These measurements represent a great opportunity for multi-data inversion algorithms: The measurement of the extension is direct, but clearly requires a realistic description of the projected shape on the plane of the sky. Considering Gaia specifications and observing geometry, Mignard *et al.* (2007) have estimated the fraction of asteroids for which one-dimensional dimension will be measured with a precision better than 10%. This fraction is highly dependent on diameter, and 20% of asteroids between 20 and 30 km will be measured at least once, while all asteroids larger than  $\sim 80$  km will be measured repeatedly.

### 3.7. Disk-Integrated Radiometry

Measurements of asteroids emission in the thermal infrared — in general at wavelengths between 4–5 and 20–30  $\mu\text{m}$  — are mostly used to determine the sizes of these bodies (Delbo and Harris, 2002; Harris and Lagerros, 2002; see also the chapters by Mainzer *et al.* and Delbo *et al.* in this volume). Groundbased telescopes can only observe in specific windows of the electromagnetic spectrum where the atmosphere is relatively transparent: i.e., the L, M, N, and Q bands at 3, 5, 10, and 20  $\mu\text{m}$ , respectively. However, such observations are strongly affected by the variability of the transparency of the atmosphere and its thermal background. The background also receives contribution from the telescope and the optics. Hence, the thermal infrared observation of asteroids from the ground is limited to relatively bright asteroids ( $V \leq 18$  mag with 10-m-class telescopes). Absolute calibration of the flux is rarely better than 5–10%. On the other hand, in space the instrument calibration is usually stable and there is no need to reduce the thermal background from the atmosphere. As a consequence, spacebased telescopes such as Spitzer can observe much fainter and smaller asteroids (Mommert *et al.*, 2014), with uncertainties in the calibration that can reach  $\sim 1\%$  error. Also, from space the range of the observational wavelength is limited only by the detector technology, typically  $\sim 3.5$ – $50$   $\mu\text{m}$ . At longer wavelengths, the telescope optics require cooling and the observation of faint objects is confronted with the background from solar system dust cloud and infrared cirrus.

In the *Asteroids III* era, the main source of thermal infrared observations of asteroids has been the Infrared Astronomical Satellite (IRAS) Minor Planet Survey, which collected observations of more than 2200 asteroids (Tedesco *et al.*, 2002). Since then, the NASA Wide-field Infrared Survey Explorer (WISE) has observed more than 130,000 main-belt asteroids

(*Masiero et al.*, 2011, 2012; see also the chapter by Mainzer et al. in this volume), about 500 near-Earth asteroids (*Mainzer et al.*, 2011, 2012a,b), about 1100 Hilda asteroids (*Grav et al.*, 2012a), and almost 2000 Jupiter-Trojan asteroids (*Grav et al.*, 2011, 2012b) in four infrared wavelengths at 3.4, 4.6, 12, and 22  $\mu\text{m}$ ; the AKARI space telescope observed more than 5000 asteroids during its mission (*Usui et al.*, 2011, 2013; *Hasegawa et al.*, 2013); the Spitzer space telescope observed hundreds of asteroids (e.g., *Emery et al.*, 2006; *Trilling et al.*, 2010; *Licandro et al.*, 2012); and the Herschel Space Observatory, due to its longer wavelengths, spanning 55–671  $\mu\text{m}$ , was primarily used to observe transneptunian objects (*Müller et al.*, 2010). For a review of all these missions and their results, see the chapter by Mainzer et al. in this volume.

The thermal infrared spectrum of asteroids carries information about their size and surface properties, such as the thermal inertia, roughness, and emissivity. These properties are typically derived by interpreting thermal infrared data by means of thermal models (*Delbo and Harris*, 2002; *Harris and Lagerros*, 2002; chapters by Mainzer et al. and Delbo et al. in this volume). The “simple” thermal models that assume a spherical shape, a Lambertian emission of the surface, and a simplified calculation of the surface temperature distribution are used when we lack knowledge of the asteroid global shape, spin vector, and rotation period, which is the majority of the cases. Widely used are, for example, the Near-Earth Asteroid Thermal Model (*Harris*, 1998) or the Standard Thermal Model (*Lebofsky et al.*, 1986).

However, in order to derive the thermal inertia of an asteroid from measurements of its thermal infrared emission, more sophisticated models, called thermophysical models (TPMs), are needed (*Spencer*, 1990; *Spencer et al.*, 1989; *Lagerros*, 1996, 1997, 1998; *Rozitis and Green*, 2011; *Müller*, 2007; *Delbo*, 2004). Such models are used to calculate the temperature distribution over the body’s surface as a function of different parameters, including the thermal inertia. In these models, the asteroid shape is usually fixed and is modeled as a mesh of planar facets. The temperature of each facet is determined by numerically solving the one-dimensional heat diffusion equation using assumed values of the thermal inertia, with the boundary condition given by the time-dependent solar energy absorbed at the surface of the facet (for a review, see the chapter by Delbo et al. in this volume). This latter quantity is calculated from the heliocentric distance of the asteroid, the value assumed for the albedo, and the solar incident angle. Macroscopic surface roughness is usually modeled by adding hemispherical section craters of variable opening angle and variable surface density to each facet. Shadowing and multiple reflections of incident solar and thermally emitted radiation inside craters as described by *Spencer* (1990), *Emery et al.* (1998), *Rozitis and Green* (2011), and *Lagerros* (1998) are taken into account. Heat conduction is also accounted for within craters (*Spencer et al.*, 1989; *Spencer*, 1990; *Lagerros*, 1996; *Delbo*, 2004). Surface roughness can be adjusted by changing the opening angle of the craters, the density of the crater distribution, or

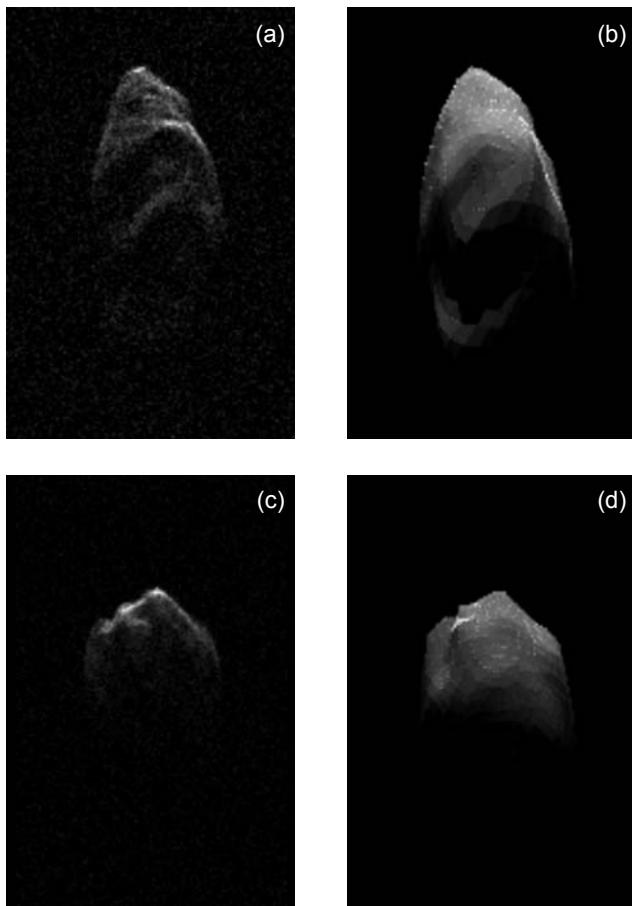

a combination of both (*Müller*, 2007). The total observable thermal emission is calculated by summing the contributions from each facet visible to the observer. Model parameters are adjusted until the best agreement with observational data is obtained, i.e., the least-squares residual of the fit is minimized, thereby constraining the physical properties (albedo, size, macroscopic roughness, and thermal inertia) of the asteroid.

From the point of view of multi-data inversion, however, the optimization of thermophysical parameters as described above is a two-step process: First, the spin and shape model is derived from one data type (photometry, radar, etc.), then this model is fixed and used for deriving thermophysical parameters from another data type (thermal infrared). This approach lacks the possibility of weighting the two data types with respect to each other. Moreover, the thermophysical parameters can be very sensitive to small modifications of the input shape and spin, so various modifications of the shape should be tested to see how stable the solution is (*Hanuš et al.*, 2015). Ideally, one should model shape and spin parameters together with thermal parameters. This multi-data approach using lightcurves and thermal infrared data simultaneously was successfully tested by *Durech et al.* (2012, 2014), and in principle it can also be used with data that are sparse in time.

### 3.8. Radar

Radar observations that measure the distribution of echo power in time delay and Doppler frequency (so-called range-Doppler or delay-Doppler measurements) are discussed in detail in *Ostro et al.* (2002) and in the chapter by Benner et al. in this volume. The delay-Doppler projection is many-to-one mapping of a three-dimensional surface of the target into a two-dimensional “image.” Each pixel on the image represents a bin containing integrated echo power from surface elements that have the same distance from the radar and the same relative speed (due to the rotation of the asteroid). From the point of view of inversion, images in the range-Doppler plane are generalized projections that can automatically be handled with the general procedure discussed in section 2 and in detail in *Viikinkoski and Kaasalainen* (2014) and *Viikinkoski et al.* (2015). In this approach, the multi-mode reconstruction is tuned to produce models with intermediate-scale resolution ( $\sim 1/10$  of the diameter) since these are computationally inexpensive (can be obtained in a few minutes with a laptop), and data sources other than radar do not contain more detailed information. An example of radar range-Doppler data of asteroid 2000 ET<sub>70</sub> is shown in Fig. 10 and the corresponding reconstructed shape model in Fig. 11. If detailed radar data are available, such models can then be further refined (*Naidu et al.*, 2013) with the radar techniques described in the chapter by Benner et al. in this volume.

Due to the steep decrease of echo power with the distance to the object (the fourth power of the distance), asteroids imaged by current radar facilities Arecibo and Goldstone are only close-approaching near-Earth asteroids or the largest

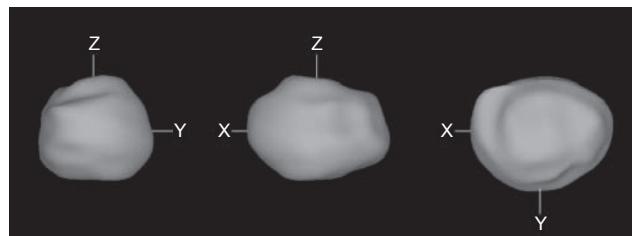

**Fig. 10.** (a), (c) Example range-Doppler radar images of asteroid 2000 ET<sub>70</sub> observed at Arecibo observatory (Naidu *et al.*, 2013). Range and frequency resolutions are 15 m and 0.075 Hz, respectively. Range increases toward the bottom, Doppler frequency increases to the right. (b), (d) The simulated images correspond to the reconstructed shape model in Fig. 11.

members of the main belt. A number of examples of what can be reconstructed from radar data is given in the chapter by Benner *et al.*

### 3.9. Asteroid Interior

We briefly discuss here the interesting possibility of peering into an asteroid. This is somewhat separate from the remote sensing framework as the data can only be obtained *in situ*; on the other hand, such data can be acquired with future space missions. The most practical option is to plant radio transmitters/receivers on the surface of a kilometer-sized asteroid and measure low-frequency ( $\sim$ 100 MHz) signals between these devices and an orbiter when the signals pass through the interior of the target.

The most robust observables are simply signal travel-time data (Pursiainen and Kaasalainen, 2013). These allow an efficient formulation of the inverse problem via the refraction index and are relatively insensitive to noise and model error.

**Fig. 11.** Shape model of the asteroid 2000 ET<sub>70</sub> reconstructed from Arecibo and Goldstone delay-Doppler radar images with ADAM (section 3.11).

Nevertheless, they suffice to give a coarse-scale picture of the general distribution of permittivity inside the asteroid, as well as the locations and sizes of large anomalies (sudden low- or high-density regions such as voids or heavier minerals). This approach has also been robustly tested in laboratory conditions (Pursiainen and Kaasalainen, 2014b). A more refined possibility is to measure changes in the pulse profile, although this is more prone to errors (Pursiainen and Kaasalainen, 2014a). The interior of the asteroid is practically impossible to model accurately in three dimensions since it is supposed to have a number of cracks, voids, discontinuities, etc., all refracting and reflecting the radio waves in complicated ways. Thus a very robust scheme is essential for extracting the available information with stability. Regardless of the data type, one or two transmitters on the surface are not sufficient for a unique solution. A tetrahedral configuration of four transmitters would be ideal, but this places heavy demands on the payload design.

### 3.10. Extension of the Model

So far, we assumed that the asteroid can be described as a solid single body with constant spin vector, i.e., rotating along the axis with the maximum moment of inertia with a constant rotation rate. Although this model represents a typical asteroid, there are other configurations that can be also treated with an extension of the simple model.

**3.10.1. Binaries.** Binary asteroids form a significant part of the population of small asteroids. Pravec *et al.* (2006) estimated that the fraction of binaries is 15% for the near-Earth population and a similar fraction is assumed for the main-belt population in the same size range (see chapter by Margot *et al.* in this volume). The formation, dynamics, and physical properties of binary and multiple asteroid systems are discussed in detail in other chapters of this volume (Walsh *et al.*, Margot *et al.*). In general, modeling of such systems is more complex because the dynamics have to be taken into account. However, in some cases described below, the technique used for modeling single asteroids can be used also for multiple systems or at least their primary components.

For binary (or multiple) systems where the primary component is much larger than the satellite, the photometric signal from the satellite can be neglected and the primary can be

modeled as a single body. For such systems, the shape of the primary and the constraints on its gravitational quadrupole  $J_2$  from the orbit analysis of the secondary can be used to investigate the distribution of the density (Berthier et al., 2014; Takahashi and Scheeres, 2014).

For systems with comparable sizes, the problem becomes complicated when the system is asynchronous, i.e., when the rotation period of the primary is different from the orbital period of the secondary. Such systems are usually modeled as two ellipsoids (Scheirich and Pravec, 2009), although more general models were created from radar observation [e.g., 1999 KW<sub>4</sub>; see Ostro et al. (2006)].

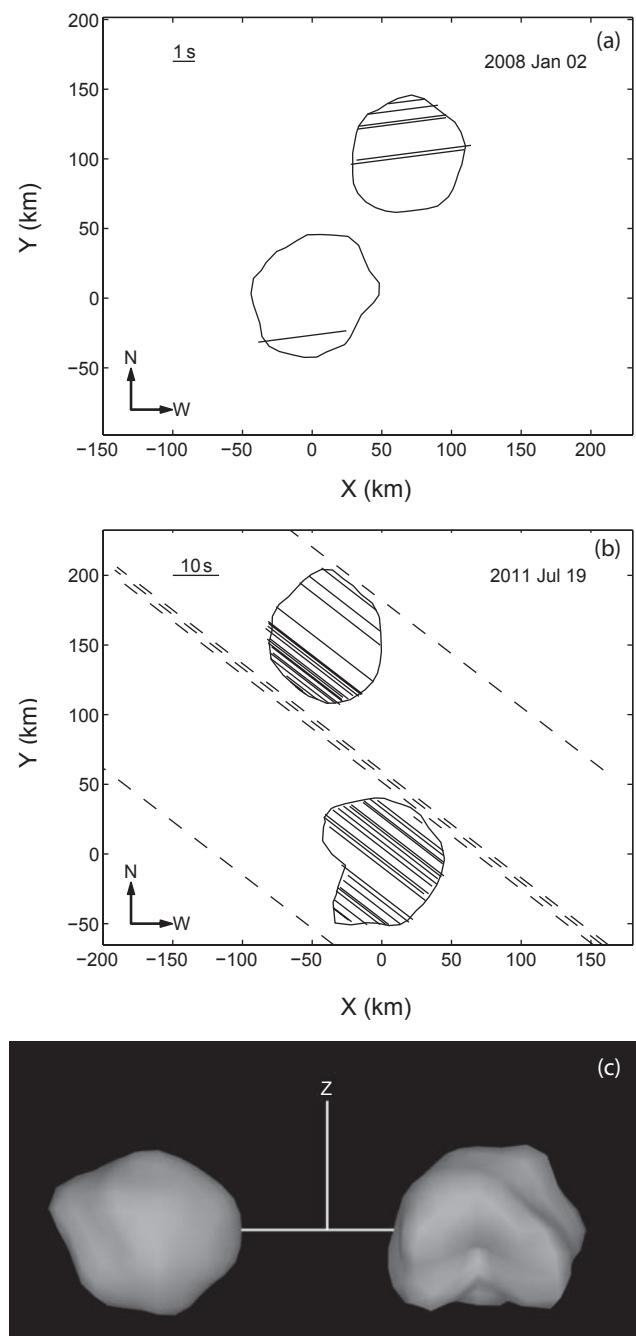

Fully synchronous binaries can be approximated by single bodies if the separation of their components is not large. Even a convex model can provide a good fit to the lightcurves (Durech and Kaasalainen, 2003). Such a model does not represent the true configuration of the system, of course, but it provides the correct rotation period and orientation of the orbital plane.

When the separation of components is larger, the system has to be modeled as a two-component system. However, from the modeling point of view, it is just a moderate modification of the nonconvex problem, where the system is described by only one rotation/orbital period and orientation of the normal of the orbital plane (parallel to the spins of the bodies). If the model is based on lightcurves only, the spin and period parameters can be reconstructed accurately, but the uncertainty in shapes is large. As has been shown by Marchis et al. (2014) on (624) Hektor, the distinction between a highly nonconvex single body, two bodies in contact, or two bodies orbiting each other is difficult to make.

An example of reconstruction of a doubly synchronous binary system (90) Antiope from lightcurves and occultations is shown in Fig. 12, where the model is shown together with the silhouettes from occultations. Tens of chords observed during the occultation in 2011 (Colas et al., 2012) portray the two components to details unattainable by any other observational technique, and the large set of lightcurves observed over many apparitions constrains the rotational parameters. A similar model can be obtained by using lightcurves separately to create a scale-free model that is then scaled by occultation data [the Shaping Asteroids with Genetic Evolution algorithm (Bartczak et al., 2014)]. However, this two-step approach lacks the advantages of simultaneous inversion, where the two data types can be weighted with respect to each other.

### 3.10.2. Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) effect.

As described in detail in the chapter by Vokrouhlický in this volume, the rotation state of small asteroids is affected by the anisotropic recoil of scattered sunlight and thermal radiation, which causes a net torque called the YORP effect. This effect secularly changes the obliquity of the spin vector and the rotation period. Whereas the former is too small to be measured with current data, the latter has been measured on several asteroids (see Table 3 in the chapter by Vokrouhlický in this volume). If the change of the rotation period is larger than the uncertainty of the period, the

**Fig. 12.** Occultations of (90) Antiope observed in (a) 2008 and (b) 2011. The model silhouette is projected on the plane of the sky; solid lines are positive chords, dashed lines are negative observations. (c) Shape model of (90) Antiope seen from its equator reconstructed from lightcurves and the 2008 and 2011 occultations.

change can be traced from apparition to apparition, as was the case for (54509) YORP (Lowry et al., 2007). In other cases, the effect was much smaller and it revealed itself by the discrepancy between the data and the model, assuming the period to be constant (Kaasalainen et al., 2007; Durech et al., 2008, 2012; Lowry et al., 2014).

The YORP effect is easy to include in the model. We assume that the rotation rate  $\omega$  changes linearly in time  $t$  as  $d\omega/dt = v$ . Then the parameter  $v$  is another free parameter of the modeling. Because the shift in the rotation phase increases quadratically in time as  $\phi = \omega t + 1/2vt^2$ , even small changes  $d\omega/dt$  on the order of  $10^{-8}$  rad/d $^2$  can be detected with datasets covering tens of years.

In principle, the measured value of  $v$  can be compared with the theoretical value computed from the spin state, shape, size, and thermal parameters of the surface with the density as a free parameter. However, due to the sensitivity of YORP on small-scale details of the shape that are far below the resolution of the model (Statler, 2009; Kaasalainen and Nortunen, 2013), as well as the problem of transverse heat diffusion (Golubov and Krugly, 2012; Golubov et al., 2014; Ševeček et al., 2015), this can hardly be more than a rough comparison.

Because the YORP effect scales as the inverse of the square of the size of the asteroid, it becomes more important for small bodies, where it might be necessary to include it in the modeling if the data cover a wider span of time. YORP is assumed to play an important role in many dynamical processes — e.g., the distribution of rotation periods and spin obliquities of small asteroids (Pravec et al., 2008; Hanuš et al., 2013b) or the creation of asteroid binaries and asteroid pairs (Pravec et al., 2010). It is important to have more asteroids with YORP detection. Better statistics of values of period change will help to constrain theories of the YORP evolution of small asteroids.

**3.10.3. Excited rotation.** Asteroids rotating in the relaxed mode are fully described by the spin axis direction, rotation rate, and initial orientation. However, some asteroids are in an excited rotation state, which can be described as a rotating free top. More parameters are needed to describe this tumbling motion (Kaasalainen, 2001). The reason why some asteroids are in this state can be (1) primordial, (2) collisional excitation (Henych and Pravec, 2013), or (3) end state of YORP-driven spindown. The approach to the modeling is in principle the same as for asteroids in principal axis rotation, only the orientation for a given time is given by solving differential equations. From lightcurves, models of asteroids 2008 TC<sub>3</sub> (Scheirich et al., 2010) and (99942) Apophis (Pravec et al., 2014) have been derived. A model of asteroid (4179) Toutatis (Hudson et al., 2003) was derived from radar data and lightcurves. This model was later compared with the flyby images of the Chang'e-2 mission — the general shape was in agreement, although there were some minor discrepancies (Zou et al., 2014).

### 3.11. Procedures: Convexinv, Knitted Occultation, Adaptive Optics and Lightcurve Analysis (KOALA), and All-Data Asteroid Modeling (ADAM)

Software for inverse problems is available at the Database of Asteroid Models from Inversion Techniques (DAMIT) (<http://astro.troja.mff.cuni.cz/projects/asteroids3D>). Convexinv is a procedure for lightcurve inversion, while All-Data

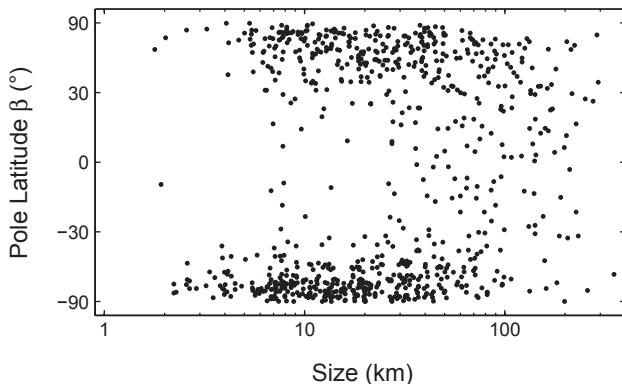

Asteroid Modeling (ADAM) is a collection of functions from which one can tailor an inversion procedure for any data sources (Viikinkoski et al., 2015). An earlier version of this is called Knitted Occultation, Adaptive optics and Lightcurve Analysis (KOALA) (Carry et al., 2012); this is based on lightcurves and silhouette contours obtainable from images and occultations (Kaasalainen, 2011; Kaasalainen and Viikinkoski, 2012). KOALA is especially suitable for lightcurve and occultation data, while ADAM allows the use of any images (camera, radar, or interferometry) with or without lightcurves without having to process them to extract contours or other information. Both KOALA and ADAM can be used for lightcurves only but, as discussed earlier, this is not reliable. Any resulting shape should only be taken in the global sense (as a more realistic-looking rendering of a convex solution), and the details or nonconvex features are seldom likely to be real (Viikinkoski et al., 2015).

## 4. WHAT HAVE WE LEARNED FROM THREE-DIMENSIONAL SHAPES?

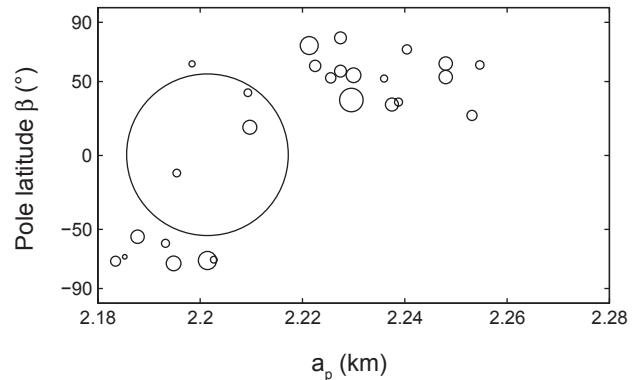

The purpose of the modeling methods described in previous sections is to reveal new facts about the nature of asteroids. The approach is made on two fronts: The first strategy is to use the most abundant data sources (photometry in visual and thermal IR) to produce many low-resolution models that will be a statistically significant sample of the whole asteroid population from which conclusions about the physical properties can be drawn. The second approach is to concentrate on selected targets, obtain as many different data types as possible, create detailed models of these asteroids, and extrapolate the obtained results to the whole class of similar objects. We describe in this section new research areas that directly benefit from the availability of spin solutions and three-dimensional shape models.

### 4.1. Spin-Axis Distribution and Evolution

One of the main results of the lightcurve inversion is the increasing sample of asteroids with known orientation of the spin axis. For main-belt asteroids, the long-known lack of asteroids with poles close to the ecliptic (Kryszczyńska et al., 2007) was confirmed and it was shown that it is more pronounced for smaller asteroids (Hanuš et al., 2011). In Fig. 13, we plot the distribution of pole latitudes for ~800 asteroid models with respect to their size [an updated version of Fig. 5 in Hanuš et al. (2011)]. The size-dependent structure can be explained by the YORP effect, which is more effective on smaller asteroids ( $\leq 30$  km) and pushes them into extreme values of obliquity ( $0^\circ$  or  $180^\circ$ ). This corresponds to the clustering of pole latitudes toward values of  $\pm 90^\circ$ . Although there are observation and modeling biases that affect the distribution of poles in the sample of available models, their effect is only marginal compared to the strong anisotropy seen in Fig. 13 (Hanuš et al., 2011). The spin-axis orientation of even smaller asteroids ( $\leq 5$  km) is still not known due to the lack of models. For the largest asteroids ( $\geq 60$  km), there

**Fig. 13.** Distribution of pole ecliptic latitude  $\beta$  with respect to the size of the asteroid for  $\sim 800$  asteroids. The scale on the vertical axis is linear in  $\sin \beta$ , which makes the vertical distribution of points in this plot uniform for an isotropic distribution of spin vectors.

**Fig. 14.** Distribution of pole ecliptic latitude  $\beta$  with respect to the proper semimajor axis  $a_p$  of the Flora family members. The relative size of each circle corresponds to the size of the asteroid.

is a statistically significant increase of prograde rotators (98 prograde vs. 63 retrograde in Fig. 13), probably of primordial origin (Johansen and Lacerda, 2010).

A different approach to the problem of spin-axis distribution was used by Bowell et al. (2014). They analyzed variations of the mean brightness with the ecliptic longitude, from which they estimated ecliptic longitudes of spin axis for about 350,000 asteroids and revealed a clearly non-uniform distribution. However, the explanation of the cause for this non-uniformity is still unknown.

With an increasing sample of models, it is also possible to study the distribution of spin axes of members of collisional families. The results of Hanuš et al. (2013a) agree with theoretical expectations: If the spread in proper semimajor axis increases with decreasing size due to the Yarkovsky effect (see chapters by Nesvorný et al. and Vokrouhlický et al. in this volume), asteroids closer to the Sun than the center of the family should rotate retrograde, and those farther should rotate prograde. This behavior is shown in Fig. 14 for the Flora family.

#### 4.2. A Prerequisite in Many Cases

Unlike most astronomical objects, the viewing geometry of asteroids continuously changes due to their motion relative to the observer. As a corollary, knowing their rotation period and spin-vector coordinates is crucial to interpret projected size measurements and tie together observations.

As already described in section 3, the spin and three-dimensional shape are required to interpret thermal infrared radiometry, stellar occultations, or apparent sizes measured by Gaia without biases. Similarly, there have been long-running discussions to explain inconsistent spectral measurements of asteroids, which can be easily solved once the spin properties (period and orientation) are known; see, e.g., the discussion on (832) Karin by Sasaki et al. (2004), Vernazza

et al. (2007), and Chapman et al. (2007), or on (21) Lutetia by Barucci et al. (2012).

#### 4.3. Density, Composition, and Internal Structure

Density is one of the most fundamental properties to constrain the composition of asteroids and investigate their internal structure (see the chapter by Scheeres et al. in this volume). With the exception of binary asteroids with observable mutual eclipses (chapter by Margot et al. in this volume), both mass and volume are required to determine the density of an asteroid. Estimating the mass of an asteroid by measuring its gravitational influence on other objects is a challenge because of the relative low mass of asteroids compared to other planetary objects. The number of mass determinations thus limits the number of density estimates. Although there are diameter, and hence volume, estimates for all asteroids with a mass determination, the uncertainty in volume generally dominates the balance on density uncertainty (Carry, 2012).

In this respect, three-dimensional shape models are required to determine accurate volume. The level of potential biases increases with stronger assumptions on the shape, and accuracy accounting for systematics improves from sphere, to ellipsoid, to convex model, to the real shape. In the decade since *Asteroids III*, the number of density estimates has increased from 20 to 300 objects (Britt et al., 2002; Carry, 2012). Among these, the most reliable are derived from binary systems for which the volume of the primary was determined after shape modeling (e.g., Ostro et al., 2006; Shepard et al., 2006; Descamps et al., 2009, 2011; Fang et al., 2011; Marchis et al., 2013).

A detailed description of the density of asteroids and their internal structure can be found in the chapter by Scheeres et al. in this volume, from underdense asteroids, hosting large voids, to overdense asteroids, likely differentiated. In the

context of this chapter, it is important to highlight that only density estimates more precise than 10–20% can be used to discriminate between different analog meteorites and provide insights on the internal structure. Such accuracy can only be achieved with volume known to 5–10% or better, which means that a proper description of the three-dimensional shape is needed.

#### 4.4. Determination of Surface Properties by Means of Thermophysical Models

The spin state and shape model of an asteroid is input information for the TPMs. While in the *Asteroids III* era, shape and spin information were available only for a handful of asteroids, preventing application of TPMs to a large number of these bodies, this situation has drastically changed in the last few years. Physical properties (such as the value of the surface thermal inertia) of about 60 asteroids are now available thanks to the application of TPMs (see the chapter by Delbo et al. in this volume). A remarkable improvement in this field is also represented by the availability of high-quality thermal infrared data, such as those produced by the WISE and the Spitzer space telescopes. In the next few years we expect the number of asteroids with known thermal inertia values to grow, thanks to the availability of more shape and spin-state models.

#### 4.5. Surface Rearrangement

From the spin, three-dimensional shape, and density, the local gravity at the surface can be computed. Unsuspected physics has been unveiled with the modeling of the near-Earth asteroid (66391) 1999 KW<sub>4</sub> by Ostro et al. (2006). Some small asteroids present an equatorial bulge, presumably generated by regolith migration toward lower-gravity regions. This process can even form binary systems if the asteroids spin fast enough (Walsh et al., 2008; Harris et al., 2009).

#### 4.6. Cratering Events

An evident outcome of shape modeling is the capability to detect large impact craters and basins. Aside from the spacecraft encounters, the first detection was the large impact basin on Vesta, progenitor of the vestoids (Binzel and Xu, 1993), detected with the HST (Thomas et al., 1997) and confirmed by NASA's Dawn spacecraft (Russell et al., 2012). Another case is the recent impact suffered by asteroid (596) Scheila, detected by the presence of a dust tail (Bodewits et al., 2011). Lightcurves obtained before and after the impact under similar geometries are different, revealing different surface properties (Bodewits et al., 2014).

#### 4.7. Mass Distribution

Because some asteroids are less or more dense than their most-likely constituents, the question of the mass

distribution (denser material or voids) in their interior can be asked. This question is intrinsically tied with the study of the gravity field around the asteroid. The latter has been measured during spacecraft encounters (e.g., see Miller et al., 2002), but studies from Earth-bound observations have recently appeared. By comparing the spherical harmonics of the gravity field as determined from the orbit of a natural satellite, with the expected coefficients resulting from the three-dimensional shape model, the hypothesis of homogeneous mass distribution can be tested (Vachier et al., 2012; Berthier et al., 2014; Takahashi and Scheeres, 2014).

### 5. FUTURE

In the decade since *Asteroids III*, in which the principles of lightcurve inversion based on dense-in-time series were presented (Kaasalainen et al., 2002b), the number of models has seen a tenfold increase — from a few tens to a few hundreds (Table 1). The increasing availability of sparse in-time photometry and its appropriate handling in the inversion, coupled with a dramatic increase of computer time (thanks to projects like Asteroids@Home), have made this possible. Upcoming all-sky surveys such as Pan-STARRS, LSST, and Gaia are expected to produce enormous datasets, and there is little doubt that thousands of models will be derived in the next decade. Our knowledge of nongravitational effects such as YORP and Yarkovsky will directly benefit from this larger sample.

With the large number of data and models, new challenges will arise — how to extract scientifically interesting information from a large set of models of asteroids. With big data flows, the processing has to be automated, with effective data processing. The obvious search for correlations has to be done with care because of large biases in the set of models. Although the importance of detailed models of individual well-studied asteroids will be important, the main shift in paradigm and probably the primary source of interesting findings will be in tens of thousands of asteroid models derived from photometry in optical and thermal infrared wavelengths. As recent as a few years ago, only photometry in the visible was available for a large number of asteroids. The situation drastically changed with the WISE catalog of thermal fluxes for 150,000 asteroids. Automated procedures capable of dealing with photometry in the visible and thermal infrared will yield not only three-dimensional shape and spin state for thousands of asteroids, but also their diameter, their albedo, and the thermal inertia of their surface. The latter will be crucial in interpreting asteroid mineralogy, once coupled with spectroscopy (see the chapter by Reddy et al. in this volume). Understanding of observational and modeling biases will be crucial for correct interpretation of the results. Connecting spin and shape distribution of asteroids with their orbital and spin evolution will hopefully lead to a clear picture of the evolution of the main asteroid belt. The ultimate goal here is the connection of models of evolution of the main belt with spin-axis evolution and current distribution of asteroid physical properties.

Another approach that is complementary to modeling individual objects is modeling distribution functions of parameters of interest. With any inversion technique and photometric data quality, the number of models will be always much lower than the number of known asteroids just because it takes time to collect enough data at different geometries. So instead of aiming to create unique models for a statistically significant sample of the (sub)populations with known observational and modeling bias, one can use other observables than the time-brightness pairs. With this approach, there is almost no “wasting” of data because essentially all photometric points are used in the statistical approach. The aim is to model characteristics of a given asteroid population as a whole when there are not enough data to model individual members. For example, one of the observables can be the mean brightness over one apparition (Bowell *et al.*, 2014) and its dispersion, which correlates with lightcurve amplitude. If there are not enough data points to estimate mean brightness and its variance, the statistics of scatter of individual pairs of observations can be used (Szabó and Kiss, 2008). If the data come in pairs of observations separated by a constant time interval (like with Pan-STARRS), the rotation period can be estimated (Ďurech *et al.*, 2007).

Another challenge for the next decade resides in the derivation of a large sample of higher-resolution models, based on multiple data sources. Building inversion techniques capable of handling different data sources had been highlighted in *Asteroids III* as the next step, and this became reality over the past few years. The models based on multiple data sources are more realistic, more reliable, and more precise than the independent analysis of individual datasets. If practical issues of merging datasets arise, mathematical solutions have been uncovered, and algorithms and software are ready and freely available. The current sample of models derived by such methods is nevertheless still limited. If multi-data analysis is more efficient than independent analysis of the individual datasets, the practical problem of data sharing arises. Although the tools to invert multiple data sources are ready and freely available, the data are still hard to get and harder to share. To maximize the scientific output, it is necessary to combine all available data sources.

The other observing techniques (i.e., disk-resolved imaging, stellar occultations, Gaia size measurements, or radar echoes) will never provide data for more than a few thousand asteroids. However, the apparent sizes by Gaia will be measured with high precision, and will cover a decent-sized sample. Because the data will be made public, they should be used on a regular basis for modeling. The number and quality of profiles derived from stellar occultations have always been restricted due to the intrinsic complexity of prediction and the cost of equipment. The parallel availability of low-cost telescopes and cameras, together with the publication of the Gaia stellar catalog and asteroid orbits, will open a new age for stellar occultations. Any mass-production procedure of asteroid models should therefore be able to deal not only with photometry (visible and infrared) but also with stellar occultations.

Finally, if the bulk of asteroids are single objects, rotating along their shortest axis, a small fraction will either be in a tumbling state or will have satellites. Automatic modeling procedures should be able to detect such cases, triggering detailed analysis of these peculiar targets.

The rising interest of private companies in near-Earth objects as mining resources will inevitably lead to further development of the analysis of remote sensing data, building dedicated groundbased or space telescopes, and eventually moving from asteroids’ surfaces into their interiors.

---

The Trojan asteroids, orbiting the Sun in Jupiter's stable Lagrange points, provide a unique perspective on the history of our solar system. As a large population of small bodies, they record important gravitational interactions in the dynamical evolution of the solar system. As primitive bodies, their compositions and physical properties provide windows into the conditions in the solar nebula in the region in which they formed. In the past decade, significant advances have been made in understanding their physical properties, and there has been a revolution in thinking about the origin of Trojans. The ice and organics generally presumed to be a significant part of Trojan composition have yet to be detected directly, although the low density of the binary system Patroclus (and possibly low density of the binary/moonlet system Hektor) is consistent with an interior ice component. By contrast, fine-grained silicates that appear to be similar to cometary silicates in composition have been detected, and a color bimodality may indicate distinct compositional groups among the Trojans. Whereas Trojans had traditionally been thought to have formed near 5 AU, a new paradigm has developed in which the Trojans formed in the proto-Kuiper belt, and were scattered inward and captured in the Trojan swarms as a result of resonant interactions of the giant planets. Whereas the orbital and population distributions of current Trojans are consistent with this origin scenario, there are significant differences between current physical properties of Trojans and those of Kuiper belt objects. These differences may be indicative of surface modification due to the inward migration of objects that became the Trojans, but understanding of appropriate modification mechanisms is poor and would benefit from additional laboratory studies. Many open questions about this intriguing population remain, and the future promises significant strides in our understanding of Trojans. The time is ripe for a spacecraft mission to the Trojans, to transform these objects into geologic worlds that can be studied in detail to unravel their complex history.

## 1. INTRODUCTION

Originally considered as simply an extension of the main belt, Trojan asteroids have become recognized as a large and important population of small bodies. Trojans share Jupiter's orbit around the Sun, residing in the L<sub>4</sub> and L<sub>5</sub> stable Lagrange regions. Leading and trailing Jupiter by 60°, these are regions of stable equilibrium in the Sun-Jupiter-asteroid three-body gravitational system. The moniker "Trojan" is an artifact of history — the first three objects discovered in Jupiter's Lagrange regions were named after heroes from the *Iliad*. The naming convention stuck for Jupiter's swarms, and

the term Trojan eventually came to be used for any object trapped in the L<sub>4</sub> or L<sub>5</sub> region of any body. Nevertheless, only Jupiter Trojans are named from the *Iliad*, and when used without a designator, "Trojan" refers either specifically to Jupiter Trojans or sometimes to the collection of all bodies in stable Lagrange points. Several other solar system bodies also support stable Trojan populations, including Mars, Neptune, and two satellites of Saturn (Tethys and Dione). The populations coorbiting with Mars and the two saturnian moons appear to be quite small, but Neptune's family of Trojans is thought to be extensive (e.g., Sheppard and Trujillo, 2010). Planets can destabilize each other's Lagrange regions. For instance,

Saturn and Uranus do not have stable Trojan populations because the other planets perturb the orbits on timescales that are short relative to the age of the solar system. The Jupiter Trojans, which are the focus of this chapter, are estimated to be nearly as populous as the main belt and have stability timescales that exceed the age of the solar system.

The history of the exploration of Trojan asteroids begins with Max Wolf, who, in the late nineteenth century, was the first to turn to wide-field astrophotography for asteroid discovery (Tenn, 1994). In early 1906 he detected an object near Jupiter's L<sub>4</sub> point, marking the first observational confirmation of Lagrange's three-body solution. An object was detected near L<sub>5</sub> later in 1906 by August Kopf, then another near L<sub>4</sub> in early 1907. These were later named (588) Achilles, (617) Patroclus, and (624) Hektor, respectively (Nicholson, 1961). As physical studies of asteroids accelerated in the 1970s and 1980s, the Trojans were included, and the first sizes, albedos, rotation periods, and (visible wavelength) spectra were published (e.g., Dunlap and Gehrels, 1969; Cruikshank, 1977; Hartmann and Cruikshank, 1978; Chapman and Gaffey, 1979). Gradie and Everka (1980) established the paradigm, which is still commonly invoked, that the low albedo and red spectral slopes are due to the presence of complex organic molecules on Trojan surfaces. By 1989, when the *Asteroids II* book was published, 157 Trojans were known, from which Shoemaker et al. (1989) estimated a total population comparable to that of the main belt — an estimate that still stands, to within a factor of a few. Discovery and characterization accelerated rapidly for Trojans (as with all asteroids) through the end of the twentieth century, and by the time of *Asteroids III* in 2002, 993 Trojans had been discovered. The number now stands at 6073.

Summarizing the state of knowledge of the physical properties of Trojans at the turn of the twenty-first century, Barucci et al. (2002) describe a population that is far more homogeneous than the main belt, with uniformly low albedos ( $p_v \sim 0.03$  to 0.07) and featureless, red-sloped spectra at visible and near-infrared (VNIR) wavelengths (0.4–2.5  $\mu\text{m}$ ). A later review by Dotto et al. (2008) reports additional spectral observations, particularly of members of potential collisional families (Dotto et al., 2006; Fornasier et al., 2007), the detection of signatures of fine-grained silicates (Emery et al., 2006), and the first bulk-density measurement (Marchis et al., 2006). From these properties and their locations at 5.2 AU, Trojans have generally been inferred to contain a large fraction of H<sub>2</sub>O ice hidden from view by a refractory mantle, and a higher abundance of complex organic molecules than most main-belt asteroids (MBAs). Since those reviews, significant strides have been made in the physical characterization of Trojans, which in turn provide new insights into the nature of these enigmatic bodies.

Marzari et al. (2002a) review models for the capture of Trojans and the stability of the Lagrange regions that had developed up to that point. Although some analytical work suggested stability regions that did not match observations, numerical work by Levison et al. (1997) showed a wide region of stability for the age of the solar system. Efforts

to explain the capture of Trojans settled on two potential mechanisms as most likely: gas drag in the early nebula (e.g., Peale, 1993) and capture during the growth of Jupiter (Marzari and Scholl, 1998a). Both mechanisms predict that the present-day Trojans formed in the middle of the solar nebula, near where they currently reside. Since there is no other reservoir of material available for study from this region, the Trojans would, in this case, be an exciting window into the conditions of the solar nebula near the snow line and near Jupiter's formation region. However, neither mechanism fully explains the current orbital properties of Trojans, particularly the high inclinations.

More recently, Morbidelli et al. (2005) proposed the capture of Trojans from the same population from which the Kuiper belt originated. The Nice model postulates that resonant interactions between Jupiter and Saturn temporarily destabilize the orbits of Uranus and Neptune, which move into the primordial Kuiper belt, scattering material widely across the solar system. In this framework, Jupiter's primordial Trojan population is lost and the Lagrange regions are repopulated with this scattered Kuiper belt material. Dotto et al. (2008) include a description of this capture scenario and a discussion of the implications for Trojans. This mechanism predicts that Trojans formed much farther out in the solar nebula (~20–35 AU). In this case, the Trojans would represent the most readily accessible repository of Kuiper belt material. In the years since those reviews, some aspects of the Nice model have been reworked, and refinements to this newer mechanism for Trojan capture have been made.

Unraveling the complex history of the Trojans promises key insight into solar system evolution. As primitive objects, Trojan compositions provide direct indicators of the conditions of the nebula in the region(s) in which they formed. As a population of small bodies, Trojans act as unique probes of the history, interaction, and physical processing of the solar system. In this chapter, we review the physical properties of Trojan asteroids and scenarios for their origin and evolution. We rely heavily on previous reviews for much of the early work (Shoemaker et al., 1989; Barucci et al., 2002; Marzari et al., 2002a; Dotto et al., 2008; Slyusarev and Belskaya, 2014), focusing here on new observations and recent advances in the knowledge of Trojans.

## 2. PHYSICAL PROPERTIES

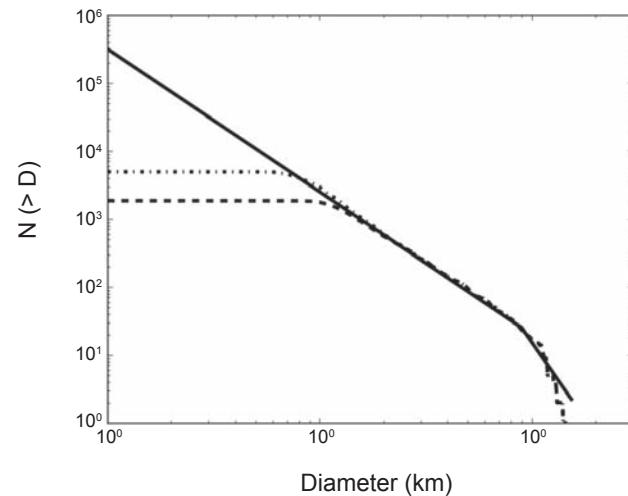

### 2.1. Size Distribution

Most asteroid surveys are conducted in visible (reflected) light, from which it is not possible to derive the size unless the albedo is known. Studies of size distributions, therefore, often use absolute magnitude ( $H_v$ ) as a proxy for size. For a population like the Trojans, where the albedo distribution is very uniform (see section 2.2), the  $H_v$  distribution should closely match the actual size distribution. Shoemaker et al. (1989) pointed out that the largest Trojans have a fairly steeply sloped cumulative  $H_v$  distribution (see Fig. 1). Jewitt et al. (2000) measured the  $H_v$  distribution for smaller Trojans, find-

ing a shallower slope for their sample of objects with  $H_v \geq 10.5$ . They interpreted this as a break between a primordial population at larger sizes and a collisionally evolved population at smaller sizes. Trojan discoveries are now complete to a bit fainter than this [ $H_v \sim 11.5$  (Karlsson, 2010)], so it is now possible to see the break in slope clearly at  $H_v \sim 9$  by downloading and plotting data from the International Astronomical Union (IAU) Minor Planet Center (MPC). Yoshida and Nakamura (2005) conducted their own survey of small Trojans in  $L_4$ . They confirmed the shallower slope for small Trojans found by Jewitt et al. (2000) and found a second break in the  $H_v$  distribution at  $H_v \sim 16$  ( $D \sim 5$  km). In a follow-up study, Yoshida and Nakamura (2008) measured a similar slope in  $L_5$  as the intermediate ( $9 \leq H_v \leq 16$ ) size range for  $L_4$ , but no break for the smallest sizes. From the same survey, Nakamura and Yoshida (2008) confirm the previously recognized population asymmetry between the two swarms.

The Near-Earth Object Wide-field Infrared Survey Explorer (NEOWISE) project, an all-sky infrared survey (Grav et al., 2011), allows for the direct derivation of diameters, since the Trojans were detected in thermal emission. This alleviates any uncertainty in converting from absolute magnitude to diameter. Figure 1 shows the cumulative size distribution of the NEOWISE sample compared to the known population of jovian Trojans. The diameters of known objects that are not in the NEOWISE sample have been estimated using an albedo of 7% (average Trojan albedo from NEOWISE, see section 2.2) and their published absolute magnitudes from the MPC catalog. The NEOWISE sample is nearly complete for diameters larger than  $\sim 20$  km, whereas the known sample dominated by optical discoveries effectively reaches to objects with diameters of about 8–10 km. Grav et al. (2011) performed preliminary debiasing that showed a size distribution that is consistent with a cumulative power law of the form  $N(>D) \sim D^{-a}$ , where the power law index  $a = 2$ , when looking at the sample with diameters from 10 to 100 km. This is consistent with the earlier estimates by Jewitt et al. (2000), which investigated the size distribution of the smaller jovian Trojans. They surveyed a 20 degree<sup>2</sup> field in the  $L_4$  cloud reaching a limiting magnitude of  $V = 22.5$  and detected 93 jovian Trojans with diameters from 4 to 40 km (where they assumed a visual albedo of 4%). They derived a power-law index of  $2.0 \pm 0.3$  for the absolute magnitude distribution in this size range.

At diameters larger than  $\sim 80$  km the distribution is significantly steeper, but the sample is limited with only 34 objects. Shoemaker et al. (1989) estimated the cumulative power law index at  $4.5 \pm 0.9$  for objects with diameters larger than 84 km. The NEOWISE results show that the slope is even steeper than that for the largest jovian Trojans. Fraser et al. (2014) reexamined the absolute magnitude distribution of bright Trojans to compare it with that of Kuiper belt objects (KBOs). They fit the observed  $H$  distribution with an exponential law  $N(H) = 10^{\alpha H}$  in different  $H$  ranges. The best-fit for bright objects was found to be  $\alpha_1 = 1.0 \pm 0.2$ , similar to the value found by Jewitt et al. (2000) and consistent with the size distribution exponent estimated in Shoemaker

**Fig. 1.** The size distribution of the jovian Trojan population from the NEOWISE sample (dashed line) is complete for diameters larger than 20 km, while optical surveys currently sample to below 10 km (dotted line). Both samples show a size distribution with a cumulative power law index of  $\sim 2$  (solid line) for diameters between 20 and 80 km. Modified from Grav et al. (2011).

et al. (1989) and Grav et al. (2011). This fit is valid only up to a ( $r'$ -band) magnitude  $H_{\text{Break}} = 8.4^{+0.2}_{-0.1}$  beyond which the exponent changes to  $\alpha_2 = 0.36 \pm 0.01$ , compatible with the slope found by Yoshida and Nakamura (2008) and the slope of the size distribution found by the NEOWISE survey.

Comparing the size distributions of Trojans and KBOs is very important in order to test the hypothesis that Trojans are KBOs that were captured during the phase of giant planet dynamical instability (see section 4.1). Fraser et al. (2014) took into account that the albedos of Trojans and KBOs are different on average and that the albedos of red and blue KBOs are different from each other as well. In summary, they found that the parent populations of the hot classical KBOs and Trojans are statistically indistinguishable. Given that the Trojan and hot classical size distributions are distinct from other analog populations (MBAs and cold classical KBOs, respectively), Fraser et al. conclude that Trojan asteroids are derived from the hot classical Kuiper belt. The same comparison between Trojans and cold classical KBOs revealed that there is a less than 1 in 1000 probability that those two populations are drawn from the same parent distribution. This is driven by the much steeper large object slope of the cold Kuiper belt magnitude distribution (with  $\alpha_1 = 1.6 \pm 0.3$ ). According to models of dynamical capture of Trojans in the context of the Nice model (Morbidelli et al., 2005; Nesvorný et al., 2013), the bodies that are captured originate from whatever portion of the original Kuiper belt is scattered. It is now considered most likely that the hot classical population is the relic of the planetesimal disk that was scattered all over the solar system at the time of the giant planet instability (e.g., Parker et al., 2011; Morbidelli et al., 2008), part of which was captured in the Trojan region.

Thus the statistical match between the size distributions of Trojans and hot classical KBOs is important observational support of the prediction of the Nice model.

*Grav et al.* (2011) detected no significant difference in the size distributions of the leading and trailing cloud, beyond the well-established observation that the leading cloud has significantly more objects than the trailing cloud, but they did not sample the small sizes at which *Yoshida and Nakamura* (2008) noticed the difference between the two swarms. *Grav et al.* (2011) estimated the fraction of objects with diameter larger than 10 km to be  $N(\text{leading})/N(\text{trailing}) = 1.4 \pm 0.2$ , which is lower than but consistent with previous estimates of  $1.6 \pm 0.1$  derived by *Szabó et al.* (2007).

As discussed below (section 2.4), Trojans separate spectrally into two groups: a “redder” group with a steep red spectral slope and a “less-red” group with a shallower spectral slope. Using absolute magnitudes ( $H$ ) from the MPC online list of Jupiter Trojans and colors from the Sloan Digital Sky Survey (SDSS) for objects with  $H < 12.3$ , *Wong et al.* (2014) found that the two spectral groups have distinct magnitude distributions (and therefore likely distinct size distributions, given the relatively uniform albedos among Trojans). Both distributions have a break in slope near  $H \sim 8.5$ , just like the total Trojan population. The redder spectral group, however, has a shallower power-law slope on both the bright (large) and faint (small) side of the break than the less-red group, but the difference is greatest on the faint (small) side. *Grav et al.* (2012) also point out a potential trend in fraction of the two spectral/color groups with size from Wide-field Infrared Survey Explorer (WISE) data, and *DeMeo and Carry* (2014) report similar changes in abundances of the two spectral groups in their SDSS taxonomy. *Wong et al.* (2014) suggest that the different power-law slopes indicate that the two spectral groups formed in different regions of the solar nebula, and likely also point to different collisional evolutions before being captured into Jupiter’s Lagrange regions. Alternatively, a scenario in which redder objects are collisionally modified into less-red objects may also be consistent with the data.

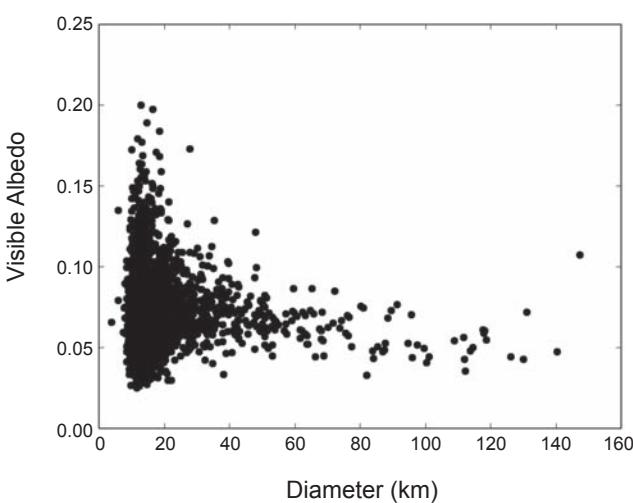

## 2.2. Albedos

Over the first few decades of physical studies of the Trojan asteroids, thermal-infrared radiometric observations of a handful of large Trojans ( $D \geq 70$  km) from groundbased telescopes (*Cruikshank*, 1977; *Fernandez et al.*, 2003) and spacebased surveys [Infrared Astronomical Satellite (IRAS) (*Tedesco et al.*, 2002), AKARI (*Usui et al.*, 2011)] revealed visible geometric albedos ( $p_v$ ) of only a few percent, making them among the darkest objects in the solar system. The NEOWISE project (*Mainzer et al.*, 2011) obtained thermal measurements of more than 1700 known Trojan asteroids during its main cryogenic operations from January to October 2010 (Fig. 2) (*Grav et al.*, 2011, 2012). This represented an order of magnitude increase over all previous publications. The NEOWISE observed sample covers almost all the largest objects, providing a sample that is more than 80% complete down to about 10 km. The albedo distribution derived from

NEOWISE over this size range is remarkably stable, having a mean albedo of  $0.07 \pm 0.03$  across all sizes, consistent with C, P, and D taxonomic classes (see section 2.4). This average albedo is somewhat higher than found by previous studies, likely a result of different observing and analysis techniques. Nevertheless, the jovian Trojan population is one of the darkest populations in the solar system. NEOWISE detected no difference evident in the albedo distribution of the leading and trailing clouds. There is also no statistical difference in the albedo distributions of the two spectral groups described below (*Grav et al.*, 2012; *Emery et al.*, 2011).

Whereas the Spitzer Space Telescope-based observations of *Fernandez* (2009) suggested an increase in albedo at sizes smaller than 20 km, the NEOWISE observations revealed no such trend. The average albedo of Trojans remains constant down to the smallest objects observed by NEOWISE ( $\sim 10$  km). Higher albedo points in Fig. 2 represent the tail end of what appears to be a Gaussian distribution of uncertainties centered on the mean albedo of the entire population (*Grav et al.*, 2011, 2012). It is not expected that any of the small objects really have high albedos.

Note that the NEOWISE-derived albedo of the largest Trojan, (624) Hektor, is significantly higher ( $0.107 \pm 0.011$ ) than derived previously (0.022 to 0.057) using simultaneous visible and infrared photometry (*Hartmann and Cruikshank*, 1978, 1980; *Fernandez et al.*, 2003) and Spitzer Space Telescope infrared spectroscopy (*Emery et al.*, 2006). Hektor is known to be either an elongated body or contact binary, and the NEOWISE observations showed peak-to-peak amplitude of  $\sim 1$  mag over the 27 h from first to last observation. Caution should be used in radiometric interpretations of albedo without simultaneous visible photometry, particularly for objects like Hektor that are highly elongated and have large obliquities. If the NEOWISE albedo turns out to be correct, then Hektor would be remarkable not only as a contact binary with moonlets (*Marchis et al.*, 2014), but also as having an anomalously high albedo among the large Trojans.

**Fig. 2.** The diameter vs. albedo distribution of the jovian Trojan population. From *Grav et al.* (2012).

*Fernandez et al.* (2003) reported an anomalously high albedo of 0.13–0.18 (depending on model parameters) for (4709) Ennomos, which they suggested might be from a recent impact excavating down to a subsurface ice layer. NEOWISE, AKARI, and IRAS all report radiometric albedos of around 0.075 for Ennomos, and *Shevchenko et al.* (2014) report occultation and phase curve observations from which they derive an albedo of 0.054. *Yang and Jewitt* (2007) see no evidence for absorptions due to H<sub>2</sub>O in near-infrared (NIR) spectra of Ennomos observed on three different nights. Unfortunately, since the rotation period is very close to 12 h [ $12.2696 \pm 0.0005$  h (*Shevchenko et al.*, 2014)], they would have been observing nearly the same hemisphere each night. It remains an open question whether Ennomos has a bright spot on its surface.

### 2.3. Rotational States and Phase Curves

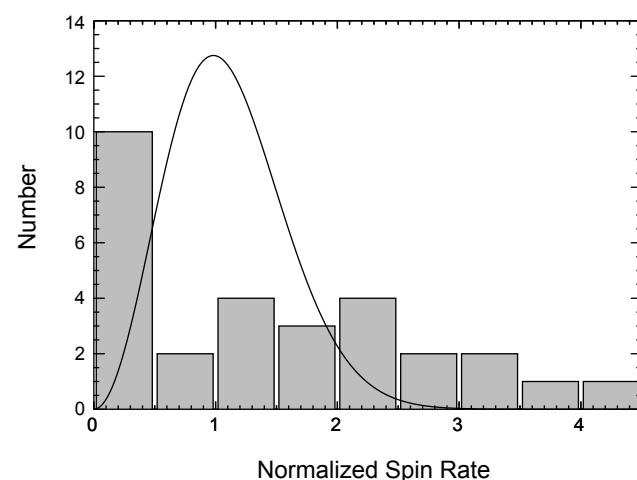

Studies of asteroid light curves provide information about important properties such as rotation rates, shape, pole orientation, and surface characteristics. Rotation properties of MBAs have been shown to vary dramatically with size (*Pravec and Harris*, 2000; *Warner et al.*, 2009). The rotation of MBAs larger than ~50 km in diameter seems to be determined largely by collisions, while that of smaller bodies is shaped primarily by Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) forces and torques (*Pravec et al.*, 2008). Rotation rates of MBAs between ~0.4 and 10 km exhibit a “spin barrier” corresponding to a rotation period of ~2.2 h (summarized by *Warner et al.*, 2009). Because of their greater heliocentric distance and low geometric albedos, the Trojans have been less studied until recently.

The orbital eccentricities of the jovian asteroids are low, with a mean value of  $0.074 \pm 0.04$  (*Mottola et al.*, 2014). They are thus physically isolated from frequent dynamical interactions with other major asteroid groups. While collisions dominate the rotation periods and shapes of large MBAs, factors such as cometary outgassing, tidal braking, and YORP may be significant for the Trojans. Early work by *French* (1987), *Hartmann et al.* (1988), *Zappala et al.* (1989), and *Binzel and Sauter* (1992) suggested that larger Trojans might have, on average, higher-amplitude light curves (meaning more elongated shapes) than MBAs of a similar size. All these studies, however, were limited to different degrees either by small sample size or by observational biases favoring large amplitudes and short periods. Because determination of the true shape, surface scattering properties, and pole direction of an asteroid requires observations at many aspect angles, most recent studies have focused on rotation periods rather than systematic coverage of light-curve amplitudes and determination of pole directions. We focus first on studies of rotation periods, and will conclude with what is known about amplitudes and surface properties.

The past decade has brought the publication of several studies dedicated to eliminating observational bias in Trojan rotation data. *Molnar et al.* (2008) and *Mottola et al.* (2010) investigated medium to large Trojans (60–180 km in diam-

eter), while *French et al.* (2011, 2012, 2013), *Stephens et al.* (2012, 2014), and *Melita et al.* (2010) have focused on Trojans less than 60 km in diameter. All investigators have concluded that a significant population of Trojans rotates slowly, with periods greater than 24 h. *Mottola et al.* (2014) compared Trojan and MBAs in the size range 60–180 km, and a Kuiper nonparametric statistical test rejects the hypothesis that the two samples belong to the same population at the 5% significance level. For smaller Trojans, the overabundance of slow rotators is even more pronounced. Figure 3, from *French et al.* (2015), shows the distribution of rotation rates for Trojans less than 30 km in diameter, along with the best-fit Maxwellian curve. The Maxwellian is the distribution that would be expected if the spin vectors were oriented isotropically, with each component of the angular velocity following a Gaussian distribution. The curve has been normalized to 1 at the geometric mean rotation frequency for the sample of  $f = 1.22$  revolutions/day ( $P = 19.7$  h). The excess of slow rotators is obvious.

The presence of large numbers of slow and fast rotators has already been observed in MBAs, particularly at small diameters. *Pravec et al.* (2008), in their study of 268 small MBAs, demonstrated that the observed distribution of rotation frequencies is consistent with the YORP effect as the controlling mechanism (*Rubincam*, 2000). The YORP effect causes a prograde-rotating asteroid to speed up in its rotation and a retrograde rotator's rotation to slow. Because the YORP effect scales as  $(R^2/a^2)$ , where  $R$  is the radius of the asteroid and  $a$  is the semimajor axis of its orbit, a Trojan asteroid would be affected by YORP to a similar degree as an MBA that is about twice as large. The slow rotation of MBAs as large as (253) Mathilde, at  $R = 26$  km, has been suggested to be caused by YORP (*Rubincam*, 2000; *Harris*, 2004). Thus, Trojans with radii in the 10–15-km range ( $D = 20$ –30 km) might be expected to show evidence of YORP,

**Fig. 3.** Distribution of rotation frequencies of 31 Trojan asteroids with  $D < 30$  km vs. the best-fit Maxwellian curve. Frequencies have been normalized to the geometric mean for this group of  $\langle f \rangle = 1.22$  rotations per day ( $\langle P \rangle = 19.8$  h). From *French et al.* (2015).

and the large numbers of slow rotators in the leftmost bin of Fig. 3 suggest that they are.

What about fast rotators? The presence of a “spin barrier” at  $P \sim 2.2$  h has been well documented for MBAs. This represents the critical rotation period,  $P_C$ , at which a body without internal material strength — a rubble pile — would be spun apart by its centripetal acceleration. This period is

$$P_C \sim 3.3 \sqrt{\frac{(1+A)}{\rho}}$$

where  $P_C$  is in hours, A is the light-curve amplitude in magnitudes, and  $\rho$  is the bulk density of the body (Pravec and Harris, 2000). Figure 2 of Mottola *et al.* (2014) shows some evidence for an excess of fast rotators among Trojans as compared to the MBA population in the 60–180-km range. The French *et al.* (2015) study includes 31 well-determined light curves for sub-30-km Trojans. Currently, no Trojan has been found with a period shorter than that of (129602) 1997 WA<sub>12</sub> ( $D = 12.5$  km) at 4.84 h (French *et al.*, 2015). Several other Trojans have periods in the ~5-h range (Mottola *et al.*, 2014; French *et al.*, 2015). The observed light-curve amplitudes give density estimates of ~0.5 g cm<sup>-3</sup> if the objects are spinning at the critical period. This value would be consistent with observed comet densities (Lamy *et al.*, 2004). More observations of Trojan rotation periods are encouraged in order to locate the Trojan spin barrier, setting a limit on Trojan densities.

The most recent survey of Trojan asteroid light-curve amplitudes remains that of Binzel and Sauter (1992). After correcting for the likely bias in published light curves due to incomplete sampling at all viewing angles, they concluded that the larger Trojans ( $D > 90$  km) have higher average amplitudes, implying a more elongated shape than MBAs in the same size range. What this means in terms of the evolutionary and collisional history of the Trojans is as yet unexplained.

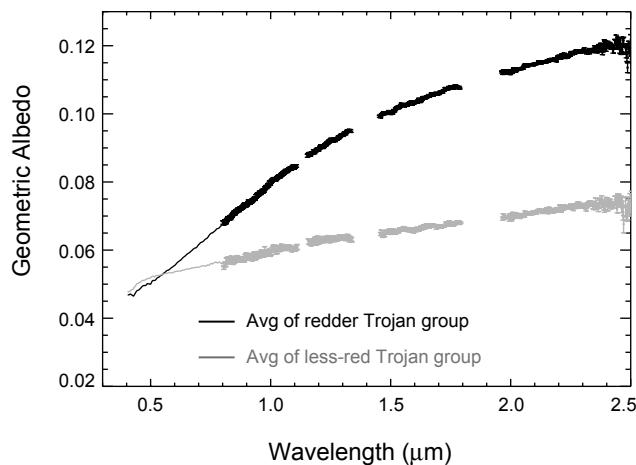

Most solar system bodies without atmospheres show an opposition effect (OE) — a sharp, nonlinear brightening near zero phase angle. (The phase angle is the angle between the Sun and Earth, as seen from the object. For Earth’s Moon this corresponds to a full Moon.) High-quality asteroid phase curves generally show a linear slope between phase angles of 5° and 25°, with differing slopes for different albedo asteroids (Belskaya and Shevchenko, 2000). At phase angles less than 5°, an opposition surge is observed; this is now understood as due to coherent backscattering, as it is stronger for higher-albedo surfaces (Muinonen *et al.*, 2002). Phase curves for Trojan asteroids are linear down to phase angles of ~0.1°–0.2° (Shevchenko *et al.*, 2012). This linear behavior differs dramatically from the sharp opposition spikes seen in several Centaurs, and is similar to what is observed for dark outer MBAs and Hilda asteroids (Shevchenko *et al.*, 2012). Shevchenko *et al.* (2012) attribute the absence of a strong opposition surge to the low albedos of Trojan asteroids. For such low albedos, multiply scattered light, which is required for the coherent-backscatter opposition effect to occur, does not provide a significant contribution to the reflected flux.

## 2.4. Spectral Properties

The first visible-wavelength reflectance spectra of Trojan asteroids were featureless, but the relatively steep, red spectral slopes were excitingly interpreted to indicate the presence of abundant complex organic molecules on the surfaces, masking an ice-rich interior (Gradie and Everka, 1980). Over the following two decades, reflectance spectroscopy at VNIR wavelengths continued to show a range of spectral slopes, but no absorption features (see Dotto *et al.*, 2008), placing strong constraints on the presence of ice near the surfaces and on the presence and form of organic material. Recent dedicated spectral searches for ices in the Eurybates family (DeLuise *et al.*, 2010), on several large Trojans, including Ennomos (Yang and Jewitt, 2007), and on several of the smaller ( $D \sim 10$ –30 km) Trojans for which the NEOWISE survey suggests high albedos (Marsset *et al.*, 2014), as well as a general NIR survey [0.7–2.5 μm (Emery *et al.*, 2011)] still reveal no spectral absorption bands. Yang and Jewitt (2011) reobserved seven large Trojans whose spectra had hinted at a possible broad 1-μm silicate band, but those also turned out to be featureless.

Statistical analyses of VNIR colors and spectra have revealed the presence of two distinct spectral groups (Fig. 4), a “red” group consistent with the asteroidal D-type taxonomic class and a “less-red” group consistent with the asteroidal P-type classification (Szabó *et al.*, 2007; Roig *et al.*, 2008; Emery *et al.*, 2011; Grav *et al.*, 2012). Emery *et al.* (2013) supplemented the NIR sample with 20 additional L<sub>5</sub> Trojans, showing that the two spectral groups appear to be equally distributed in the two swarms. The NIR sample is restricted to objects larger than ~70 km, and it is not yet clear if the bimodality extends to smaller sizes (e.g., Karlsson *et al.*, 2009). Emery *et al.* (2011) suggest that the spectral groups represent two compositional classes that potentially formed in different regions of the solar nebula. Otherwise, no strong correlations between spectral and any physical or orbital parameter are present (Fornasier *et al.*, 2007; Melita *et al.*, 2008; Emery *et al.*, 2011), although Szabó *et al.* (2007) suggest a weak correlation of color with orbital inclination in the L<sub>4</sub> swarm that Fornasier *et al.* (2007) attribute to the presence of the Eurybates family. Brown *et al.* (2014) presented spectra in the 2.85–4.0-μm region showing a possible absorption for a few “less-red” Trojans similar to that seen on (24) Themis (Campins *et al.*, 2010; Rivkin and Emery, 2010). The objects that Brown *et al.* (2014) observed from the “red” group showed no absorption.

Mid-infrared (MIR) (5–38 μm) emissivity spectra have been published of four Trojan asteroids [(624) Hektor, (911) Agamemnon, (1172) Aneas, and (617) Patroclus], and all four show strong emissivity peaks near 10 and 20 μm (Emery *et al.*, 2006; Mueller *et al.*, 2010). It is interesting to note that although the emissivity features seen in Patroclus, the only “less-red” object among the four, are in the same location as for the other three Trojans, the spectral contrast is significantly weaker. Whether this is a trend that follows the spectral groups remains to be discovered. From mutual eclipses of the binary

**Fig. 4.** Combined visible and NIR average spectra of the two spectral groups. The spectral groups are separated more clearly when both visible and NIR wavelength ranges are considered. These spectra have been scaled to  $p_v = 0.055$ . From Emery et al. (2011).

components, Mueller et al. (2010) derived a very low thermal inertia ( $\sim 6\text{--}20 \text{ J m}^{-2} \text{ K}^{-1} \text{ s}^{-1/2}$ ) for Patroclus. Thermal spectral energy distributions of other (large) Trojans are also consistent with very low thermal inertia surfaces (e.g., Fernandez et al., 2003; Emery et al., 2006), suggesting very fine grained, porous regoliths. Horner et al. (2012) computed a slightly higher thermal inertia of  $25\text{--}100 \text{ m}^{-2} \text{ K}^{-1} \text{ s}^{-1/2}$  for (1173) Anchises, but still consistent with a “fluffy” regolith.

## 2.5. Binarity/Densities

Binaries provide invaluable data about the physical nature of asteroids. Two are presently known among the Trojans, and they present intriguing comparisons. (617) Patroclus has a less-red surface, and the two components are nearly equal in size (Merline et al., 2002). The bulk density of the components is  $1.08 \pm 0.33 \text{ g cm}^{-3}$  (Marchis et al., 2006). The orbit is nearly circular, and the rotation periods appear to be synchronized with the orbital motion, implying that the bodies are in a principal-axis rotation state (Mueller et al., 2010). The 102.5-h period is well explained by tidal braking. (624) Hektor, on the other hand, has a rotation period of 6.924 h and appears to be either a contact binary or one extremely elongated object with a small moon  $\sim 12 \text{ km}$  in diameter (Marchis et al., 2014). Its bulk density has been determined to be  $1.0 \pm 0.3 \text{ g cm}^{-3}$  (Marchis et al., 2014), very close to that of the Patroclus system. Hektor has a redder spectrum (Emery et al., 2011), suggesting a possible difference in composition. Analysis of the Hektor system suggests a high-inclination ( $\sim 166^\circ$ ) and high-eccentricity ( $\sim 0.3$ ) orbit for the satellite, with an orbital period just between two spin-orbit resonances. This implies that the orbit has not evolved significantly since the formation of the system and is therefore primordial (Marchis et al., 2014). Most recently, Descamps (2015) reanalyzed light-curve data and adaptive

optics images of the Hektor contact binary in terms of a dumbbell shape, finding a better fit to the data and a smaller volume than the previous shape model. This smaller volume results in a higher density estimate of  $2.43 \pm 0.35 \text{ g cm}^{-3}$ . Hektor and Patroclus may therefore have different internal structures as well as belonging to different spectral groups.

Searches for other Trojan binaries have been undertaken by several researchers. In a study of light-curve amplitudes, Mann et al. (2007) report two objects with light-curve amplitudes of  $\sim 1 \text{ mag}$  [(17365) 1978 VF<sub>11</sub> and (29314) Eurydamas] and suggest these might be contact binaries. From their survey of 114 Trojans, they estimate that 6–10% of Trojans might be contact binaries. While observing a stellar occultation by (911) Agamemnon, Timerson et al. (2013) detected a brief dip after the main occultation, which they interpret as a potential moonlet. Most recently, Noll et al. (2013) observed eight outer main belt and Trojan asteroids with long rotational periods. No binaries were found, and those authors concluded that binaries are less frequent in the outer main belt and Trojan regions than in the Kuiper belt.

## 2.6. Physical Interpretation of Observations

In some ways, it seems that the Trojans are conspiring to keep the secret of their compositions and physical structure hidden. Nevertheless, the persistent effort of characterization described in the previous sections is paying off. The clearest indication of internal structure comes from the determination that (617) Patroclus and (624) Hektor both have bulk densities near  $1 \text{ g cm}^{-3}$ . This low density, relative to rock and even carbonaceous chondrites, indicates either a significant low-density component (i.e., ice), a large macroporosity, or, more likely, a combination of the two. However, the interpretation for Hektor’s interior will differ if the latest, higher-density estimate is correct. The distribution of rotation rates and sizes have both been used to argue for a division in which the largest Trojans ( $D > 80\text{--}130 \text{ km}$ ) are intact, primordial planetesimals, whereas the smaller bodies are collisional fragments (Binzel and Sauer, 1992; Jewitt et al., 2000; Yoshida and Nakamura, 2005, 2008; Grav et al., 2011; Fraser et al., 2014). If the internal compositions are distinct from surface compositions (i.e., if a surface crust hides an ice-rich interior), one would expect the properties of smaller Trojans to be systematically different from those of larger Trojans. The small Trojans are at the limit of current observing capabilities from most characterization techniques, but there does not appear to be a systematic difference between large and small Trojans.

The featureless VNIR spectra can be used to assess what is *not* on Trojan surfaces, but do not give a clear indication of what *is* on these surfaces. The red VNIR slopes have often been cited as suggestive of abundant organic material. However, Emery and Brown (2003, 2004) argue that the absence of strong absorptions in the  $2.85\text{--}4.0 \mu\text{m}$  spectral range strongly limits the types and abundance of organics, and therefore the spectral slopes cannot be due to organics. Rather, they and Emery et al. (2011) demonstrate that the

featureless, low-albedo, red-sloped VNIR spectra can be fit by amorphous and/or space-weathered silicates. Spectral models have been used to place upper limits of only a few weight % of H<sub>2</sub>O ice on the surfaces (e.g., *Emery and Brown*, 2004; *Yang and Jewitt*, 2007).

The MIR emissivity spectra that have been published demonstrate convincingly that Trojan surfaces are populated by silicate dust. The large spectral contrast and positive polarity (i.e., that the features appear as peaks rather than valleys) indicate that the dust is very fine-grained ( $\leq 10\text{-}\mu\text{m}$ -sized grains) and that the grains are fairly well separated (*Emery et al.*, 2006). No cometary (extended) emission has been detected around Trojans, so these spectra provide constraints on the surface structure. *Vernazza et al.* (2012) investigated a model in which the regolith is very porous (i.e., an extreme “fairy-castle” structure; Fig. 5a) using laboratory measurements of meteorite powders mixed with KBr. Their experiments demonstrate the viability of reproducing the MIR spectra, and they find that the features indicate dust composed primarily of amorphous forsteritic olivine, but with a nonnegligible crystalline fraction as well. This model is consistent with the very low thermal inertias measured for Trojans. *Yang et al.* (2013), on the other hand, envision a surface where silicates are embedded in a transparent matrix. They demonstrate, with laboratory measurements and spectral modeling, that salts could provide the matrix, and discuss possible evolutionary scenarios (Fig 5b). In either case, the MIR emissivity spectra point to a silicate fraction that is compositionally similar to cometary silicates (*Emery et al.*, 2006; *Vernazza et al.*, 2012).

### 3. ORIGIN AND EVOLUTION

#### 3.1. Origin of Jupiter Trojans

The capture mechanisms proposed so far for explaining the presence of Trojan populations in the Lagrange regions of the planets can be broadly divided into two main classes:

1. Trapping due to nongravitational perturbations on primordial planetesimals passing by the planet. Trapping can occur because of:

- Drift into the Trojan region due to the action of a dissipative force like gas drag (*Yoder*, 1979; *Peale*, 1993) or the Yarkovsky effect. These processes affect small bodies, which could have subsequently grown into larger asteroids once trapped in tadpole orbits.
- Collisions occurring close to the resonance border that can inject fragments into Trojans orbits (*Shoemaker et al.*, 1989).

2. Changes in the physical and orbital parameters of the planet, which can lead to a shift in the position of the Lagrange points, causing the capture of local planetesimals. Four specific mechanisms have been proposed:

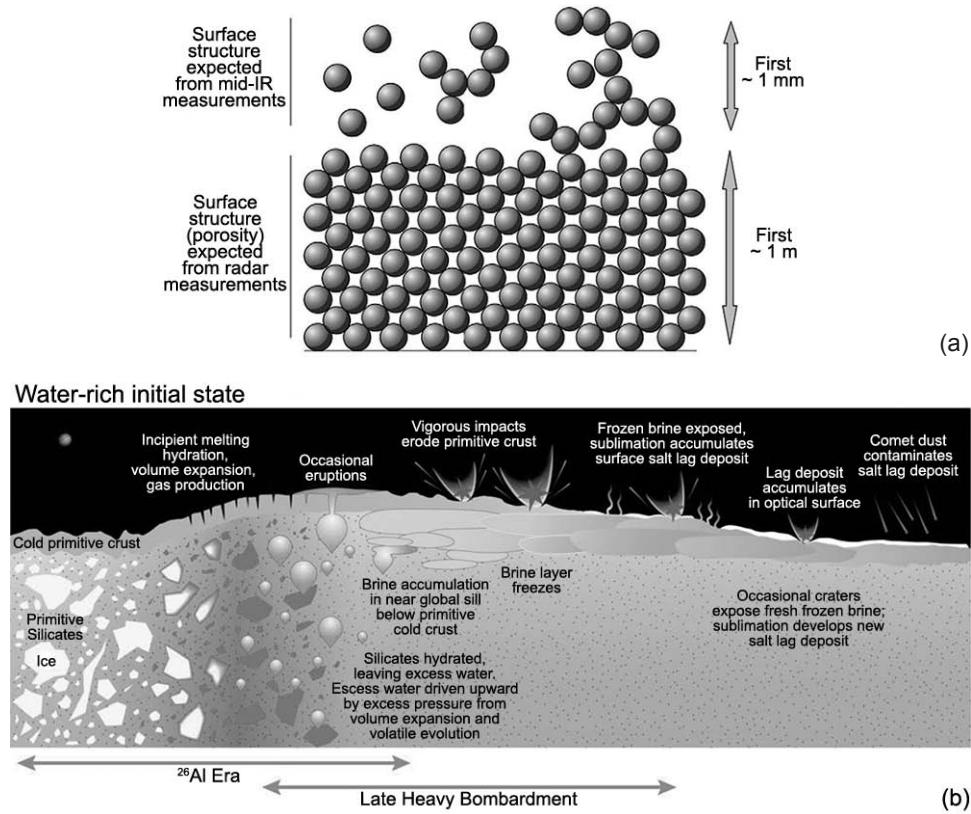

- Mass growth of the planet, which causes an expansion of the resonant area, capturing close-by planetesimals as Trojans (*Marzari and Scholl*, 1998a,b; *Fleming and Hamilton*, 2000).

- Smooth migration of the planet, during which objects are swept into the Lagrange regions (*Lykawka et al.*, 2009).
- Crossing of a mean-motion resonance of the planet with another planet. A chaotic path can be opened during the evolution due to secular resonance sweeping and the superposition of secondary resonances between harmonics of the Trojan libration frequency and the critical argument of mean-motion planetary resonance. Planetesimals can be trapped in tadpole orbits via this chaotic path, which is closed once the resonance crossing has taken place (*Morbidelli et al.*, 2005; *Marzari and Scholl*, 2007). The crossing of the 2:1 resonance between Jupiter and Saturn has been invoked in the Nice model to explain the capture of the Jupiter Trojans.
- “Jumping Jupiter,” which is a period of instability of the planet orbit due to close encounters with a second planet, causing steps in semimajor axis that may lead to the capture of leftover planetesimals due to their sudden dislocation within the stable tadpole regions of the planet (*Nesvorný et al.*, 2013). This might explain an asymmetry between L<sub>4</sub> and L<sub>5</sub> since the perturbing planet may temporarily cross the Trojan region, dispersing a fraction of the local population.

The early models of the origin of Jupiter Trojans are reviewed in *Marzari et al.* (2002a). In essence, they considered capture by gas drag or the pull-down process, which is due to the broadening of the tadpole region around the Lagrange triangular points occurring during the increase of the mass of the planet. Both of these models have several problems in reproducing the observations, the most severe of which is the inclination distribution. Jupiter’s Trojans cover the inclination range 0°–35°, with a median inclination of 10° (which becomes 18° for bright Trojans with H < 12, for which our knowledge of the population is bias free), and the aforementioned capture models had problems explaining any significant inclination excitation.

It is worth noting that for the Trojan population the eccentricity excitation is much less than twice the inclination excitation (the relationship expected for a randomly excited disk). In fact, the eccentricities are smaller than 0.15, with a few exceptions. But this is due to the boundaries of the stability region. *Levison et al.* (1997) mapped these boundaries with long-term numerical simulations and demonstrated that the Trojans fill the entire region that is stable over the age of the solar system.

A decade ago, *Morbidelli et al.* (2005) proposed a radically different model for the origin of the Trojans, developed in the framework of a scenario later named the “Nice model.” In the original version of the Nice model, the giant planets formed in a more compact configuration on quasicircular and coplanar orbits. The planets migrated slowly in divergent directions as they scattered planetesimals, originally located beyond Neptune’s orbit. As the initial ratio of the orbital periods of Saturn and Jupiter was postulated to be slightly less than 2, the divergent migration brought these planets to

**Fig. 5.** See Plate 1 for color version. (a) Schematic model of an underdense, “fairy-castle” regolith on Trojan asteroids deduced from comparisons between MIR emissivity spectra of Trojans and laboratory measurements of powdered meteorites mixed with KBr. From Vernazza et al. (2012). (b) Evolutionary scenario that might produce salt-rich surfaces, in which embedded fine-grained silicate dust could explain measured MIR emissivity spectra of Trojans. From Yang et al. (2013).

cross their mutual 1:2 mean-motion resonance. This resonance crossing excited the eccentricities of Jupiter and Saturn and destabilized the planetary system as a whole. A phase of close encounters among the planets followed, with Uranus and Neptune scattered outward onto large-eccentricity orbits. Thus Uranus and Neptune dispersed the original transneptunian disk and, by a feedback process, all planetary eccentricities were damped to moderate values, consistent with the current ones, and the giant planet system eventually developed the current orbital configuration. In this model, the capture of Trojans occurred during the 1:2 resonance crossing. In fact, the tadpole region becomes fully unstable when the planets are near this resonance. This means that the planetesimals scattered from the transneptunian region can enter and exit the tadpole region. But when Jupiter and Saturn migrate far enough from the 1:2 resonance, the tadpole region suddenly becomes stable. The planetesimals that are there at that time are then trapped forever. A detailed map of the stability of the tadpole region as a function of the Saturn/Jupiter period ratio can be found in Robutel and Bodossian (2009).

Thus, the Morbidelli et al. (2005) paper was the first prediction of capture of Jupiter Trojans from the transneptunian disk. The simulations allowed reproducing, at least

qualitatively, the distribution of the observed Trojans in eccentricity, inclination, and libration amplitude. The capture probability into the Trojan region was shown to be large enough to justify the currently observed population, starting from a primordial transneptunian disk of  $50 M_{\oplus}$ , with a Kuiper-belt-like size-frequency distribution.

The original version of the Nice model, however, proved to be not entirely satisfactory. Further investigation of the dynamics of the giant planets in the primordial disk of gas showed that the giant planets should have emerged from the gas-disk phase locked in mean-motion resonances with each other (Morbidelli et al., 2007; Walsh et al., 2011; see Morbidelli, 2013, for a review). The instability of the planetary system then occurred when two planets fell off resonance, under the perturbations of the planetesimal disk and not when Jupiter and Saturn crossed their 1:2 mean-motion resonance (Levison et al., 2011). Also, of all the possible evolutions that the giant planets can follow during the instability phase, it was shown that the only acceptable ones are the “jumping Jupiter type,” which are evolutions in which Jupiter scatters outward a planet (Uranus, Neptune, or a rogue fifth planet of comparable mass) that had been previously scattered inward by Saturn. In this case, the

period ratio between Saturn and Jupiter impulsively jumps up. This is needed because otherwise the slow increase in the orbital separation between Saturn and Jupiter drives secular resonances across the asteroid belt (*Morbidelli et al.*, 2010) and the terrestrial planet region (*Brasser et al.*, 2009), leaving both populations on orbits inconsistent with the current ones. For this not to happen, the period ratio between Saturn and Jupiter has to jump from the original value of  $\sim 1.5$  (the 2:3 mean-motion resonance) to more than 2.3. This has become a basic requirement of success for the modern Nice model simulations (see, e.g., *Nesvorný and Morbidelli*, 2012). In this case, however, there is no 1:2 resonance crossing and the original Trojan capture model of *Morbidelli et al.* (2005) is invalidated.

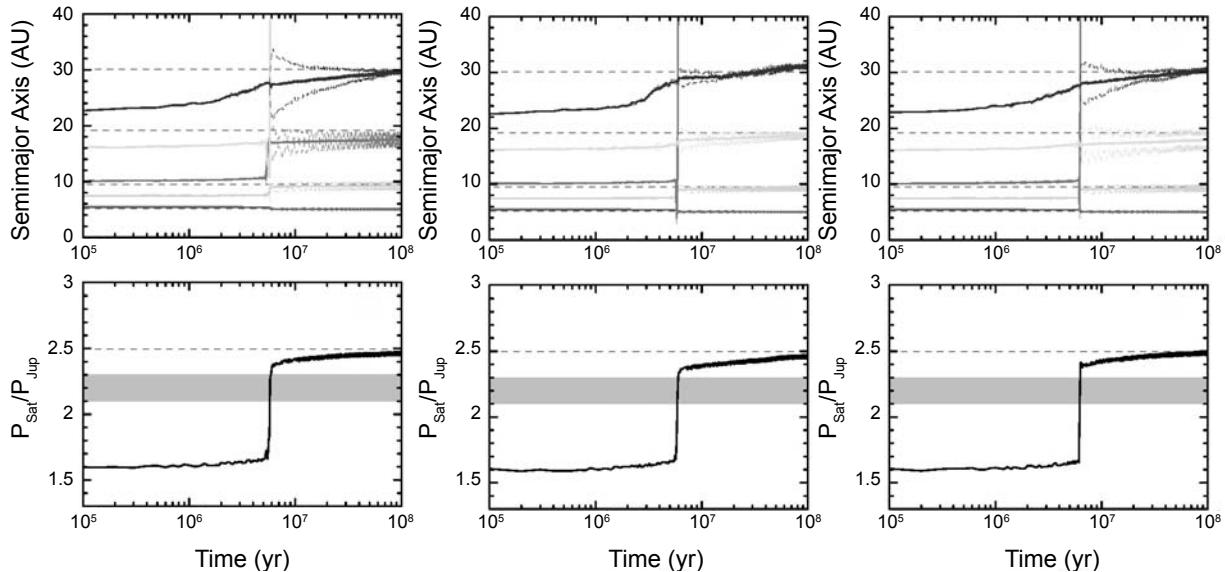

*Nesvorný et al.* (2013) have reinvestigated the possibility of capture of Jupiter Trojans in the framework of the jumping-Jupiter scenario. They did this using three simulations of evolution of the giant planets [all starting initially with five planets (see *Nesvorný and Morbidelli*, 2012)] satisfying all constraints, particularly the jump of the period ratio to a value larger than 2.3, with a residual migration not driving the period ratio beyond 2.5 (the 2:5 resonance). These planetary evolutions are shown in Fig. 6.

They found that Trojans can be captured during Jupiter's jump. In essence, the captured planetesimals are those that, by chance, are on a moderate eccentricity orbit just inward of Jupiter's location at the time of the jump. When Jupiter jumps inward, these planetesimals can then fortuitously find themselves in the tadpole region. This mechanism is illustrated in Fig. 7.

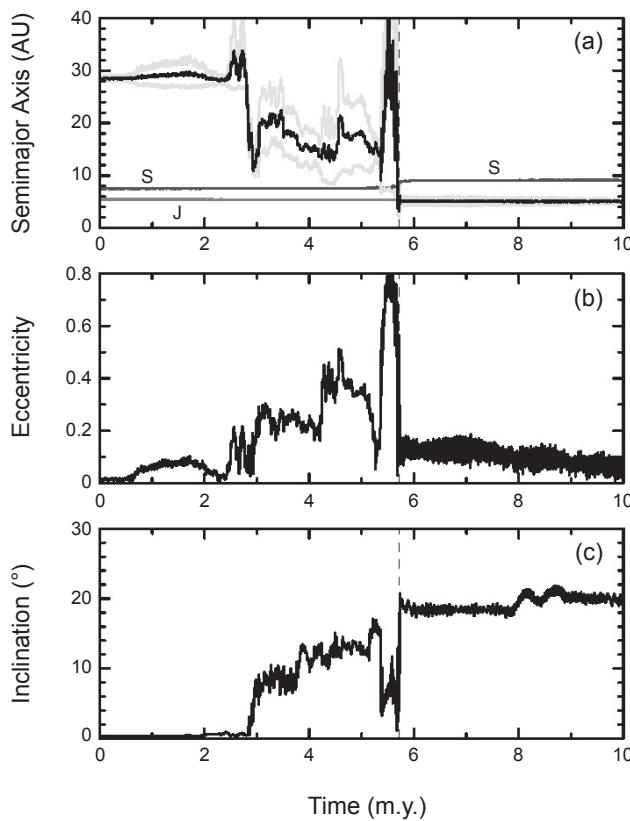

Most of the captured planetesimals turned out to be only temporarily stable, so *Nesvorný et al.* (2013) continued the simulations of the captured bodies over 4 G.y. and finally they analyzed the orbits of the Trojans surviving in the tadpole region until the end. The resulting orbital distribution turned out to be remarkably similar to that observed. This is illustrated in Fig. 8 through cumulative distributions. Only the inclination distribution seems inaccurate, the observed one being less excited than the synthetic one. However, the Trojans' observed distribution is biased toward low inclinations. To remove the bias, *Nesvorný et al.* also considered the Trojans with  $H < 12$ , which constitute a complete set (*Szabó et al.*, 2007). The match becomes excellent. This model reproduces the observed distribution even better than the original 2005 model.

In addition to the orbital distribution, there are two qualitative advantages of the new model over the previous one. First, this model has the potential to explain the  $\sim 30\%$  asymmetry between the  $L_4$  and  $L_5$  populations. In fact, unlike the previous model, which was strictly symmetric for the two tadpole regions, the new model can capture more or fewer bodies in one of the two clouds depending on the specific geometry of the planetary encounter that causes the jump in Jupiter's orbit. Imagine, for instance, that the rogue planet passes through one of the two tadpole regions coming out of its last encounter with Jupiter, and it is intuitive to understand that fewer bodies will remain stable there. Indeed, the three simulations presented in *Nesvorný et al.* (2013) produced asymmetries at the 30–80% level (not necessarily in favor of  $L_4$ ).

The second advantage is that in the new model, the capture of Trojans occurs with some time-lag relative to

**Fig. 6.** The evolution of the giant planets in the three simulations considered in *Nesvorný et al.* (2013) for the capture of Jupiter's Trojans. The top panels show the evolution of semimajor axis (solid), perihelion and aphelion distances (dashed) for Jupiter (bottom, dark gray), Saturn (second from bottom, light gray), Uranus (middle, dark, or light gray, depending on which remains), Neptune (top, dark gray), and the planet ultimately ejected from the system (middle, light or dark gray, depending on which is ejected). The lower panels show the evolution of the period ratio between Jupiter and Saturn. The gray band shows the forbidden region, corresponding to secular resonances in the asteroid belt or in the terrestrial planet region.

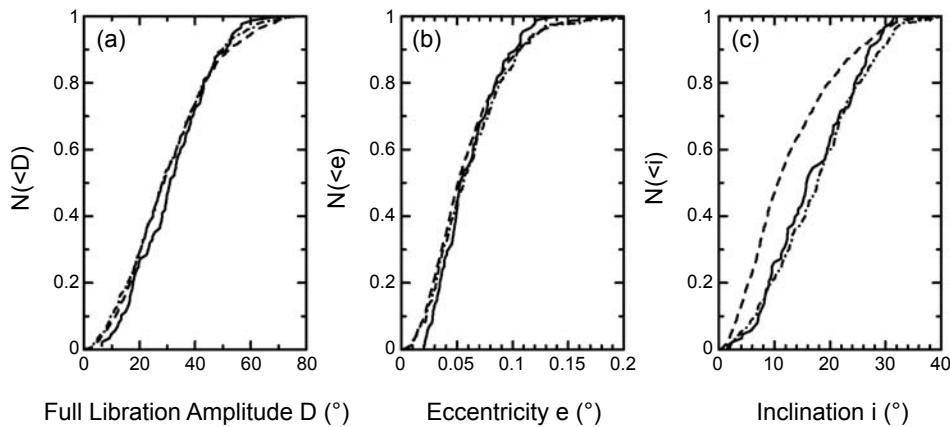

**Fig. 7.** An example of capture of a Trojan body. **(a)** Evolution of semimajor axis of the body in black and of its perihelion and aphelion distances (light gray), together with the semimajor axes of Jupiter (bottom gray curve marked “J”) and Saturn (dark gray curve marked “S”). Notice the perfect overlapping of the particle’s semimajor axis, perihelion, and aphelion and Jupiter’s semimajor axis at the end, proving the capture of a low-eccentricity Trojan. **(b)** Evolution of the eccentricity of the captured particle. **(c)** Evolution of the inclination of the captured particle. From Nesvorný et al. (2013).

the onset of the instability of the giant planets. The latter occurs when two planets fall out of resonance, whereas the capture of Trojans occurs during the last encounter of Jupiter with the scattered planet, which can only take place once the unstable phase is occurring. By contrast, in the original model the capture occurred at the 1:2 resonance crossing, which triggered the instability. The difference may be important for the capture of asteroids into Lagrange regions. If the capture of Trojans occurs at the beginning of the planet instability, the asteroid belt does not have the time to be partially destabilized and therefore asteroids cannot be captured in the Trojan region. However, this can occur in the new model. Thus, this opens the possibility that some Trojans, for instance, those consistent with the asteroidal C-types, which are a minority of the Trojan population, may come from the outer asteroid belt.

Nesvorný et al. (2013) found that the probability of an original transneptunian object to be captured over the age of the solar system as a Trojan is  $6\text{--}8 \times 10^{-7}$ . This implies  $3\text{--}4 \times 10^7$  planetesimals with  $H < 9$  ( $D > 80$  km for  $a = 7\%$  albedo) in the original transneptunian disk. With a Kuiper-belt-like size frequency distribution, this is consistent with the mass needed in the new version of the Nice model (Nesvorný and Morbidelli, 2012). This disk population is also consistent with the crater record on Iapetus (Rivera-Valentin et al., 2014), showing the overall consistency of the new Nice/jumping-Jupiter model.

Thus, the Nesvorný et al. (2013) model reinforces the idea that most Trojans are objects captured from the transneptunian disk. The same disk also gave origin to the hot Kuiper belt population and the scattered disk (Levison et al., 2008), whereas the cold Kuiper belt population might have been a separate population not significantly affected during the giant planet instability (Parker and Kavelaars, 2012; Batygin et al., 2011; Fraser et al., 2014). Because both the hot population and the Trojan population should not have suffered any significant collisional evolution at large sizes since the time

**Fig. 8.** The cumulative distribution of real (dashed) and captured Trojans (solid) in **(a)** libration amplitude, **(b)** eccentricity, and **(c)** inclination. In **(c)**, the dash-dotted curve shows the observed inclination distribution of Trojans with  $H < 12$ . Unlike the dashed distribution, the latter should be bias free. From Nesvorný et al. (2013).

of giant planet instability (Levison *et al.*, 2009), Morbidelli *et al.* (2009) predicted that size distributions of the Trojans and of the hot population should have been the same. At the time, this was a real prediction, because the size distribution of the hot population was known only for sizes much larger than the largest Trojan, and it looked much shallower. So, the prediction was that at sizes comparable to those of the Trojans (less than 200 km in diameter), the size distribution of the hot population would steepen up and look like that of the Trojans. This prediction has been recently supported by Fraser *et al.* (2014) and confirmed by Adams *et al.* (2014). We refer the reader to section 2.1 for a more detailed discussion of the Trojans' size distribution.

### 3.2. Stability Properties

The dynamical stability of Trojans is affected by different types of resonances that influence their survival in the present solar system and may have even played a significant role during the potential migration of planets in early solar system evolution. These resonances involve the fundamental frequencies of the Trojan motion, which can be related by a ratio of two small integers to those of the planetary system. Approximate analytical expressions have been derived for the frequencies of the Trojan motion within the simplified elliptical restricted three-body problem (ERTBP). The libration motion around either  $L_4$  or  $L_5$  is characterized by a long-period frequency given by  $v_l = \frac{1}{2} [1 - \sqrt{1 - 27\mu(1 - \mu)}]^{\frac{1}{2}} n_p = \sqrt{27/4\mu} n_p$  and a short-period frequency  $v_s = \frac{1}{2} [1 + \sqrt{1 - 27\mu(1 - \mu)}]^{\frac{1}{2}} n_p \approx \sqrt{1 - 27/4\mu} n_p$  (Erdi *et al.*, 2007, 2009), where  $\mu = \frac{m_p}{m_s + m_p}$  is the mass ratio and  $n_p$  is the planet mean motion. As an example, for Jupiter's Trojans  $T_l \approx 147.8$  yr and  $T_s \approx 11.9$  yr. The secular frequency of the perihelion longitude precession  $g^{\text{ERTBP}}$  is analytically given, at the second order in the libration amplitude  $d$ , as  $g^{\text{ERTBP}} = (27/8 + (129/2^6)d^2)\mu n_p$  (Erdi, 1988), while the precession frequency of the nodes is computed as  $s^{\text{ERTBP}} = 3/4d^2\mu n_p$ . In the more general problem of the Trojan motion in the full planetary system, the values of the frequencies  $v_{ls}$ ,  $g$ , and  $s$  depend on the orbital elements of the Trojan orbit and of the planets. In particular, the secular frequencies  $g$  and  $s$  include the contribution of the planets, becoming  $g = g^{\text{ERTBP}} + \sum_{j \neq p} g_j$  and  $s = s^{\text{ERTBP}} + \sum_{j \neq p} s_j$ , where  $g_j$  and  $s_j$  are the eigenfrequencies of the classical Lagrange-Laplace solution of the secular problem. Precise semi-empirical expressions have been derived for  $g$  and  $s$  as a function of the Trojan orbital parameters, fitting the outcomes of direct numerical integrations of Trojan trajectories and of all the planets of the solar system (Marzari *et al.*, 2002b, 2003a,b; Scholl *et al.*, 2005b). An integer, or near integer, relation between a frequency of the Trojan motion and one or more frequencies of the planets leads to a resonant interaction that can destabilize the tadpole motion. The possible different types of resonances have been grouped (Robutel and Gabern, 2006; Erdi *et al.*, 2007; Robutel and Bodossian, 2009) into four families:

*Family I:* Commensurabilities between the orbital frequency of the planet  $n_p$  and the libration frequencies of the Trojan

motion  $v_l$  and  $v_s$  enriched by additional secular frequencies of the planetary system. They are defined by the expression  $iv_{ls} + jn_p = -(kg + ls + \sum_n k_n g_n + \sum_n l_n s_n)$  where  $i, j, k, l, k_n, l_n$  are integers satisfying the relation  $j + k + l + \sum_n k_n + \sum_n l_n = 0$  imposed by the d'Alembert rules.

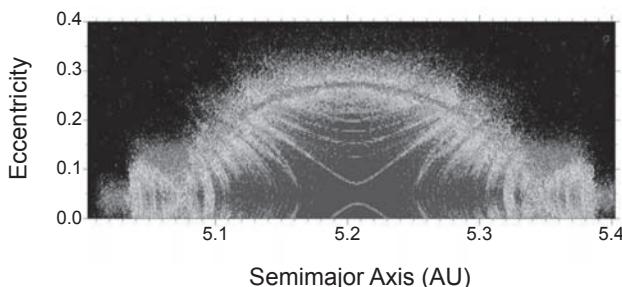

*Family II:* Commensurabilities between  $v_l$ ,  $v_s$  and the libration frequency  $\psi_{p,q}$  of the critical angle  $\theta = p\lambda_m - q\lambda_n + \dots$  of a  $p:q$  mean-motion resonance between two planets,  $n$  and  $m$ , defined as  $\psi_{p,q} = pn - qn_m$ . In this case the relation among the frequencies becomes  $iv_{ls} - j\psi_{p,q} = -(kg + ls + \sum_n k_n g_n + \sum_n l_n s_n)$ , with  $j(q-p) + k + l + \sum_n k_n + \sum_n l_n = 0$ . In the solar system, an important almost-resonance between Jupiter and Saturn is the so-called "great inequality 5:2."

*Family III:* Secular resonances between  $g$ ,  $s$ , and the eigenfrequencies of the solar system, defined by the condition  $kg + ls = -(\sum_n k_n g_n + \sum_n l_n s_n)$  and  $k + l + \sum_n k_n + \sum_n l_n = 0$ .

*Family IV:* Commensurabilities between the libration frequency of the planetary resonance  $p:q$  and the secular frequency of the Trojan motion  $g$  defined as  $ig + j\psi_{p,q} = -(ls + \sum_n k_n g_n + \sum_n l_n s_n)$  with  $i + j(q-p) + l + \sum_n k_n + \sum_n l_n = 0$ .

Present Jupiter Trojans are perturbed by all these families of resonances. Overlap of these resonances generates extended chaotic regions, which limits the extent of the phase space populated by stable orbits. In Fig. 9, a diffusion map (Robutel and Gabern, 2006) shows the stability properties of fictitious Trojan orbits of Jupiter as a function of their initial semimajor axis and eccentricity. The color coding measures the diffusion rate in the phase space computed by means of frequency map analysis (FMA) (Laskar, 1990), a powerful numerical tool for the detection of chaos from numerical integration. The color scale ranges from blue, corresponding to stable regions, to red for highly chaotic orbits, while in black are displayed those test bodies that are ejected on a short timescale. The red arch limiting the stable region from above is due to the family III nodal secular resonance  $s - s_6$ , as clearly shown in the power spectrum of a Trojan orbit lying close to the arch (Fig. 10) (Marzari *et al.*, 2003a). For higher inclinations of the test Trojan orbits, additional secular resonances such as  $s - 2s_6 + s_7$ ,  $3s - 4s_6 + s_7$ ,  $2s - 3s_5 + g_6$ ,  $3s - s_6 - 2g_5$ , and others come into play, reducing the size of the stable region. Superposition of family I resonances is responsible for the large chaotic zone extending beyond 5.35 AU, limiting the libration amplitude of Trojan orbits. The  $i = 13$  and  $i = 14$  family I resonances generate the two main v-shaped unstable yellow structures within 5.25 AU. Family II resonances, whose influence was also argued by Nesvorný and Dones (2002), are responsible for the finger-like structures extending from the outer layer of the stable region toward small eccentricities in between 5.25 and 5.35 AU. Finally, the thin yellow structures in the small libration region for  $a \leq 5.27$  are due to family IV resonances. When the initial inclination of the orbits is varied, all resonances change location since the main frequencies of the Trojan motion ( $v$ ,  $g$ , and  $s$ ) depend on inclination, but they are still responsible for the main features of the stable regions.

The resonant structure described above evolves during planet migration and can explain the chaotic capture of

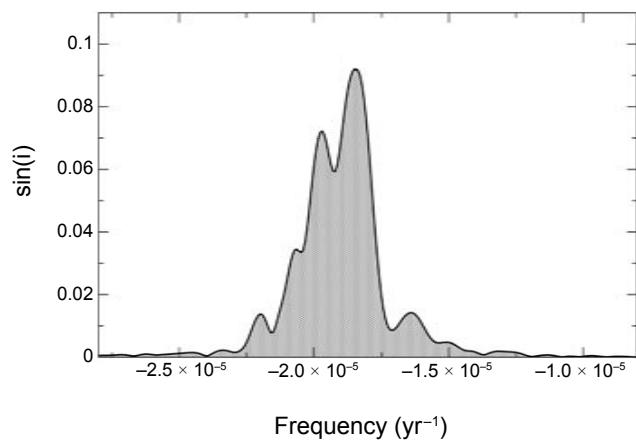

**Fig. 9.** See Plate 2 for color version. Diffusion map around  $L_4$  for an N-body model including the outer four planets. Blue indicates stable orbits while red corresponds to highly chaotic motion. The black zone marks trajectories that lead to ejection from  $L_4$  on a short timescale. From Robutel and Gabern (2006).

primordial Trojans in the original version of the Nice model (Morbidelli *et al.*, 2005). In a simplified four-body model with Jupiter and Saturn migrating through the 1:2 mean-motion resonance, Marzari and Scholl (2007) showed that a secular resonance (family III) between  $g$  and one of the two eigenfrequencies of the planetary system sweeps the Trojan region, leading to a chaotic evolution. This instability is reinforced by the sweeping of family II and family IV resonances (Morbidelli *et al.*, 2005; Robutel and Bodossian, 2009), with family IV resonances being more effective close to the resonance. Family II resonances with  $\psi_{2,1}$ ,  $\psi_{3,1}$ ,  $\psi_{4,1}$ , and  $\psi_{5,2}$  contribute to instability with different strengths during the migration of Jupiter and Saturn through the 1:2 and toward the 2:5 mean-motion resonances.

According to the numerical explorations of Nesvorný and Dones (2002) and Marzari *et al.* (2002b) with chaos detection tools, Saturn Trojans are mostly unstable and any primordial population should have been severely depleted at present. The fast diffusion in the phase space is due to family III secular resonances like the  $2g_6 - g_5$  and family II resonances with  $\psi_{5,2} = 5n_J - 2n_s$ . The same fate is shared by Uranus Trojans, which are affected by secular resonances with  $s_7$ ,  $g_7$ , and  $g_5$  (Marzari *et al.*, 2003b) and by family II resonances with  $\psi_{2,1} = 2n_U - 1n_N$  (Nesvorný and Dones, 2002). The situation is different for Neptune Trojans, which, in spite of some perturbations from the  $s_8$ , have large regions of stability with low diffusion speed (Marzari *et al.*, 2003b; Nesvorný and Dones, 2002).

The long-term stability of Venus, Earth, and Mars Trojans have been investigated mostly with Laskar's FMA (Scholl *et al.*, 2005a,b; Dvorak *et al.*, 2012; Marzari and Scholl, 2013). These studies show that Trojans of the terrestrial planets are predominantly perturbed by family III secular resonances with the eigenfrequencies  $g_2$ ,  $g_3$ ,  $g_4$ ,  $g_5$  (V, E, M) and  $s_3$ ,  $s_4$  (M). Due to the influence of these resonances, Venus Trojans are unstable with a half-life of about  $6 \times 10^8$  yr, which is further reduced when the Yarkovsky effect is included in the numerical integration of fictitious populations of tadpole orbits. Earth Trojans have, by contrast, large stability regions up to  $40^\circ$  in inclination, with the peculiarity of favoring

**Fig. 10.** Power spectrum of the  $p, q$  nonsingular variables for a Trojan orbit close to the  $s_6$  secular resonance. The forced component due to  $s_6$  is comparable to the proper frequency  $s$ . From Marzari *et al.* (2003a).

middle- to large-libration amplitude orbits for long-term survival, contrary to what is observed for Trojans of the outer planets. The dynamical stability of Mars Trojans is granted only for inclinations between  $15^\circ$  and  $30^\circ$  and, even in this case, the Yarkovsky force has some perturbing effect when very small bodies (in the meter size range) are considered.

### 3.3. Collisional Evolution

The collisional evolution of Trojan asteroids, initially explored by Marzari *et al.* (1997), has been recently revisited by De Elia and Brunini (2007, 2010). The newer work employs a refined collisional model that includes an updated treatment of the fragmentation physics, the escape of bodies suffering impacts that eject them out of the Trojan swarm, and the effects of Poynting-Robertson drag on small particles in the micrometer size range.

They find that the size distribution for diameters larger than about 60 km has a power-law slope that is substantially unaltered after 4.5 G.y. of evolution. The measured slope would therefore be primordial, reflecting the size distribution of the planetesimals that were trapped as Trojans during the early evolution of the solar system. This result is agreement with the suggestion of Morbidelli *et al.* (2009) that Trojans and KBOs share a common origin not only on dynamical grounds, but also because they have similar slopes to their size distributions, indicating a common origin.

Below 60 km, collisions dominate the evolution, and the slope of the size distribution relaxes toward the Dohnanyi's equilibrium value. The primordial population inferred by the models of De Elia and Brunini (2007, 2010) would include about  $1 \times 10^8$  bodies larger than 1 km, of which  $1 \times 10^6$  would survive at present. The erosion of the Trojan population leads to the formation of families, injection of bodies into Centaur and Jupiter-family comet (JFC) trajectories (Marzari *et al.*, 1995; Levison *et al.*, 1997), and the formation of a dusty ring around the orbit of Jupiter. According

to *De Elia and Brunini* (2007), the flux of Trojans into the current population of Centaurs and JFCs is negligible, with about 50 objects larger than 1 km in diameter per million years from the L<sub>4</sub> swarm. The flux from L<sub>5</sub> is expected to be even lower due to the reduced number of Trojans populating the L<sub>5</sub> swarm. This estimate is about 2 orders of magnitude smaller than that given by *Marzari et al.* (1997), and the difference can mostly be ascribed to the different scaling laws adopted in the collisional models.

A few family-forming events are expected for bodies larger than 50 km, which would produce the largest families predicted by *Beaugé and Roig* (2001) and observed by *Dotto et al.* (2006) and *Fornasier et al.* (2007). The robustness of the families identified by *Beaugé and Roig* (2001) have been recently questioned by *Broz and Rozehnal* (2011) on the grounds that the newly discovered Trojans dilute the clusters, interpreted as families, into the background. They claim that only the large family Eurybates is a real outcome of a breakup event, and the Ennomos group may be real. Family membership is based on proper elements, and *Di Sisto et al.* (2014) found that computation of proper elements for nonnumbered Trojans may not be reliable, even if observations are available over multiple oppositions. Caution is therefore advised in using nonnumbered asteroids in the family identification process.

*De Elia and Brunini* (2010) also explored the production of dust by collisions within the L<sub>4</sub> swarm and its lifetime against the Poynting-Robertson drag erosion. They estimate that the present thermal emission in the L<sub>4</sub> jovian swarm could be as high as  $\sim 3.2 \times 10^{-8}$ – $3.4 \times 10^{-8}$  L<sub>⊙</sub>, comparable to the luminosity of the inner solar system dust produced by asteroid collisions and cometary activity. This interesting prediction suggests that extrasolar giant planets could also be detected by the emission of a dusty ring produced by collisions of putative Trojans.

#### 4. DISCUSSION AND FUTURE DIRECTIONS

The Trojan asteroids remain one of the most fascinating and enigmatic group of small bodies in the solar system. Perhaps the best established property of the Trojans is their dynamical stability. Although several mechanisms are capable of capturing Trojans, the “jumping-Jupiter” version of the Nice model does the best job of matching the orbital distributions and, at the same time, fits the total population, size distribution, and L<sub>4</sub>/L<sub>5</sub> population asymmetry in a way that is consistent with the overall dynamical evolution of the outer solar system. As a result, it has become widely accepted that the majority of Trojan asteroids are likely refugees from the primordial Kuiper belt, and therefore have genetic affinities to the scattered (or scattering) and hot classical KBOs.

Studies of the physical properties of Trojans, however, do not paint such a clear picture. The low albedos and featureless spectra leave the interpretation of surface compositions open. Direct spectral comparisons with KBOs show significant differences between the two populations. Kuiper belt objects have a much wider range of albedos than

Trojans, extending in particular to higher albedos. Whereas the Trojans and small KBOs (and Centaurs) both exhibit color bimodalities, the color groups do not overlap. The “ultra-red” (RR) (*Barucci et al.*, 2005) spectral group of KBOs are completely absent from the Trojan swarms. The “red” Trojan group overlaps with the moderately red (BR) spectral group of KBOs and Centaurs, and the “less-red” Trojan group does not have a clear analog among KBOs, although some KBOs do overlap this group spectrally.

The possibility that surface compositions may have been modified by the changing irradiation and thermal environments as KBOs migrated inward is intriguing. The presence of ultra-red slopes, strong, broad absorptions at 3.6 and 4.5 μm, and a feature near 2.35 μm attributed to methanol suggest the presence of complex organics on at least some KBOs and Centaurs (e.g., *Cruikshank et al.*, 1998; *Barucci et al.*, 2006; *Emery et al.*, 2007; *Dalle Ore et al.*, 2013, 2015). Irradiation of these materials could lead to a decrease in spectral slope (e.g., *Moroz et al.*, 2004). Nevertheless, the absence of any organic absorptions, combined with clear signatures of silicate dust on Trojans, challenges any simple irradiation hypothesis (e.g., *Jewitt*, 2002; *Melita et al.*, 2009). Periods of cometary activity are likely involved (*Melita and Licandro*, 2012), especially if, as *Morbidelli et al.* (2005) discuss, the KBOs that migrated into the Trojan swarms spent significant time in orbits that brought them close to the Sun, but no satisfactory surface evolution scenario has yet been put forth that could explain the two Trojan spectral groups from a single parent population.

*Guilbert-Lepoutre* (2014) demonstrated that H<sub>2</sub>O ice can be stable on Trojans for the lifetime of the solar system if covered by ~10 m of dust at the equator (~10 cm near the poles). We might therefore expect to see some evidence for exposure by impact, particularly for smaller Trojans. Nevertheless, there is no indication that albedos increase even for the smallest Trojans currently observable. On the other hand, the very weak 3-μm absorption reported by *Brown* (2014) may be the first hint of a subsurface ice reservoir. Whether Trojans formed near 5 AU or in the Kuiper belt, they should have accreted abundant H<sub>2</sub>O ice, so the absence of any spectral signature of ice among the Trojans is curious.

Very little is known about the interior structure of Trojan asteroids. The only direct constraint comes from the densities that have been derived for a few Trojans. The low density of (617) Patroclus suggests a porous, ice-rich interior. Conflicting reports regarding (624) Hektor’s density make it difficult to assess the potential interior structure. Potential geochemical evolution of the interiors is also an open question. The apparently comet-like silicate dust reported by *Emery et al.* (2006) may suggest very little parent-body processing. On the other hand, the model of a salt-rich surface described by *Yang et al.* (2013) would require a significant amount of thermal processing of original primitive ices and silicates. Without detailed models of the thermal and chemical evolution of Trojan asteroids, it is difficult to interpret present surface compositions in terms of possible interior structures and evolutionary scenarios.

The two primary questions about the Trojans remain (1) where did they form, and (2) what are they made of? As described above, the past decade has seen advances in dynamical simulations and observations of physical properties that have drawn us significantly closer to the answers to these questions, but several particular areas are ripe for future investigations:

- What is the size distribution at small sizes?
  - How different is it for the two spectral groups?
  - What is the significance of the difference between L<sub>4</sub> and L<sub>5</sub> at small sizes?
- Why is the one robust family (Eurybates) spectrally anomalous?
- Does the capture mechanism preferentially select any original population?
  - What fraction, if any, might be from the Jupiter region (or closer)?
- Is the dust environment as predicted?
- How is Kuiper belt material (simple ices, organics, cometary silicates) modified as a body migrates inward to the thermal and irradiation environment of the Trojans?
- What is the ice fraction in the interiors of Trojans?
  - How deep is any extant ice buried?
  - Are any ices aside from H<sub>2</sub>O present?
- What is the nature of the low-albedo material on Trojan surfaces?
  - Are organic materials present on the surfaces? If so, what are its structural and chemical forms?
- Are smaller Trojans different in spectra and/or albedo from their larger siblings?
- Are Trojan silicates (and ices, if present) more similar to cometary or asteroidal material?
- Geologically, do Trojans resemble asteroids, comets, or irregular satellites (e.g., Pheobe)?
- Is there any outgassing or other source of extended emission on Trojans?
- Is the surface structure extremely porous (“fluffy”), or are the fine-grained silicates embedded in some matrix, such as a salt?
- What are the ranges of possible thermal and chemical histories for the interiors of Trojans, and how can current or future observations constrain those possible histories?

Fortunately, exciting prospects are on the horizon for learning more about Trojan asteroids and answering some of these important questions. In the nearest term, recent work by, e.g., Marsset et al. (2014), Brown (2014), and Wong et al. (2014) demonstrate the possibility of pushing spectral studies to smaller sizes with existing telescopes and instrumentation. Such observations will continue to test the hypothesis that the interiors of Trojans are distinct from their surfaces and, if the Brown (2014) and Wong et al. (2014) studies are indicative, may well surprise. Rotation properties of Trojans have long been uncertain, and the new works revealing such flat period distributions are important for understanding nongravitational torques at large distances

from the Sun. Additional information on amplitudes and spin-pole orientations will provide important constraints on these torques as well as the collisional environment. Extending spectral studies to the UV, which is currently possible with the Hubble Space Telescope, would also provide new insight into the silicates (and any ices) on the surfaces.

Through a series of workshops focused on “*In Situ* Science and Instrumentation for Primitive Bodies” that included scientists of diverse backgrounds (observers, laboratory cosmochemists, dynamical modelers), supported by the Keck Institute for Space Studies, Blacksberg et al. (2013) concluded that devising advances in instrumentation for surface science on primitive bodies, particularly the Trojan asteroids, is premature because of the fundamental uncertainties that remain in what chemical, mineralogical, and isotopic compositions to expect on the surfaces. They instead recommended a program of laboratory study to investigate the potential alteration pathways that KBO surface materials might go through on their journey to the Trojan swarms (or closer). Such laboratory work has the potential to enable direct tests of potential dynamical pathways by linking them to expected compositional changes and would thereby lead to significant advances in understanding Trojan surfaces even from the current observational dataset.

Several planned and potential groundbased and space-based survey programs are expected to lead to significant improvements in discovery and characterization of Trojans. The European Space Agency’s (ESA) Gaia mission, which started its science observations in mid-2014, will provide spectral characterization at visible wavelengths of asteroids down to V ~ 20. The Large Synoptic Survey Telescope (LSST) and the Panoramic Survey Telescope and Rapid Response System (Pan-STARRS), when fully operational, are anticipated to discover and record colors of hundreds of thousands of Trojan asteroids. Significant interest has been expressed recently in an infrared space telescope for asteroid discovery, for hazard mitigation, to support human exploration, and for science. The benefit of infrared discovery, particularly with at least two infrared pass-bands, as with the NEOWISE survey (Mainzer et al., 2011), is that the discovery data directly provide sizes. Such a mission would likely discover, and measure sizes of, large number of Trojans, and it is also likely that temporal coverage would enable estimates of thermophysical properties of the surfaces.

In terms of surface characterization, the next leap forward in terms of Trojan asteroids will probably come from the James Webb Space Telescope (JWST). With spectral coverage from 1 to 28 μm, JWST is ideally suited for searches for ices and organics, characterization of silicates, and determination of thermophysical properties. The sensitivities of JWST at wavelengths longward of 2.5 μm will significantly exceed those of current groundbased telescopes, and will enable observations of much smaller Trojans than is now possible.

Perhaps the most exciting future prospect for advances in our understanding of Trojans is the possibility of spacecraft missions to observe this population close-up. Because Trojans are, in many ways, key to understanding the evolution

of the solar system, there has been significant international interest in targeting the Trojan asteroids with an upcoming mission. The Trojans have been called out in each of the two last decadal surveys for NASA planetary science, making the short list for desired missions in the New Frontiers class. Lamy *et al.* (2012) make the case for a mission to the Trojans in the context of ESA's program of solar system exploration. Diniega *et al.* (2013) report the results of a Jet Propulsion Laboratory (JPL) Planetary Science Summer School design exercise for a mission to the Trojans. The Japan Aerospace Exploration Agency (JAXA) has been developing solar sail technology that may be well suited to provide propulsion for a deep space mission to the Trojan asteroids (e.g., Yano, 2013).

The details of a spacecraft mission to the Trojans could take many forms. A mission that includes flybys of several objects would provide important information on diversity among the Trojan swarms. An orbiter mission could return detailed geologic and spectral maps, as well as information on the interior structure and chemical composition of the body. A coordinated orbiter and lander could provide even more detailed "ground truth" for the orbital investigation. The key is to get close enough to one, or better yet several, Trojans to reveal them as geologic bodies rather than the point sources we know them as from Earth.

There is growing momentum behind determining the nature of this large, enigmatic population of primitive bodies, and it would be reasonable to expect, by whatever avenue the information may come, a revolution in the understanding of Trojan asteroids by the time *Asteroids V* goes to press.

---

Some asteroids eject dust, producing transient, comet-like comae and tails; these are the active asteroids. The causes of activity in this newly identified population are many and varied. They include impact ejection and disruption, rotational instabilities, electrostatic repulsion, radiation pressure sweeping, dehydration stresses, and thermal fracture, in addition to the sublimation of asteroidal ice. These processes were either unsuspected or thought to lie beyond the realm of observation before the discovery of asteroid activity. Scientific interest in the active asteroids lies in their promise to open new avenues into the direct study of asteroid destruction, the production of interplanetary debris, the abundance of asteroid ice, and the origin of terrestrial planet volatiles.

## 1. INTRODUCTION

Small solar system bodies are conventionally labeled as either asteroids or comets, based on three distinct properties: (1) Observationally, small bodies with unbound atmospheres (“comae”) are known as comets, while objects lacking such atmospheres are called asteroids. (2) Dynamically, comets and asteroids are broadly distinguished by the use of a dynamical parameter, most commonly the Tisserand parameter measured with respect to Jupiter (*Kresak*, 1982; *Kosai*, 1992). It is defined by

$$T_J = \frac{a_J}{a} + 2 \left[ \left(1 - e^2\right) \frac{a}{a_J} \right]^{1/2} \cos(i) \quad (1)$$

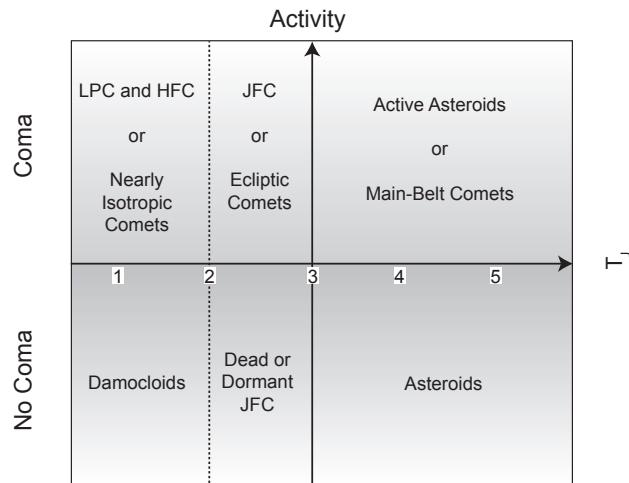

where  $a$ ,  $e$ , and  $i$  are the semimajor axis, eccentricity, and inclination of the orbit (relative to Jupiter’s orbit), while  $a_J = 5.2$  AU is the semimajor axis of the orbit of Jupiter. This parameter, which is conserved in the circular, restricted three-body problem, provides a measure of the close-approach speed to Jupiter. Jupiter itself has  $T_J = 3$ . Main-belt asteroids have  $a < a_J$  and  $T_J > 3$ , while dynamical comets (from the Kuiper belt and Oort cloud) have  $T_J < 3$ . (3) Compositionally, comets are ice-rich small bodies formed beyond the snow line in the protoplanetary disk, while the asteroids are ice-free and formed inside it.

While there is often a reassuring concordance among these classification systems, all three are potentially fallible. For instance, the ability to detect a low surface brightness coma or tail is, in part, a function of instrumental parameters and observing conditions. The utility of equation (1)

is limited for objects with  $T_J$  very close to 3 because the underlying criterion is based on an idealized representation of the solar system (e.g., Jupiter’s orbit is not a circle, the gravity of other planets is not negligible, and nongravitational forces due to outgassing and photon momentum can be important). The least useful metric is the composition because, except in special cases, we have neither any practical way to measure the composition of a small body nor can we determine its formation location.

Taken together, the observational and dynamical classifications suggest a simple two-parameter schematic that usefully describes the solar system’s small body populations (Fig. 1). The four quadrants in Fig. 1 conveniently separate comets (upper left) from asteroids (lower right) and distinguish likely defunct comets (lower left) in which there is no activity, presumably due to the past depletion of near-surface volatiles (*Hartmann et al.*, 1987), from the newly recognized active asteroid class (upper right).

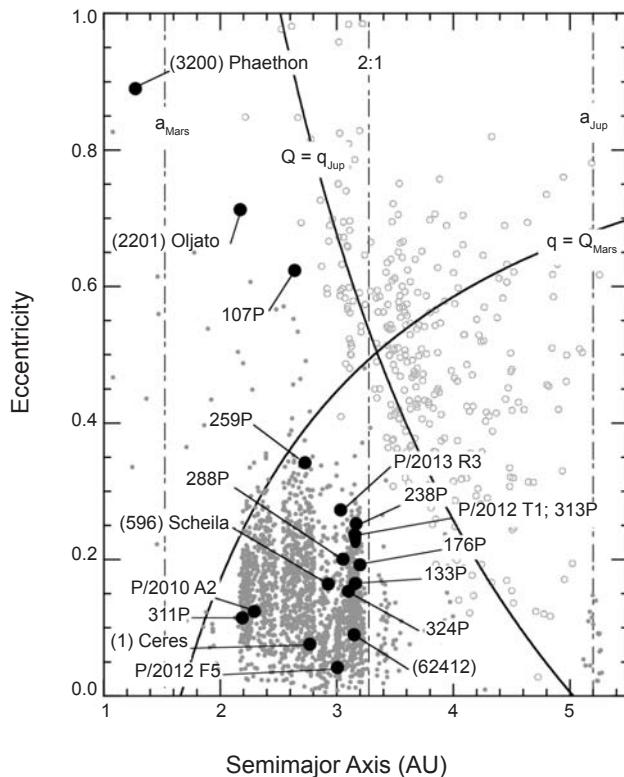

The working definition employed here is that active asteroids are small bodies that (1) have semimajor axis  $a < a_J$ , (2) have  $T_J > 3.08$ , and (3) show evidence for mass loss, e.g., in the form of a resolved coma or tail. In defining the critical Tisserand parameter separating asteroids from comets as  $T_J = 3.08$ , rather than 3.0, we avoid many ambiguous cases caused by deviations of the real solar system from the circular, restricted three-body approximation. This definition also excludes Encke-type comets (2P/Encke has  $T_J = 3.02$ ), and the quasi-Hilda comets ( $T_J \sim 2.9$ –3.04). The orbital distribution of the currently known active asteroids is shown in Fig. 2. Three objects occupy planet-crossing orbits while the remaining 15 orbit in the main belt.

**Fig. 1.** See Plate 3 for color version. Empirical classification of small bodies based on the Tisserand parameter,  $T_J$  (x-axis), and the presence or absence of coma (y-axis). JFC, LPC, and HFC are the Jupiter-family, long-period, and Halley-family comet subtypes, distinguished by their dynamics. From Jewitt (2012).

The active asteroids are remarkable for being an entirely new population located in one of the closest and most intensively studied regions of the solar system. Their activity is driven by a surprisingly diverse set of physical processes. Reported examples include hypervelocity impact [e.g., (596) Scheila], rotational instability probably driven by Yarkovsky-O’Keefe-Radzievskii-Paddack (YORP) torques (e.g., 311P, P/2013 R3), thermal disintegration driven by intense solar heating of minerals [(3200) Phaethon] and the sublimation of ice [(1) Ceres, 133P, 238P, 313P, and 324P are the strongest examples]. Impact and rotational disruptions are primary sources of meteorites and larger planet impactors. Observations promise to improve our understanding of the physics, and of the rates, of both asteroid destruction processes and meteoroid production. Analogous disruptions occurring around other stars are likely responsible for the creation of debris disks (e.g., *Shannon and Wu*, 2011). A common dynamical end-fate of planet-crossing bodies is to strike the Sun; a better understanding of the role of thermal disintegration will be important both in the solar system and in the context of photospheric impactors in polluted white dwarf systems (*Jura and Xu*, 2013). Finally, the survival of primordial ice in the asteroids may offer the opportunity to sample volatiles from a region of the protoplanetary disk different from that in which the Kuiper belt and Oort cloud comets formed. The outer asteroid belt is also a likely source region for the volatile inventory of Earth (*Morbidelli et al.*, 2000; *O’Brien and Greenberg*, 2005), giving new relevance to the origin of the oceans.

The active asteroids were called “main-belt comets” by *Hsieh and Jewitt* (2006), while *Hsieh et al.* (2012a) employed the term “disrupted asteroids” to refer to objects that exhibit comet-like activity believed to be non-sublimation-

**Fig. 2.** See Plate 4 for color version. Distribution of the active asteroids in the semimajor axis vs. orbital eccentricity plane. Dynamical asteroids are shown as filled gray circles, comets as empty circles, and the active asteroids as black circles, each labeled with the object name (cf. Table 1). Objects plotted above the diagonal arcs cross either the orbit of Mars or Jupiter.

driven. We use the more general term “active asteroids” both because some of the known examples are not in the main belt (cf. Fig. 2), and because this nomenclature implies no supposition about the cause of the activity.

The active asteroids were reviewed by *Bertini* (2011) and, in more detail, by *Jewitt* (2012). This chapter updates the latter paper with many new observations and examples of asteroid activity and adopts a tutorial style in the interests of clarity.

## 2. CURRENTLY KNOWN ACTIVE ASTEROIDS

We list the active asteroids in the order of decreasing Tisserand parameter in Table 1 and discuss them briefly here.

### 2.1. (3200) Phaethon, $T_J = 4.508$

Phaethon is a B-type asteroid with a 0.14-AU perihelion distance, a dynamical lifetime to scattering by the terrestrial planets  $\sim 100$  m.y., and a source in the main asteroid belt that may be related to (2) Pallas (*de Leon et al.*, 2010). This 5-km-diameter body is the source of the Geminid meteor stream (e.g., *Williams and Wu*, 1993) and is dynamically related to kilometer-sized asteroids 2005 UD (*Ohtsuka et al.*,

2006; Jewitt and Hsieh, 2006; Kinoshita et al., 2007) and 1999 YC (Kasuga and Jewitt, 2008). The dispersion age of the Geminid stream is  $t \sim 10^3$  yr (Ohtsuka et al., 2006), meaning that Phaethon is active on this or a shorter timescale. The timescale for the separation of 2005 UD and 1999 YC is not known but presumably is much longer. No gas has been reported in optical spectra (Chamberlin et al., 1996), but near-Sun brightening of Phaethon by a factor of 2 was detected in Solar Terrestrial Relations Observatory (STEREO) spacecraft data in 2009 (Jewitt and Li, 2010) and 2012 (Li and Jewitt, 2013), while the ejected dust has also been resolved (Jewitt et al., 2013a) (cf. Fig. 3). However, the sudden appearance and position angle of the Phaethon dust tail indicate that the ejected particles are small, with an effective radius  $\sim 1\text{ }\mu\text{m}$  and a combined mass  $\sim 3 \times 10^5\text{ kg}$  (Jewitt et al., 2013a). This is tiny compared to the  $M_s \sim 10^{12}\text{--}10^{13}\text{ kg}$  Geminid stream mass (Hughes and McBride, 1989; Jenniskens, 1994) and suggests that the Geminids are produced by a different process. In any case, 1- $\mu\text{m}$  particles are quickly accelerated by solar radiation pressure to faster than the solar system escape speed, and cannot contribute to the Geminid stream. Larger particles evidently contribute too little to the optical scattering cross-section to be discerned in STEREO near-Sun observations taken against the bright coronal background. However, particles with sizes  $>10\text{ }\mu\text{m}$  were recently reported in thermal emission at  $25\text{ }\mu\text{m}$  (Arendt, 2014), while kilogram-mass Geminids have been recorded striking the nightside of the Moon (Yanagisawa et al., 2008). Some such bodies might survive passage through Earth's atmosphere (Madiedo et al., 2013) and could already be present, but unrecognized, in terrestrial meteorite collections.

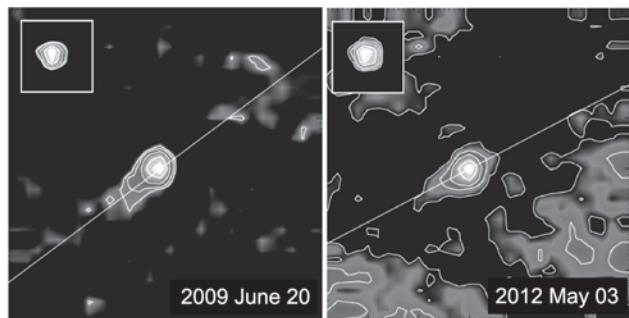

The Geminid stream mass and dynamical age together could imply ejection of debris from Phaethon, if in steady-state, at rates  $30 \leq M_s/t \leq 300\text{ kg s}^{-1}$ . More likely, mass loss from Phaethon is highly variable, with dramatic bursts interspersed with long periods of quiescence. Continued observations of Phaethon, especially at long wavelengths sensitive to large particles, are needed.

## 2.2. 311P/PanSTARRS (P/2013 P5), $T_J = 3.662$

311P is an inner-belt asteroid (Table 1) that ejected dust episodically over at least nine months in 2013, creating a remarkable multi-tail appearance (Jewitt et al., 2013c, 2014c; Hainaut et al., 2014; Moreno et al., 2014) (cf. Fig. 4). Interpreted as synchrones (the sky-plane projected positions of dust particles of different sizes released simultaneously from the nucleus), each tail has a position angle linked to the ejection date. The intervals between ejections appear random.

The episodic mass loss is unlike that seen in any previously observed comet. This fact alone argues against ice sublimation as the driving agent. An additional consideration is that the orbit of 311P lies near the inner edge of the asteroid belt, in the vicinity of the Flora family. The Floras have been associated with the LL chondrites (Vernazza et al., 2008), which themselves reflect metamorphism to temperatures  $\sim 800^\circ\text{C}$  to  $960^\circ\text{C}$  (Keil, 2000). It is improbable that water ice could survive in such a body. Impact likewise offers an untenable explanation for activity that occurs episodically over many months.

The color of 311P indicates an S-type classification (Jewitt et al., 2013c; Hainaut et al., 2014), consistent with its

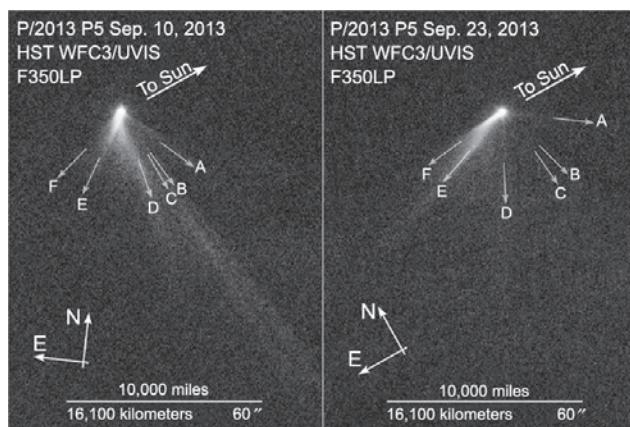

**Fig. 3.** (3200) Phaethon at perihelion in 2009 and 2012 showing extended emission along the projected Sun-comet line. The insets show the point-spread function of the STEREO camera. Each panel shows a region  $490''$  square and is the median of  $\sim 30$  images taken over a one-day period. From Jewitt *et al.* (2013a).

inner-belt orbit and with the Floras. Flora-family asteroids have a mean visual geometric albedo  $0.29 \pm 0.09$  (Masiero *et al.*, 2013). With this assumed albedo, the nucleus of 311P has a radius  $r_n \leq 240 \pm 40$  m (Jewitt *et al.*, 2013c). This small size, combined with the inner-belt location, renders 311P susceptible to spinup by radiation forces. Specifically, the YORP timescale for 311P is  $< 10^6$  yr, shorter than the collisional lifetime. Therefore, it is reasonable to conjecture that episodic mass loss from 311P results from a rotational instability in which regolith is locally unstable and occasionally avalanches off the surface in response to rapid spin (Jewitt *et al.*, 2013c). This “rotational mass shedding” qualitatively accounts for the nonsteady tail formation and the success of synchrone models, which assume ejection from the nucleus at zero initial velocity. Unstable material on 311P would depart at the gravitational escape speed,  $v_e \sim 0.3$  m s $^{-1}$  for a body with  $\rho = 3300$  kg m $^{-3}$ , the density of the LL chondrites, or less. Hainaut *et al.* (2014) suggest an alternative model in which dust production results from friction between two oscillating components of a contact binary nucleus.

### 2.3. P/2010 A2 (LINEAR), $T_J = 3.582$

P/2010 A2 showed a distinctive morphology with a leading, point-like nucleus about 120 m in diameter (Table 2), trailed by an extended tail of dust in which are embedded ribbon-like structures (Jewitt *et al.*, 2010) (see Fig. 5). The position angle of the tail and its variation with time are consistent with the action of radiation pressure on millimeter- to centimeter-sized dust particles, following impulsive ejection at very low speeds ( $\sim 0.2$  m s $^{-1}$ ) in February–March 2009, nearly a year before discovery (Jewitt *et al.*, 2010; Snodgrass *et al.*, 2010). Prediscovery observations were found as early as November 22, 2009 (UT), while detection in the first  $\sim 6$  months after the dust ejection event was impeded by the angular proximity of P/2010 A2 to the Sun (Jewitt *et al.*, 2011a). Before discovery, a large quantity of fast-moving particles are presumed to have left the vicinity of the main nucleus. The mass of particles remaining in the tail

**Fig. 4.** 311P observed on two epochs showing the distinctive evolving, multiple tail structure. From Jewitt *et al.* (2013c).

at discovery is estimated to be in the range  $(6\text{--}60) \times 10^7$  kg (Jewitt *et al.*, 2010; Moreno *et al.*, 2010; Snodgrass *et al.*, 2010). Observations in October 2012 reveal a surviving trail of particles up to 20 cm in radius and a differential power-law size distribution index  $3.5 \pm 0.1$  (Jewitt *et al.*, 2013b). Kim *et al.* (2012) found that the colors most closely resemble those of an H5 chondrite. The estimated total debris mass is  $\sim 5 \times 10^8$  kg, about 10% of the mass of the nucleus.

The properties of P/2010 A2 appear consistent both with an impact origin (with a meter-scale projectile striking at  $5$  km s $^{-1}$ ) and with rotational instability (Jewitt *et al.*, 2010), although an impact origin is often assumed (Snodgrass *et al.*, 2010; Hainaut *et al.*, 2012). In the former interpretation, the distinctive arms seen in Fig. 5 are projections of the impact cone (Kleyna *et al.*, 2013), while in the latter they are ribbons of debris shed in the rotational equator (Agarwal *et al.*, 2013).

### 2.4. (1) Ceres, $T_J = 3.309$

Ceres is unique among the known active asteroids in that it is the only object for which water sublimation has been spectroscopically detected. The 556.936-GHz water ground-state line was reported in absorption by Küppers *et al.* (2014). The line area is time-variable, and can be fitted by a model-dependent water production rate  $dM/dt \sim 6$  kg s $^{-1}$ . Unlike other active asteroids, however, no dust emission has ever been reported for Ceres.

At the subsolar point on Ceres (heliocentric distance 2.6 AU), a perfectly absorbing water ice surface would sublimate in equilibrium with sunlight at the specific rate  $f_s = 5 \times 10^{-5}$  kg m $^{-2}$  s $^{-1}$  (cf. section 3.4). An exposed, subsolar ice patch of area  $(dM/dt)/f_s = 0.12$  km $^2$ , corresponding to a circle of radius 200 m, could supply water vapor. A larger area of exposed ice would be needed if the ice were more reflective, or if it were located away from the subsolar point. One possibility is that ice has been recently exposed on Ceres by a surface disturbance, possibly by the formation of a small impact crater or other geological instability. Alternatively, the

water vapor might not be produced by sublimation in sunlight, but by subsurface heating followed by escape through a vent (cf. Enceladus) (Porco et al., 2014), since Ceres is potentially large enough to maintain significant internal heat (Castillo-Rogez and McCord, 2010). Additional measure-

ments, presumably from the Dawn mission, will be needed to distinguish between these possibilities.

## 2.5. (2201) Oljato, $T_J = 3.299$

In the 1980s, magnetometers on the Pioneer Venus spacecraft revealed multiple, symmetric interplanetary magnetic field enhancements, clumped nonrandomly in time (Russell et al., 1984). About 25% of these events are associated with planet-crossing asteroid (2201) Oljato, whose orbit lies interior to Venus' when near perihelion. Russell et al. suggested that the magnetic disturbances result from deceleration of the solar wind, perhaps caused by mass loading from ionized gases released by an unknown process from debris distributed along Oljato's orbit. A mass-loading rate of only ~5 kg s<sup>-1</sup> is reportedly needed. Observations in 2006–2012 with the Venus Express under a similar geometry reveal no events related with Oljato. Lai et al. (2014) argue that the field enhancements were due to loading of the interplanetary wind by charged nanoscale dust in Oljato's orbit, and that the quantity of this dust decreased between the Pioneer and Venus Express missions. A spectroscopic search for gas produced by Oljato itself proved negative (Chamberlin et al., 1996), with upper limits to the CN production rate near  $10^{23}$  s<sup>-1</sup>. With a

**Fig. 5.** Trailing structures in P/2010 A2 observed January 29, 2010 (UT). The full image width is ~1' while the inset width is ~12''. From Jewitt et al. (2010).

standard H<sub>2</sub>O/CN mixing ratio of 360 (*A'Hearn et al.*, 1995), the corresponding limit to the mass production rate in water is  $\leq 1.5 \text{ kg s}^{-1}$ . Whatever the cause of the repetitive magnetic disturbances, they are not products of an inert asteroid and imply mass loss from Oljato. A dynamical simulation indicates that (2201) Oljato has negligible chance of being a captured Jupiter-family comet (*Bottke et al.*, 2002).

## 2.6. P/2012 F5 (Gibbs), T<sub>J</sub> = 3.228

P/2012 F5 was observed on September 18, 2012, to exhibit a dust trail extending  $>15'$  in the plane of the sky while at a heliocentric distance of R  $\sim 3.1$  AU. Follow-up observations in 2013 showed the object to be largely inactive and set an upper limit on the diameter of the nucleus of  $\sim 2$  km, although residual dust contamination of the nucleus photometry at the time could not be completely ruled out (*Novaković et al.*, 2014). A series of deep images in 2014 showed rapid nucleus rotation (period 3.24 h) and revealed four condensations in an orbit-aligned dust trail (Fig. 6). Dynamical analysis of the object found it to be dynamically stable over at least 1 G.y., and therefore unlikely to be recently implanted from elsewhere in the solar system (*Stevenson et al.*, 2012), although it was also found to be a member of an extremely compact asteroid cluster determined to be just  $1.5 \pm 0.1$  m.y. in age (*Novaković et al.*, 2014).

The origin of the mass loss is unclear, with evidence consistent both with impact and rotational instability. The dust trail was determined via numerical modeling to consist of particles ejected in a single impulsive event, consistent with impact, roughly nine months prior to the discovery of activity (*Moreno et al.*, 2012; *Stevenson et al.*, 2012). In

contrast, the rapid rotation suggests that material may have been lost from F5 by rotational instability. Future observations are needed to determine the ejection times and fates of the trail condensations.

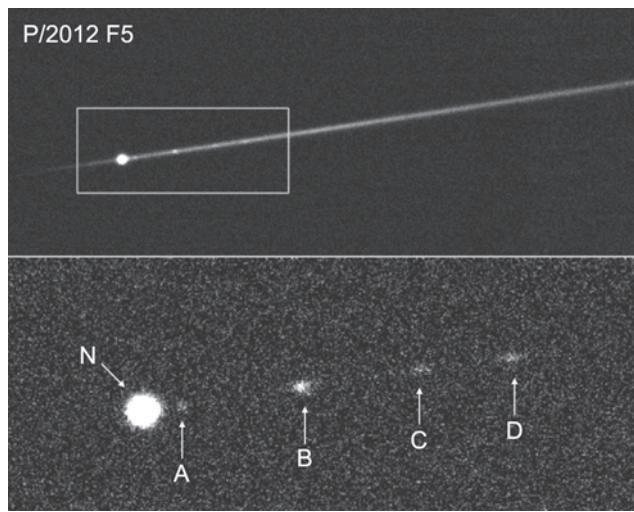

## 2.7. 259P/(Garradd) (P/2008 R1), T<sub>J</sub> = 3.216

259P was observed over a  $\sim 45$ -day interval in 2008 to have the appearance of an active comet with a typical flared tail while at a heliocentric distance of R  $\sim 2$  AU (*Jewitt et al.*, 2009). The object's intrinsic brightness decreased by a factor of about 2 over the course of those observations, corresponding to a mass loss rate on the order of  $\sim 10^{-2} \text{ kg s}^{-1}$ , assuming mean grain radii of 10  $\mu\text{m}$  and bulk densities of  $\rho = 1300 \text{ kg m}^{-3}$  (*MacLennan and Hsieh*, 2012). Subsequent observations of the inactive nucleus found an effective nucleus radius of  $r = 0.30 \pm 0.02$  km (Table 2) (*MacLennan and Hsieh*, 2012), assuming a red geometric albedo of 0.05. Spectral observations limited the production of the CN radical to  $Q_{\text{CN}} \leq 1.4 \times 10^{23} \text{ s}^{-1}$ , corresponding to a water production rate  $\leq 1.5 \text{ kg s}^{-1}$  assuming H<sub>2</sub>O/CN = 360. 259P is located near the 8:3 mean-motion resonance with Jupiter and is also affected by the v<sub>6</sub> secular resonance. The dynamical lifetime in this orbit is short (20–30 m.y.) compared to the age of the solar system, suggesting that 259P was scattered into its present location from elsewhere in the asteroid belt, or possibly even from elsewhere in the solar system.

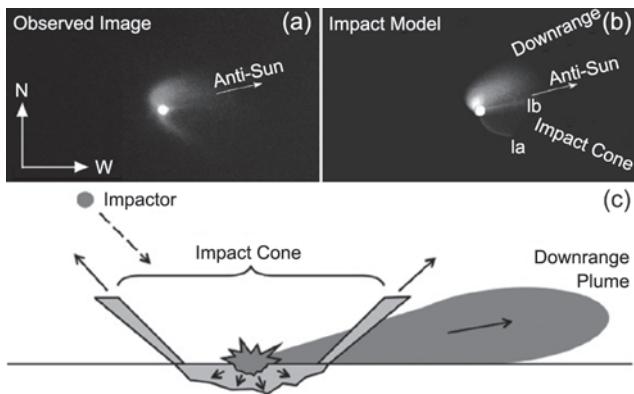

## 2.8. (596) Scheila, T<sub>J</sub> = 3.208

(596) Scheila, a 113-km-diameter object with red geometric albedo  $\sim 0.04$  (Table 2), developed a comet-like appearance in late 2010 in the form of two prominent dust plumes. Over the course of a month, dust in these plumes dispersed from the nucleus due to solar radiation pressure, apparently without any continued replenishment of particles from the nucleus (*Bodewits et al.*, 2011; *Jewitt et al.*, 2011b; *Moreno et al.*, 2011a). Dust modeling by *Ishiguro et al.* (2011a,b) demonstrated that the morphology of the observed dust plumes was consistent with the results of an impact-driven ejecta cloud consisting of a circularly symmetric ejecta cone (subsequently inverted by radiation pressure) and a down-range plume (Fig. 7). *Bodewits et al.* (2014) subsequently reported a change in the rotational lightcurve, which they attributed to the signature of the impact scar.

Upper limits to the gas production from the nucleus of  $Q_{\text{OH}} \leq 10^{26} \text{ s}^{-1}$  [corresponding to a water production rate of  $< 3 \text{ kg s}^{-1}$  (*Howell and Lovell*, 2011)] and  $Q_{\text{CN}} < 9 \times 10^{23}$  [corresponding to  $Q_{\text{H}_2\text{O}} \leq 10 \text{ kg s}^{-1}$  (*Hsieh et al.*, 2012a)] were found, though the meaning of these limits is unclear given the apparently impulsive nature of the mass loss event from Scheila. *Jewitt et al.* (2011b) calculated the mass of dust in micrometer-sized grains to be  $4 \times 10^7 \text{ kg}$ , while more model-dependent attempts to account for larger particles gave total dust masses of  $\sim 10^8$ – $10^{10} \text{ kg}$  (*Bodewits et al.*, 2011; *Ishiguro et al.*, 2011a; *Moreno et al.*, 2011a). No ice was observed in the coma (*Yang and Hsieh*, 2011).

**Fig. 6.** Keck telescope images of P/2012 F5 on August 26, 2014 (UT). The region shown is  $1.0 \times 2.5'$ . The rectangular box in the top panel shows the region enlarged in the bottom panel, where a model of the trail has also been subtracted. Letters mark the primary nucleus, N, and tail condensations, A–D. From *Drahus et al.* (2015).

### 2.9. 288P/(300163) 2006 VW<sub>139</sub>, T<sub>J</sub> = 3.203

Discovered in 2006 as an inactive asteroid, 288P was found to be cometary in 2011 by the Pan-STARRS1 survey telescope (Hsieh et al., 2012b) (cf. Fig. 8). A short ( $\sim 10''$ ) antisolar dust tail and a longer ( $\sim 60''$ ) dust trail aligned with the object's orbit plane were seen in deep follow-up images, indicating the simultaneous presence of both recent and months-old dust emission, strongly suggesting that the observed activity was due to a long-duration emission event, consistent with sublimation. Photometric monitoring showed that intrinsic brightness of the near-nucleus coma remained constant for at least one month, before then declining by 40% over the next month, again consistent with a long-duration emission event where the coma was continually replenished by fast-dissipating small dust particles over its period of constant brightness, and then faded quickly once the replenishment rate slowed.

Spectroscopic observations did not detect any gaseous sublimation products, setting an upper limit to the CN production rate of  $Q_{\text{CN}} < 10^{24} \text{ mol s}^{-1}$  (Hsieh et al., 2012b; Licandro et al., 2013). However, dust modeling found that the onset of activity occurred shortly after perihelion, and persisted for about 100 d (Licandro et al., 2013). A dynamical analysis by Novaković et al. (2012) found that 288P belongs to a compact cluster of 24 asteroids believed to originate from the fragmentation of a  $\sim 11\text{-km-diameter}$  parent body  $7.5 \pm 0.3$  m.y. ago.

### 2.10. (62412) 2000 SY<sub>178</sub>, T<sub>J</sub> = 3.197

(62412) 2000 SY<sub>178</sub> has diameter  $7.8 \pm 0.6$  km, geometric albedo  $0.065 \pm 0.010$ , and is a probable C-type (Sheppard and Trujillo, 2015). The nearly circular orbit at 3.146 AU is consistent with membership of the 2–3-G.y.-old Hygiea family. While the origin of the activity is unknown, the 3.33-h rotation period and 0.45-mag light curve range suggest, by analogy with 133P (Jewitt et al., 2014a), that rotation may play a role.

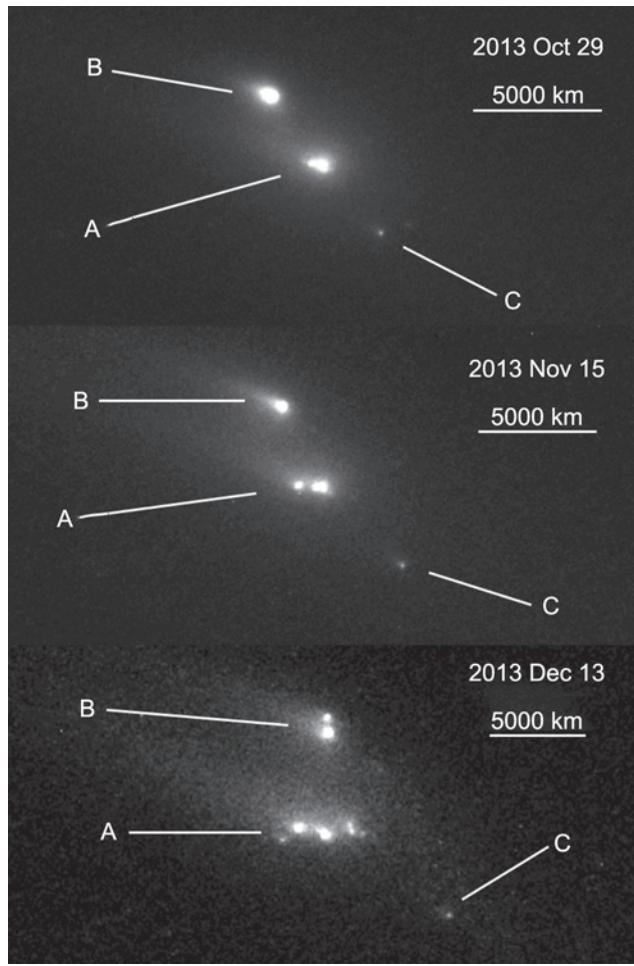

**Fig. 8.** (a) Image of 288P and (b) corresponding syndyne plot. A syndyne is the locus of positions of particles of one size released from the nucleus at zero speed over a range of times. From Hsieh et al. (2012b).

### 2.11. P/2013 R3 (Catalina-PanSTARRS), T<sub>J</sub> = 3.185

P/2013 R3 is a dust enshrouded outer-belt asteroid observed in a state of disintegration (Jewitt et al., 2014b) (cf. Fig. 9). Ten distinct components were detected in the interval from October to December 2014, with a velocity dispersion between fragments on the order of  $0.3\text{--}0.5 \text{ m s}^{-1}$ . Because of dust contamination in 2014 it is only possible to set upper limits to the size of the fragments. Assuming geometric albedo 0.05, the four largest have radii  $\leq 200$  m. The gravitational escape velocities of the largest fragments (assuming density  $\rho = 1000\text{--}3000 \text{ kg m}^{-3}$ ) are  $0.15\text{--}0.25 \text{ m s}^{-1}$ , comparable to the measured fragment-velocity dispersion. The fragmentation took place successively over a period of several months at least, excluding an impact as the cause. Disruption due to the pressure of a subsurface volatile reservoir was also excluded, although the continued dust activity of the fragments may have been caused by the sublimation of newly exposed ice. Rotational breakup seems the most likely cause of the catastrophic disruption of R3, supported by the close-to-escape-speed relative velocities of the fragments (Hirabayashi et al., 2014).

### 2.12. 133P/(7968) Elst-Pizarro, T<sub>J</sub> = 3.184

133P was first observed to be active in 1996, exhibiting a long, narrow dust trail with no visible coma, making it the first known (and currently best characterized) active asteroid in the main asteroid belt. At first suspected to be the product of a collision (Boehnhardt et al., 1998; Toth, 2000), it has since been observed to be active on three additional

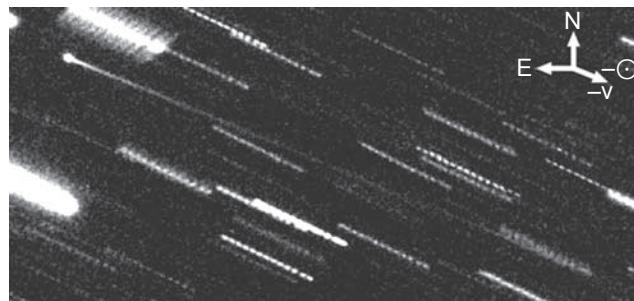

**Fig. 9.** Evolution of the components of P/2013 R3 over six weeks in 2014. The components, labeled A, B, and C, show progressive splitting and are enveloped in a  $10^8$ -kg debris cloud. Scale bars mark 5000 km at the distance of the object. Adapted from Jewitt *et al.* (2014b).

occasions in 2002, 2007, and 2013, and inactive in between (e.g., Hsieh *et al.*, 2004, 2010; Jewitt *et al.*, 2014a).

The appearance of 133P when active is typically that of a point-like nucleus with a thin tail (or “trail”) of dust following in the projected orbit (Fig. 10). Order-of-magnitude dust mass loss rates, inferred from surface photometry of the tail (Hsieh *et al.*, 2004), reach  $\sim 0.02 \text{ kg s}^{-1}$ , while comparable upper limits in gas are inferred from spectroscopy (Licandro *et al.*, 2011a). The thin tail indicates that particles are ejected very slowly from the nucleus with characteristic speeds  $\sim 1.8 a_{\mu\text{m}}^{-1/2} \text{ m s}^{-1}$ , where  $a_{\mu\text{m}}$  is the grain radius expressed in micrometers (Jewitt *et al.*, 2014a). Curiously, particles larger than a few micrometers leave the nucleus at speeds below the  $\sim 2 \text{ m s}^{-1}$  gravitational escape speed (e.g., millimeter-sized particles have  $v \sim 6 \text{ cm s}^{-1}$ ). This is inconsistent with a pure sublimation origin, and appears to require centripetal assistance and a spatially subdivided sublimating surface (Jewitt *et al.*, 2014a).

The nucleus has a rotation period of  $3.471 \pm 0.001 \text{ h}$  (Hsieh *et al.*, 2004), a spectrum similar to those of B- or

**Fig. 10.** 133P imaged September 7 2002 (UT). From Hsieh *et al.* (2004).

F-type asteroids (e.g., Bagnulo *et al.*, 2010; Licandro *et al.*, 2011a), and an optical albedo of  $p_R \sim p_V \sim 0.05$  (Hsieh *et al.*, 2009; Bauer *et al.*, 2012).

### 2.13. 176P/(118401) LINEAR, $T_J = 3.167$

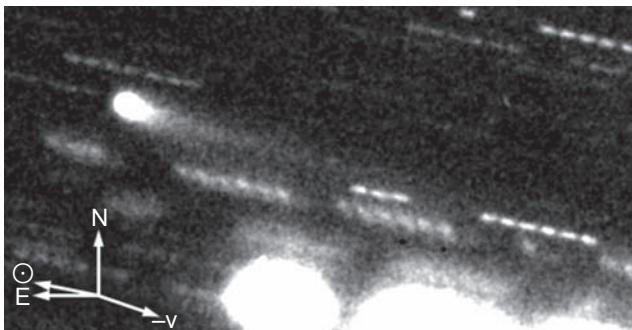

176P/LINEAR was observed to exhibit a short fan-shaped tail over a single, month-long interval in 2005 (Hsieh *et al.*, 2011a). During this time, the object was about 30% brighter than the bare nucleus, leading to an implied dust mass  $\sim 10^5 \text{ kg}$ . The properties of the dust can be approximately matched by models in which the characteristic particle size is  $10 \mu\text{m}$ , the ejection speed  $\sim 5 \text{ m s}^{-1}$ , and the dust production rate  $\sim 0.07 \text{ kg s}^{-1}$ , all similar to values inferred in 133P. Activity was sought but not detected in 2011 (Hsieh *et al.*, 2014), and the water-production rate was spectroscopically limited to  $Q_{\text{H}_2\text{O}} \leq 4 \times 10^{25} \text{ s}^{-1}$  ( $\leq 1.0 \text{ kg s}^{-1}$ ) in Herschel observations 40 days after perihelion on August 8, 2011 (UT) (de Val-Borro, 2012). The  $4.0 \pm 0.4$ -km-diameter nucleus rotates with a period near 22.2 h (Table 2).

### 2.14. 238P/Read, $T_J = 3.152$

The second active asteroid in the main belt, 238P, exhibited a strong coma and dust tail when discovered in October 2005 at a heliocentric distance of  $R \sim 2.4 \text{ AU}$  (Fig. 11). Like 259P, the nucleus of 238P is tiny, with a diameter of  $\sim 0.8 \text{ km}$  (Hsieh *et al.*, 2011b). It was observed to be active in both 2005 and 2010, with a period of inactivity in between, with a coma dust mass on the order of  $10^5 \text{ kg}$  and a production rate estimated (from published photometry) near  $\sim 0.1 \text{ kg s}^{-1}$ . Also like 259P, 238P is dynamically unstable, with a survival time on the order of 20 m.y., although unlike 259P, which may have been recently implanted at its current location, 238P is hypothesized to have diffused in eccentricity from its original location within the Themis family (which also contains 133P, 176P, and 288P) due to its proximity to the 2:1 mean-motion resonance with Jupiter (Haghishipour, 2009).

### 2.15. P/2012 T1 (PanSTARRS), $T_J = 3.134$

P/2012 T1 was discovered to exhibit a diffuse coma and a featureless fan-shaped antisolar tail in October 2012.

**Fig. 11.** 238P imaged on November 10, 2005 (UT). From Hsieh et al. (2009).

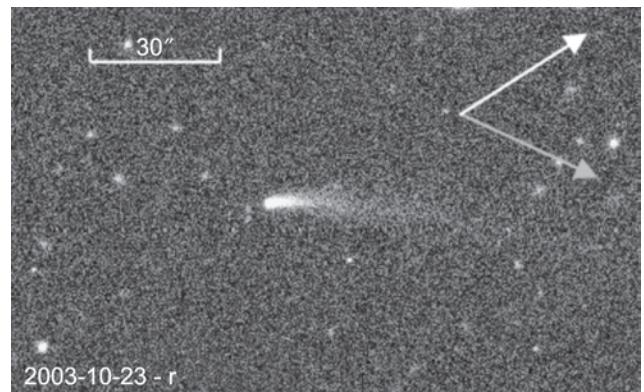

Photometric monitoring showed that the total scattering cross-section of the comet's coma and tail doubled over a period of about a month, remained approximately constant for another 1.5 months, and then declined by ~60% over the next 1.5 months (Hsieh et al., 2013). Spectroscopic observations using the Keck I telescope found an upper limit CN production rate of  $Q_{\text{CN}} < 1.5 \times 10^{23} \text{ mol s}^{-1}$ , and no evidence of absorption at  $0.7 \mu\text{m}$  that would indicate the presence of hydrated minerals (Hsieh et al., 2013), while Herschel Space Telescope observations were used to set an upper limit  $\text{H}_2\text{O}$  production rate of  $Q_{\text{H}_2\text{O}} < 7.6 \times 10^{25} \text{ mol s}^{-1}$  (O'Rourke et al., 2013). Dust modeling by Moreno et al. (2013) indicated that dust production began near perihelion and lasted for a period of ~4–6 months, with a total ejected dust mass on the order of  $10^7 \text{ kg}$  for maximum grain sizes of  $a = 1\text{--}10 \text{ cm}$ .

### 2.16. 313P/Gibbs (2014 S<sub>4</sub>), $T_J = 3.132$

Discovered September 24, 2014 (UT), this object has a semimajor axis 3.156 AU and is located near at least eight other active asteroids in the outer belt (Fig. 2). The nucleus radius is 500 m (albedo 0.04 assumed). Prediscovery observations from 2003 (Fig. 12) reveal 313P as only the third object, after 133P and 238P, to be active in more than one orbit, consistent with mass loss driven by the sublimation of ice. It displays a fan-shaped dust tail in both 2003 and 2014 that is well approximated by syndyne dust emission models, indicating that the dust is ejected over a period of at least three months during each active episode (Jewitt et al., 2015; Hsieh et al., 2015b; Hui and Jewitt, 2015). The object is found near two three-body mean-motion resonances with Jupiter and Saturn (11J-1S-5A and 10J+12S-7A), and its orbit has been found to be intrinsically chaotic with a Lyapunov time of  $T_L = 12,000 \text{ yr}$ , yet numerical simulations show that it is stable over at least 50 m.y. 313P is the second active asteroid, after P/2012 T1, to be associated with the ~155-m.y.-old Lixiaohua asteroid family (Hsieh et al., 2015b).

### 2.17. 324P/2010 R2 (La Sagra), $T_J = 3.098$

324P/2010 R2 was observed to be active from September 2010 to January 2011, at  $R = 2.6$  to  $2.7 \text{ AU}$ , and has a mea-

**Fig. 12.** Prediscovery image of 313P at 2.47 AU on October 23, 2003 (UT). White and gray arrows show the directions of the projected anti-solar and heliocentric velocity vectors, respectively. From Hui and Jewitt (2015).

sured nucleus size of  $r = 0.55 \pm 0.05 \text{ km}$  (Hsieh, 2012c). Moreno et al. (2011b) inferred dust production at the peak rate of  $\sim 4 \text{ kg s}^{-1}$ , with centimeter-sized particles ejected at about  $0.1\text{--}0.2 \text{ m s}^{-1}$ . A limit to the outgassing rate  $Q_{\text{CN}} \leq 3 \times 10^{23} \text{ s}^{-1}$  (corresponding to  $\sim 3 \text{ kg s}^{-1}$  in water) was placed spectroscopically (Hsieh et al., 2012c). The latter authors found (neglecting possible nongravitational forces due to outgassing) that the orbit of 324P/2010 R2 is stable on timescales  $\sim 100 \text{ m.y.}$  and argue that this object was likely formed *in situ*. Reactivation of 324P was reported in the summer of 2015, suggesting that the activity is driven by sublimation and ruling out impact as a likely cause (Hsieh and Sheppard, 2015).

### 2.18. 107P/(4015) Wilson-Harrington, $T_J = 3.083$

107P showed a prominent diffuse tail about  $2'$  in length on a blue-sensitive photographic plate taken November 19, 1949, when at  $R = 1.148 \text{ AU}$  (Fernandez et al., 1997). A red-sensitive plate taken nearly simultaneously shows only a hint of this tail. 107P appears strongly trailed on both plates owing to its noncircular motion. The tail color ( $B-R = -1$ ) is too blue to be caused by scattering from dust, and the tail position angle ( $\sim 15^\circ$  from radial to the Sun) is also inconsistent with the expected direction of a dust tail blown by radiation pressure. 107P was reobserved on November 22 and 25 but then showed no trace of a tail (Cunningham, 1950), and no comet-like activity has been reported since (Chamberlin et al., 1996; Ishiguro et al., 2011c). We regard 107P as the least convincing example of the active asteroids, both because the observations are old and unrepeated and because 107P lies very near the  $T_J > 3.08$  cut-off. Bottke et al. (2002) used a statistical dynamical model to conclude that there is a 4% chance that 107P is a captured Jupiter-family comet.

### 2.19. Related Observations

Features in the 3.0–3.5- $\mu\text{m}$  reflection spectra of large main-belt asteroids (24) Themis (diameter  $198 \pm 20 \text{ km}$ )

and (65) Cybele ( $273 \pm 12$  km) have been interpreted as absorptions due to O-H stretch in water ice and C-H stretch in an unidentified organic molecule (Campins *et al.*, 2010; Rivkin and Emery, 2010; Licandro *et al.*, 2011b). The shape of the band in Themis requires a thin, widespread, or global ice film (“frost”) only 100 Å to 1000 Å thick (Rivkin and Emery, 2010). However, such a thin film would be highly unstable to sublimation and would lead to gas production rates  $10^5$ – $10^6$  kg s $^{-1}$ , violating observational limits set spectroscopically [ $\leq 400$  kg s $^{-1}$  (Jewitt and Guillet-Lepoutre, 2012)]. The latter authors showed that, if water ice exists on these asteroids, it must be of high albedo ( $>0.3$ ) and spatially confined to regions far from the subsolar point (e.g., near the poles on objects having small obliquity) in order to keep sublimation below observational limits. The spectra of Themis and Cybele are similar to that of the iron-rich mineral goethite (Beck *et al.*, 2011), but this offers a less plausible explanation because goethite is rare in meteorites and normally attributed to weathering of the meteorites once fallen on Earth.

### 3. MECHANISMS

In this section we discuss possible mechanisms able to eject dust from asteroids. The group properties offer few clues, given the modest size of the active asteroids sample (cf. Table 2). Licandro *et al.* (2011a), for example, suggest that the color distribution of active asteroids is different from that of classical cometary nuclei. Even if future measurements prove this to be true, its significance is unclear given that a wide range of mechanisms are known to drive the observed activity in these bodies (Jewitt, 2012). Furthermore, while they are discussed separately for clarity, it is likely that different mechanisms operate together in real objects. For example, the loss of particles produced in (3200) Phaethon by thermal disintegration is likely assisted by rotation and radiation pressure sweeping. Sublimation driven mass loss from 133P is probably also rotation assisted.

#### 3.1. Rotational Mass Loss

For a sphere of density  $\rho$  the critical period at which the gravitational acceleration equals the centripetal acceleration at the equator is

$$P_c = \left( \frac{3\pi}{G\rho} \right)^{1/2} \quad (2)$$

where G is the gravitational constant. For example, with  $\rho = 1000$  kg m $^{-3}$ ,  $P_c = 3.3$  h. The critical period is independent of the asteroid size, is shorter for higher densities, and is longer for elongated spheroids in rotation about a minor axis (by a factor approximately equal to the ratio of the long to short axes of the body). The rotation and the shape of a fluid body are related, in equilibrium, by the classic MacLaurin and Jacobi ellipsoid series. However, while most asteroids may have been severely weakened by repeated impact fracturing and the formation of a rubble-pile structure, they are

not strengthless. van der Waals and other weak forces can imbue a rubble pile with a cohesive strength, while friction can provide resistance to deformation even in the absence of cohesion, and critical periods much shorter than given by equation (2) are possible (Holsapple, 2007; Sanchez and Scheeres, 2014). Calculation of the rotational stability of rubble piles remains an important but challenging and underconstrained problem in asteroid science.

Evidence for rotational instability comes from the observation that most asteroids larger than a few hundred meters in size rotate more slowly than a “barrier” period at about 2.2 h (Warner *et al.*, 2009). This is widely interpreted as meaning that faster-rotating asteroids have lost mass or have even disrupted due to centripetal forces. Recent observations of active asteroids 311P and P/2013 R3 (and possibly P/2010 A2) appear to show asteroids losing mass rotationally, so that we can begin to study this process as it happens.

In principle, the rotation rates of asteroids can be driven to critical values by external torques exerted by the gravity of other objects, by chance impacts, by outgassing, and by electromagnetic radiation. In the main belt, gravitational torques are negligible (except within binary and other multiple systems). Collisions add angular momentum stochastically, leading to a slow random walk toward larger angular momenta. Outgassing from icy asteroids can be very efficient in changing the spin but, for ice-free asteroids, radiation torques offer the most potential for driving the rotation steadily up to critical values.

Power absorbed from the Sun by the surface of an asteroid is reradiated to space as heat. Asteroids are aspherical and anisothermal, causing the radiated infrared photons to be emitted anisotropically. The angle-averaged momentum carried by thermal photons per second corresponds to a net reaction thrust on the asteroid, known as the Yarkovsky force. It has important dynamical consequences on small main-belt asteroids. If the vector representing the net force does not pass through the center of mass of the asteroid, the result is the so-called YORP torque, which can change the magnitude of the spin and excite precession (see the chapter by Vokrouhlický *et al.* in this volume).

We focus on changes in the magnitude of the spin, and estimate the relevant timescale from the ratio of the rotational angular momentum, L, to the torque, T. Ignoring the vector nature of these quantities, for simplicity, the torque is proportional to the number of photons radiated per second, which varies in proportion to  $r_n^2/R^2$ , where  $r_n$  is the asteroid radius and R is the distance from the Sun. Torque also depends on the moment-arm, defined as the perpendicular distance between the instantaneous direction of the net force and the center of mass. Statistically, at least, we expect the moment arm  $\propto r_n$ . Together, these dependences give  $T \propto r_n^3/R^2$ . Meanwhile, the spin angular momentum is  $L \propto Mr_n^2\omega$ , where M is the body mass and  $\omega$  the angular rotation rate, related to the rotational period, P, by  $\omega = 2\pi/P$ . Substituting  $M \propto pr_n^3$  gives  $L \propto pr_n^5\omega$ . Finally, the timescale for YORP to change the angular momentum is  $\tau_y = L/T$ , or  $\tau_y = K pr_n^2R^2\omega$ , where K is a constant.

The value of constant K depends sensitively on the body shape, surface texture, thermal properties, and spin vector of the asteroid. We estimate its magnitude from measurements of YORP acceleration in five asteroids (*Rozitis and Green*, 2013; *Lowry et al.*, 2014), scaled to assumed density  $\rho = 2000 \text{ kg m}^{-3}$  and spin period  $P = 5 \text{ h}$ , to obtain

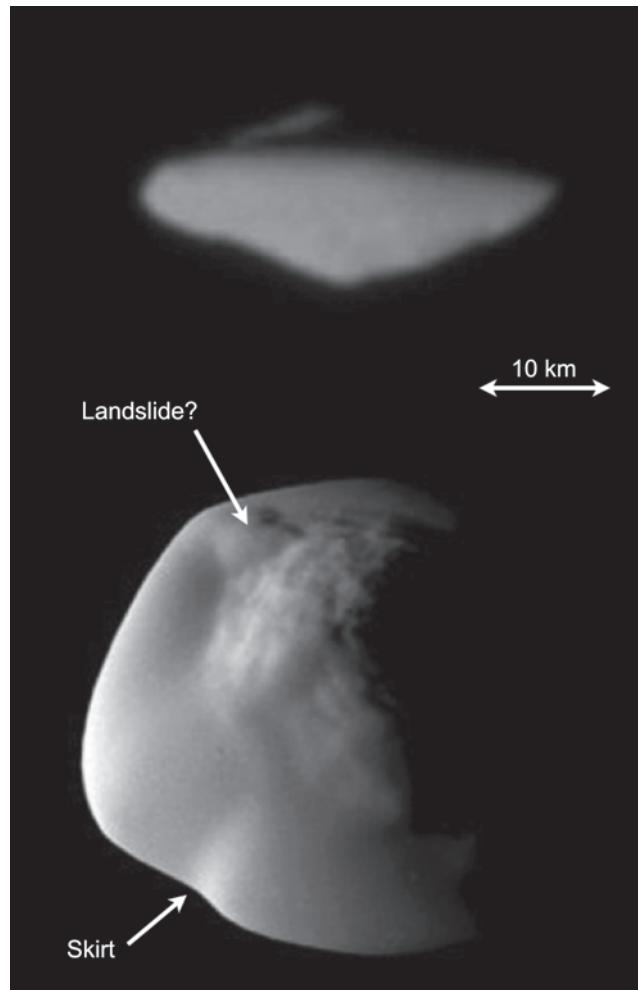

$$\tau_y (\text{m.y.}) \sim 4 \left[ \frac{r_n}{1 \text{ km}} \right]^2 \left[ \frac{R}{3 \text{ AU}} \right]^2 \quad (3)$$

Order-of-magnitude deviations from equation (3) can result from peculiarities of the asteroid shape, texture, thermal properties, and spin. Still, equation (3) gives a crude but useful estimate, by showing that the angular momentum of a 1-km-radius asteroid at 3 AU can be modified significantly on timescales of just a few million years. A sustained YORP torque can drive a kilometer-scale body to rotational instability in a few times  $\tau_y$ , and the spins of subkilometer, low-density, near-Sun asteroids should be particularly susceptible to YORP torques. Setting  $\tau_y < 4.5 \times 10^9 \text{ yr}$  in equation (3) shows that asteroids as large as  $r_n \sim 30 \text{ km}$  can be affected by YORP in the age of the solar system, provided they survive against collisions for such a long time. Most of the objects in Table 2 are small enough to be potentially affected by YORP.

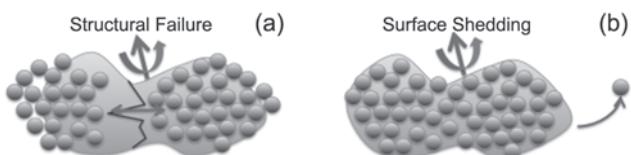

A major complication is that YORP torques can change not just the rotation state but the shape of an asteroid, as material slides, bounces, or rolls toward the rotational equator on its way to escape (e.g., *Harris et al.*, 2009; *Statler*, 2009). Changing the shape affects the magnitude and possibly the direction of the YORP torque (*Cotto-Figueroa et al.*, 2015), creating a feedback loop that can change the timescale for spinup relative to the value in equation (3). Evidence for equatorial accumulation of particulate matter is present in images of UFO-shaped saturnian satellites (cf. Fig. 13) and in the shapes of some rapidly rotating near-Earth asteroids, as determined by radar (*Ostro et al.*, 2006).

In part because of the complex interplay between torque, spin, material properties, shape, and mass loss, no comprehensive models of asteroid evolution and disruption by rotation have been computed, although many interesting approximations exist (*Holsapple*, 2007, 2010; *Walsh et al.*, 2008, 2012; *Jacobson and Scheeres*, 2011; *Marzari et al.*, 2011; *Hirabayashi and Scheeres*, 2014; *Sánchez and Scheeres*, 2012, 2014; *Cotto-Figueroa et al.*, 2015; *Scheeres*, 2015). These models, not always in agreement with one another, attempt to investigate the role of small torques in the production of distinctive body spins and shapes, in mass-shedding and structural failure (cf. Fig. 14), and in the formation of both binaries and unbound pairs (*Pravec et al.*, 2010; *Moskovitz*, 2012; *Polishook*, 2014).

The cohesive strength is a key parameter in all such models because, given sufficient cohesive strength, an asteroid can resist rotational forces at an arbitrarily high rotation rate (e.g., *Rozitis et al.*, 2014). Fortunately, new observations of active asteroids allow us to obtain a useful estimate of the cohesive strength.

**Fig. 13.** Two views of UFO-shaped saturnian satellite Atlas showing a dust skirt around the equator where the effective gravitational attraction to the body approaches zero. Atlas is a slow rotator (period 14 hr), but it fills its Roche lobe within the saturnian system, making it a suitable analog for a body at the stability limit (*Minton* 2008). The paucity of craters indicates youth, which results from the mobility of surface dust. A possible landslide is visible on the dust skirt; corresponding landslides or avalanches leading to escape are likely responsible for the impulsive tail ejections in 311P (cf. Fig. 4). The bulk density is  $\sim 400 \text{ kg m}^{-3}$ . Credit: NASA/JPL/SSI.

**Fig. 14.** Schematic diagram distinguishing (a) structural failure, as may be seen in P/2013 R3, from (b) surface shedding (for which 311P is a candidate). From *Hirabayashi and Scheeres* (2014).

First, we consider a toy model of two bodies in contact, both of density  $\rho$  and having dimensions  $r_p$  and  $r_s$ , with  $r_p \gg r_s$ . Assume that the smaller body sits on the rotational equator of the larger body and take the area of contact between them to be  $\sim r_s^2$ . Let the critical frequency of rotation at which gravitational attraction is balanced by centripetal acceleration be  $\omega_c$ . Then, when rotating with an angular frequency  $\omega > \omega_c$ , the minimum cohesive strength needed to bind the two bodies together may be written

$$S \sim \frac{m_s r_p (\omega^2 - \omega_c^2)}{r_s^2} \quad (4)$$

where  $m_s$  is the mass of the smaller component. If detachment occurs when  $\omega^2 \gg \omega_c^2$ , the smaller mass  $m_s$  will leave with a relative velocity,  $\Delta V$ , comparable to the instantaneous equatorial velocity of the primary, namely  $\Delta V = r_p \omega$ . Substituting for  $\Delta V$  and  $m_s = \rho r_s^3$  into equation (4), we obtain

$$S \sim \rho \left( \frac{r_s}{r_p} \right) (\Delta V)^2 \quad (5)$$

The six measured components of P/2013 R3 (Table 2 of Jewitt *et al.*, 2014b) are equivalent in volume to a single precursor body of dimension  $r_p = 350$  m. Four of these six nuclei have  $r_s \sim 200$  m and are separating at characteristic speeds  $0.2 \leq \Delta V \leq 0.5$  m s $^{-1}$ . Assuming density  $\rho = 1000$  kg m $^{-3}$  (equation (5)) gives an estimate of the cohesive strength as  $16 \leq S \leq 140$  N m $^{-2}$ . A mathematically more refined analysis, in which the initial body shape is represented by a rotational ellipsoid, gives  $40 \leq S \leq 210$  N m $^{-2}$  (Hirabayashi *et al.*, 2014). In both cases, these very small cohesive strengths are comparable to the  $\sim 25$  N m $^{-2}$  strength expected of a rubble pile bound by van der Waals forces acting on the smallest particles (Sanchez and Scheeres, 2014). The small size of the P/2013 R3 precursor body is compatible with a short YORP timescale ( $\tau_y \sim 0.5$  m.y. by equation (3)), lending credibility to the YORP spinup hypothesis for this object. Active asteroid 311P has also been interpreted (Jewitt *et al.*, 2013c, 2014c) as rotational instability of a different sort, in which only surface particulates escape from the rotating central body (Hirabayashi *et al.*, 2014).

This first determination of the cohesive strength, if broadly applicable, shows that rotation of asteroids can play a major disruptive role. Indeed, the rotational disruption rate may exceed the impact destruction rate for asteroids  $\leq 1$  km in diameter (Fig. 15). However, many questions remain about the process. In 311P, what determines the intervals between successive dust releases, and for how long will they continue? More specifically, does the distribution of dust releases resemble the power-law spectra of self-organized critical sandpiles (Laurson *et al.*, 2005), as might be expected if avalanches are responsible? Could this object be in the process of forming a binary (cf. Walsh *et al.*, 2008; Jacobson and Scheeres, 2011), or has it already formed one? Will the nucleus eventually be driven to structural instability, as has

occurred in P/2013 R3? Or could 311P be a fragment of a rotationally disrupted precursor body whose components are so widely spread as to have escaped notice?

### 3.2. Impacts

The average velocity dispersion among main-belt asteroids is  $U \sim 5$  km s $^{-1}$ , enough to cause vaporization as well as shattering and, potentially, disruption upon impact. Experiments at laboratory scales show that the ratio of  $m_e$ , the mass ejected faster than speed  $v$ , to the projectile mass,  $M$ , is

$$\frac{m_e}{M} = A \left( \frac{v}{U} \right)^\alpha \quad (6)$$

with  $A \sim 0.01$  and, very roughly,  $\alpha \sim -1.5$  (Housen and Holsapple, 2011). For an assumed spherical projectile, the mass is  $M = 4\pi\rho r_p^3/3$ , where  $r_p$  is the radius. Equation (6) is valid provided the impact does not have enough energy to completely disrupt the target asteroid. For example, an impact at 5 km s $^{-1}$  into a 1-km-radius body, with escape velocity  $v_e \sim 1$  m s $^{-1}$ , would have an ejecta to projectile mass ratio  $m_e/M \sim 3500$  by equation (6). The mass of ejecta and the scattering cross-section,  $C$ , are related by

$$m_e = \chi \rho \bar{a} C \quad (7)$$

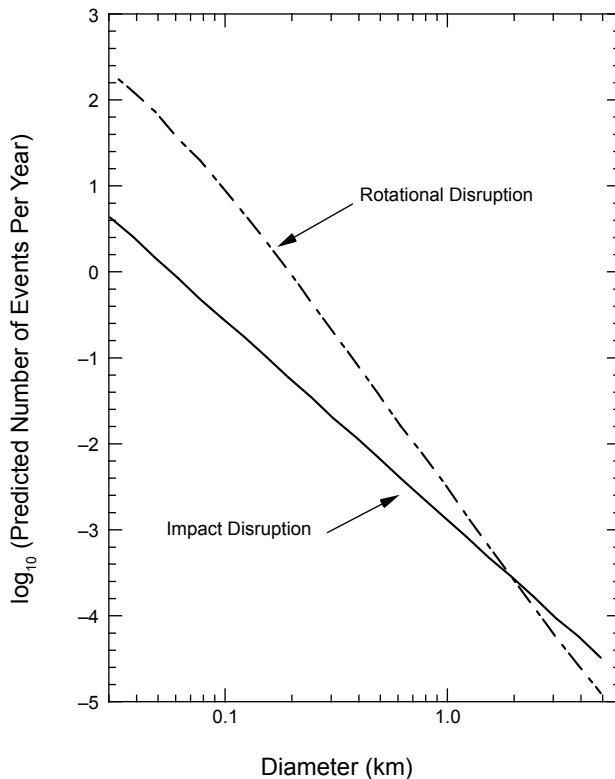

where  $\bar{a}$  is the weighted mean particle size in the ejecta and  $\chi$  is a dimensionless constant on the order of unity. Very modest projectiles are capable of creating ejecta with a substantial cross-section. We write  $C = f\pi r_n^2$ , where  $r_n$  is the radius of the target asteroid and  $f$  is a constant. The case  $f = 1$  corresponds to ejecta with a cross-section equal to that of the target asteroid. Such an impact would result in a doubling of the asteroid brightness, and therefore should be readily detected. We set  $v = (8\pi G \rho / 3)^{1/2} r_n$ , the gravitational escape speed from the target asteroid, and combine equations (6) and (7) to obtain

$$r_p = \left( \frac{3\bar{a}f}{4A} \right)^{1/3} \left( \frac{8\pi G \rho}{3} \right)^{-\alpha/6} U^{\alpha/3} r_n^{[(2-\alpha)/3]} \quad (8)$$

Equation (8) assumes that the densities of the target and projectile are equal. Substituting the above parameters, equation (8) reduces to

$$r_p = 0.29 f^{1/3} r_n^{7/6} \quad (9)$$

Equation (9) is plotted in Fig. 16 for  $f = 0.1, 1, 10$ , and  $100$ , corresponding to changes in the apparent magnitude due to impact of  $\Delta m \sim 2.5 \log_{10} f = 0.1, 0.7, 2.5$ , and  $5$  mag, respectively. The figure shows that a 20-cm projectile striking a 1-km asteroid would eject enough material to double the total cross-section and brightness. Very modest impacts should create observable ejecta signatures.

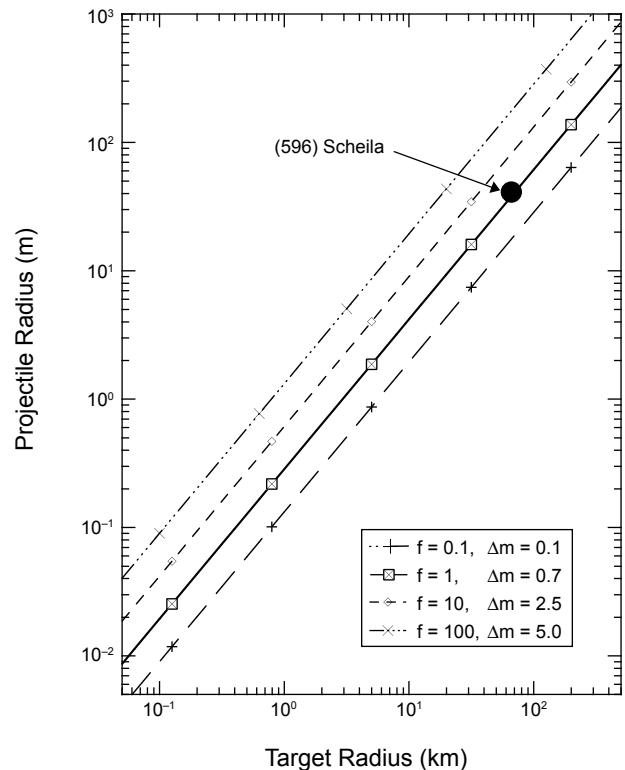

**Fig. 15.** Model rates of asteroid disruption due to impact and rotational bursting as a function of asteroid diameter. From Marzari et al. (2011).

The number of boulders in the asteroid belt is very uncertain, because these small objects are too faint to be observed directly from Earth. Models extrapolating from larger sizes suggest that the number of objects with  $r_p > 1$  m is roughly  $10^{13 \pm 1}$  (O'Brien and Greenberg, 2005). The rates at which small-scale impacts occur is correspondingly uncertain by at least an order of magnitude.

Survey observations by Denneau et al. (2015) have been interpreted, through a simple model, to show a discrepancy with the rate of asteroid disruption predicted by Bottke et al. (2005).

### 3.3. Thermal Disintegration

Forces caused by thermal expansion can exceed the fracture strength of a material, leading to cracking and the production of dust. On a low-gravity body, excess thermal strain energy can eject fragments faster than the gravitational escape speed, leading to a net loss of material (Jewitt, 2012). In a uniform material, stresses arise from differential thermal expansion across a temperature gradient. Most minerals are non-uniform in structure, consisting of compositionally distinct grains. Non-uniform materials are susceptible to fracture because of differential expansion between the component materials, with or without a temperature gradient. The thermal skin depth in the material (across which temperature gradients are particularly marked, and variable) is related to the period of

**Fig. 16.** Projectile radius (y-axis) needed to generate ejecta with cross-section  $f = 0.1, 1, 10$ , and  $100 \times$  the geometric cross-section of the target asteroid, whose radius is plotted on the x-axis (cf. equation (9)). Impacted asteroid (596) Scheila ( $r_p = 65$  km) brightened by about 1 mag following impact. The figure shows that the projectile radius was several tens of meters.

the temperature variation,  $\tau$ , and to the thermal diffusivity,  $\kappa$ , by  $\ell \sim (\kappa\tau)^{1/2}$ . For example, an asteroid with diffusivity  $\kappa = 10^{-6} \text{ m}^2 \text{ s}^{-1}$ , rotating with period  $\tau = 5$  h, would have a skin depth  $\ell \sim 0.1$  m. Thermal fracture occurring within a thermal skin depth of the physical surface may contribute to the production of regolith (Delbo et al., 2014). Desiccation (the loss of bound water from a hydrated mineral) is a separate process leading to fracture and dust production when the stresses induced by shrinkage exceed the material strength. On Earth, mudcracks in dry lake beds made of clay minerals are the most easily recognized examples of desiccation cracking.

Among the active asteroids, the most convincing evidence for thermal disintegration is from (3200) Phaethon (Li and Jewitt, 2013; Jewitt and Li, 2010; Jewitt et al., 2013a). The eccentric orbit and high obliquity [Phaethon's pole is at ecliptic coordinates  $\lambda, \beta = 85^\circ \pm 14^\circ, -20^\circ \pm 10^\circ$  (Ansdel et al., 2014)] lead to highly non-uniform surface heating, with peak temperatures near 1000 K at perihelion (Ohtsuka et al., 2009). The temperature is further modulated by Phaethon's rapid rotation (3.6-h period), with a diurnal variation of hundreds of Kelvin. Furthermore, the escape speed from the ~5-km-diameter nucleus is a few meters per second, sufficiently

small that grains produced by fracture can easily be ejected (Jewitt, 2012). While Phaethon's composition is unknown, hydrated mineralogies (montmorillonite clays) have been suggested based on the blue optical/near-infrared reflection spectrum (Licandro *et al.*, 2007). Hydrated materials, if present, would be highly susceptible to desiccation, shrinkage, and fracture. Nine asteroids with perihelia  $\leq 0.25$  AU (subsolar temperatures  $\geq 800$  K) have been searched for activity, setting upper limits to the mass loss rate from  $\leq 0.1$  to  $1 \text{ kg s}^{-1}$  (Jewitt, 2013).

On a larger scale, thermal disintegration may be important in dust disks surrounding white dwarf stars. Such disks are inferred from photospheric, heavy-element pollution (Jura and Xu, 2013).

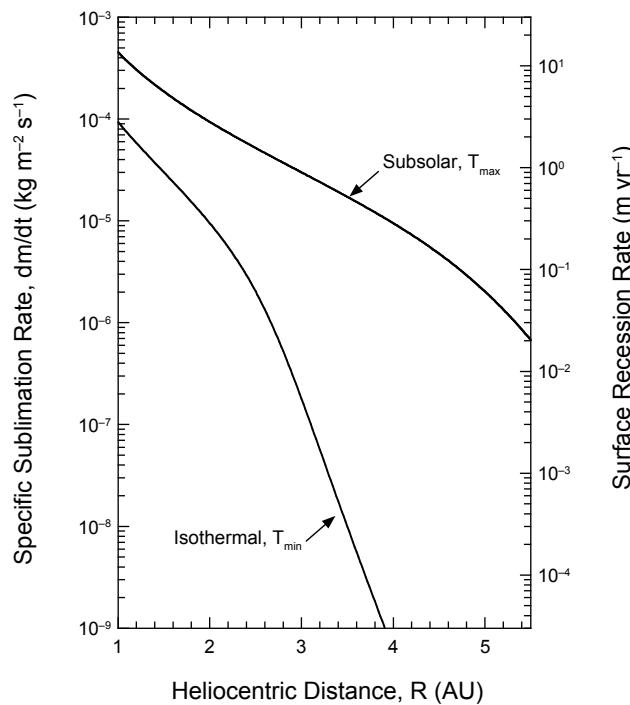

### 3.4. Sublimation of Ice

Ice exposed at the surface of an asteroid at distance  $R$  AU from the Sun will sublimate, in equilibrium, at a specific rate  $dm/dt$  ( $\text{kg m}^{-2} \text{s}^{-1}$ ), given by the solution to

$$\frac{F_{\odot}(1-A)}{R^2} \cos(\theta) = \varepsilon\sigma T^4 + L(T) \frac{dm}{dt} \quad (10)$$

where the term on the left represents the absorbed solar power per unit area, the first term on the right represents thermal radiation to space per unit area, and the second term represents the power used per unit area in breaking bonds to sublime ice.  $F_{\odot} = 1360 \text{ W m}^{-2}$  is the solar constant,  $A$  is the Bond albedo,  $\varepsilon$  is the emissivity of the asteroid, and  $L(T)$  is the latent heat of sublimation of ice at temperature  $T$ . Here  $\theta$  is the angle between the Sun and the surface normal as seen from the sublimating surface. Values of  $\cos(\theta)$  range from 1/4 (the isothermal case, corresponding to the lowest possible temperatures) to 1 (for normal illumination at the subsolar point, the maximum-temperature case). Conduction is ignored for simplicity — its effect will be to reduce  $dm/dt$  relative to the value computed from equation (10) by an amount that depends on the conductivity (measurements of small-body regoliths suggest that the conductivity is very small, so that the error incurred by its neglect should be minor). Equation (10) can be solved in combination with the Clausius-Clapeyron relation for water ice, to evaluate  $dm/dt(R)$ , as in Fig. 17. The figure also shows (on the right-hand axis) the rate of recession of the sublimating surface due to mass loss, given by  $dr/dt = \rho^{-1} dm/dt$  ( $\text{m s}^{-1}$ ).

Maximum sublimation rates vary by nearly an order of magnitude from  $\sim 10^{-4} \text{ kg m}^{-2} \text{s}^{-1}$  at 2 AU to  $\sim 10^{-5} \text{ kg m}^{-2} \text{s}^{-1}$  at 3.5 AU, corresponding to the inner and outer edges of the main belt. The corresponding surface recession rates are from a few meters to a few  $\times 0.1$  meters per year. Water ice is thermodynamically unstable when exposed to sunlight at asteroid belt distances, but can be preserved on billion-year timescales beneath meter-thick or greater layers of porous refractory debris (Fanale and Salvail, 1989; Schorghofer, 2008). Sublimation at rates sufficient to launch dust from a small body would then require that the protective regolith be removed, perhaps

**Fig. 17.** Solutions to equation (10) for the extreme cases of subsolar sublimation ( $\theta = 0^\circ$ ) and for isothermal sublimation. The righthand axis shows the rate of recession of the sublimating surface due to mass loss, given by  $dr/dt = \rho^{-1} dm/dt$  ( $\text{m s}^{-1}$ ), where  $\rho$  is the density, taken here to be  $1000 \text{ kg m}^{-3}$ . From Jewitt (2012).

by a small impact or some other disturbance of the surface. In this scenario, sublimation would proceed from an exposed region until a new refractory covering, consisting of particles too large to be lifted by gas drag (a so-called “rubble mantle”), chokes off the flow. The ratio of the lifetime of the sublimating surface patch to the interval between successive impacts (or other surface disturbances) defines the “duty cycle”,  $f_d$ . For example, the timescale for formation of a rubble mantle on a kilometer-scale body at 3 AU is estimated from a simple model (Fig. 4 of Jewitt, 2002) at  $\sim 1$  yr, increasing to 10 yr at 4 AU. The interval between impacts of meter-scale projectiles (needed to expose ice sufficient to account for the mass loss) onto this body is perhaps  $t \sim 10^4$  yr, giving  $f_d \sim 10^{-4}-10^{-3}$ . Neither the rescaling timescale nor the excavation timescale can be specified with confidence, but  $f_d \ll 1$  is assured. As noted in section 3.2, impacts at  $5 \text{ km s}^{-1}$  are highly erosive, with an ejecta to projectile mass ratio  $m_e/M \sim 3500$  for a 1-km target asteroid (equation (6)). At this rate, the asteroid can survive for  $\sim 10^9$  yr.

### 3.5. Radiation Pressure Sweeping

Particles lifted above the surface of an asteroid are susceptible to solar radiation pressure and, if sufficiently small, can be blown away. The critical size for radiation pressure sweeping on a nonrotating asteroid is (Jewitt, 2012)

$$a_\beta (\mu\text{m}) = 10 \left( \frac{1 \text{ km}}{r_n} \right) \left( \frac{1 \text{ AU}}{R} \right)^2 \quad (11)$$

At  $R = 3 \text{ AU}$ , a 1-μm-radius grain detached from the surface (by any process) can be blown away from a nonrotating asteroid 1 km in radius.

### 3.6. Electrostatics and Gardening

Dielectric surfaces exposed to ionizing (UV and X-ray) solar radiation develop a positive electric potential (of perhaps 5 to 10 V) through the loss of photoelectrons. Conversely, electrons impacting in shadowed regions imbue a locally negative potential. The resulting electric fields near shadow boundaries can grow large enough ( $\sim 10 \text{ V m}^{-1}$  to  $100 \text{ V m}^{-1}$ ) to mobilize dust. On the Moon, horizon glow (Rennilson and Criswell, 1974) and dust impact counter experiments (Berg et al., 1976) show that charging effects near the terminator lift 10-μm-sized dust particles to meter heights and greater, at implied ejection speeds,  $\sim 1 \text{ m s}^{-1}$ . Smooth dust ponds on asteroids strongly suggest electrostatic mobilization (but not ejection) of grains in a much-lower-gravity environment (Poppe et al., 2012; see also the chapter by Murdoch et al. in this volume).

On small asteroids, electrostatic forces can potentially accelerate particles to speeds exceeding the gravitational escape speed. To within a numerical factor on the order of unity, particles smaller than a critical radius

$$a_e (\mu\text{m}) \sim 2 \left( \frac{1 \text{ km}}{r_n} \right) \quad (12)$$

can be electrostatically ejected against gravity from a nonrotating body of radius  $r_n$  (Jewitt 2012).

Larger particles are too heavy to lift against gravity, at least on a nonrotating body, whereas smaller particles are trapped by cohesive forces on the surface (Hartzell and Scheeres, 2011). Electrostatically ejected particles should therefore be confined to a narrow range of sizes near  $a_e$ . Note that equation (12) is independent of the heliocentric distance because the potential,  $V$ , depends on photon energy, not flux. Since, in the asteroid belt at 2–3 AU,  $a_e \leq a_\beta$ , particles launched electrostatically should be picked up by solar radiation pressure and propelled into comet-like dust tails.

Although electrostatic ejection must operate at some level, in practice the rate of loss of small particles from an asteroid will be limited by the rate of their production, presumably by micrometeorite bombardment. This distinguishes the role of electrostatics on the asteroids from the circumstance on the Moon, where ejected particles fall back to the surface under the high lunar gravity, to be repeatedly relaunched at each terminator crossing (Berg et al., 1976).

We crudely limit the ejected mass flux from asteroids as follows. On the Moon, impact overturn of the regolith (“gardening”) reaches to depths  $\delta r \leq 1 \text{ m}$  on timescale  $t = 1 \text{ G.y.}$  (Gault et al., 1974). Impact-produced fragments that

are largely retained on the Moon by gravity will, on the small asteroids, be immediately lost. Therefore, a strong upper limit to the electrostatic mass loss from asteroids can be obtained by assuming that the gardening rates are comparable and that none of the gardened layer is retained. The mass loss rate from a spherical asteroid is  $dM/dt \sim 4\pi r_n^2 \rho \delta r/t$ , where  $r_n$  is the radius and  $\rho$  is the density. For an  $r_n = 1\text{-km}$  asteroid with  $\rho = 2000 \text{ kg m}^{-3}$  and  $\delta r = 1 \text{ m}$ , this gives  $dM/dt \leq 10^{-6} \text{ kg s}^{-1}$ . This is 4 to 6 orders of magnitude smaller than the mass loss rates inferred from observations of active asteroids (Table 2). Of course, we cannot exclude spatially or temporally enhanced micrometeorite impact fluxes in the asteroid belt, but enhancements sufficient to bring the mass loss rates up to those in Table 2 seem unlikely. The only observation possibly supporting the existence of widespread, very low level mass loss is by Sonnett et al. (2011). If this observation is confirmed, it might be evidence for very low level ejection of dust owing to gardening losses, possibly assisted by electrostatic effects.

### 3.7. Observational Diagnostics

Diagnosing the cause of mass loss from any particular object is difficult, both because of limitations of the data and because of uncertainties in models of the mass loss mechanisms. It is often easier to rule out possible explanations than to rule them in. Spectroscopic detections of water vapor or another sublimation product would provide the most solid evidence of sublimation-driven activity, but such evidence has only been obtained for Ceres (Küppers et al., 2014). Unsuccessful attempts have been made to detect water vapor or CN emission from several other active asteroids (e.g., Jewitt et al., 2009; Licandro et al., 2011a, 2013; Hsieh et al., 2012a,b,c, 2013; de Val-Borro et al., 2012; O’Rourke et al., 2013). Typical derived upper limits to gas loss rates are  $\leq 1 \text{ kg s}^{-1}$ . Unfortunately, the significance of these nondetections is inconclusive, for two reasons. First, CN is a prominent trace species in the spectra of Kuiper belt and Oort cloud comets (with  $\text{H}_2\text{O}/\text{CN} \sim 360$ ); it might be strongly depleted in icy asteroids. Second, spectra are typically obtained long after continuum observations have revealed the mass loss — the gas could simply have escaped on a timescale short compared to the radiation pressure sweeping time for dust.

Another potential indicator is the recoil (or “rocket”) acceleration produced on the nucleus by anisotropic sublimation. Specifically, a nongravitational acceleration,  $\alpha$ , implies a mass loss rate

$$\frac{dM}{dt} = \frac{\alpha M_n}{f_\theta v_0} \quad (13)$$

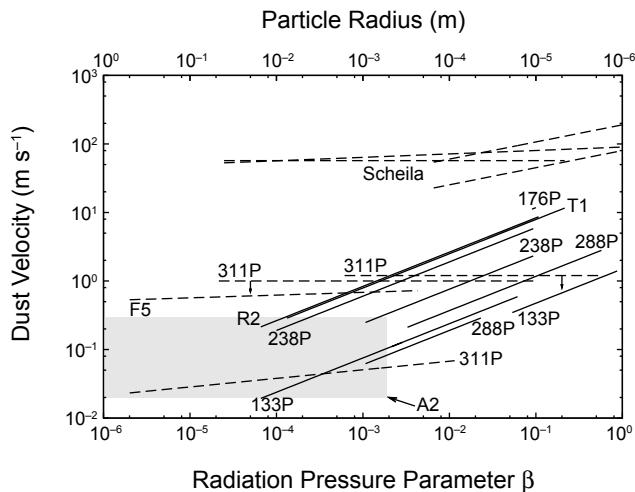

where  $M_n$  is the mass of the nucleus and  $v_0$  is the velocity of the material ejected. Dimensionless parameter  $f_\theta$  accounts for the directional pattern of the mass loss, with  $f_\theta = 0$  and 1 corresponding to isotropic and perfectly collimated ejection, respectively. In fact, nongravitational acceleration of 133P at  $\alpha = 2.5 \times 10^{-10} \text{ m s}^{-2}$  has been reported (Chesley

*et al.*, 2010), albeit with only  $3\sigma$  statistical significance. To obtain the smallest possible estimate of  $dM/dt$  from equation (13), we maximize  $f_0 = 1$  and use the sound speed in H<sub>2</sub>O gas at the blackbody temperature appropriate to 3 AU, namely  $v_0 = 500$  m s<sup>-1</sup>. Approximated as a sphere of radius 2.2 km and density 1000 kg m<sup>-3</sup>, the nucleus mass is  $M_n = 4 \times 10^{13}$  kg, giving  $dM/dt \sim 20$  kg s<sup>-1</sup>. This rate exceeds the dust production rates measured in 133P by 2 to 3 orders of magnitude, forcing us to conclude either that  $\alpha$  has another cause or that the reported value should be considered only as an upper limit. *Nugent et al.* (2012) measured small semi-major axis drift rates in 42 near-Earth asteroids consistent with the Yarkovsky (radiation) acceleration. An additional 12 asteroids showed drift rates too large to be explained by the Yarkovsky effect. If confirmed, the accelerations of these asteroids, none of which is a known active asteroid, might suggest anisotropic mass loss.

Less-direct inferences can be made in the absence of spectroscopic detection of gas. Activity that repeats on the orbital timescale, as in 133P and 238P, is naturally explained only by sublimation. A prolonged period of dust emission is also suggestive of sublimation and difficult to explain as the result of a simple impact. However, prolonged emission may not be unique to sublimation. Evidence from 311P shows that mass shedding can continue for months, raising the potential for confusion with protracted emission caused by sublimation. The size vs. velocity relation for ejected dust particles also differs between mechanisms, with gas drag giving  $v \propto a^{-1/2}$ , where  $a$  is the dust radius, and rotational instabilities and impact giving a flatter dependence (Fig. 18).

Sublimation will preferentially lift small, micrometer-sized particles that are quickly dispersed by radiation pressure. Objects typically have a bright coma and tail for a few months, as long as the sublimation is ongoing, followed by a rapid fading and return to the appearance of a point source. During rotational breakup, the ejecta sizes are not constrained at all, due to the compensation of gravity by the centrifugal force. Also, impacts are expected to excavate much larger pieces of debris, depending on the escape speed from the parent body. Characteristically, small objects suspected to have undergone an impact or rotational breakup display long-lived trails of centimeter- to meter-sized debris along their orbits for many years after the event, because such large grains are not efficiently removed by radiation pressure. (596) Scheila, although clearly impacted, did not develop a debris trail because the high escape speed prevented the ejection of large debris. The absence of debris trails in sublimation-driven active asteroids is different from comets, likely because cometary sublimation is much stronger and is also able to lift large debris.

Numerical modeling is necessary because the appearance of long-lived activity can be produced either by the lingering of large, slow-dissipating dust grains, or the ongoing replenishment of small, fast-dissipating dust grains. Under the right conditions, however, dust modeling can break this degeneracy and give us insights into the origin of active asteroid activity (e.g., *Hsieh et al.*, 2004; *Ishiguro et al.*, 2011b; *Agarwal et al.*, 2013).

**Fig. 18.** Dust ejection velocities as function of the radiation pressure coefficient  $\beta$  or particle size. The plot is a compilation of published models for individual objects. Such models typically simulate the motion of dust grains ejected from the nucleus over a range of times, particle sizes, and velocities. The best-fitting parameters are determined from comparison with the observed shapes of the dust tails. Solid lines indicate objects with protracted, likely sublimation-driven dust emission; dashed lines and the shaded area for P/2010 A2 refer to objects with impulsive emission. Arrows indicate upper limits; the shaded area for P/2010 A2 illustrates that particles of all sizes were ejected with the same range of velocities.

Pinpointing cases of rotational instability can be difficult because there are few clear predictions about the likely appearances of such bodies. The repeated dust ejections from 311P, for example, can be reconciled with a rotational shedding instability, but it is quite likely that a range of morphologies and time-dependent emission profiles can be produced by this mechanism. Significantly, other mechanisms seem incompatible with the observations. The multiple object P/2013 R3 is self-evidently a result of breakup, with rotation as the likely cause.

Table 3 summarizes our conclusions about the mechanisms driving activity in each object. For many objects, we can eliminate several processes but cannot isolate a unique cause. This partly reflects the inadequacies of the data, but is also a true consequence of the nature of the activity. For example, in those cases where sublimation is believed to be the primary activity driver, an impact (or other disturbance) may be needed to excavate buried ice to trigger sublimation, and mass loss may be assisted by rapid rotation. We emphasize that, in many cases, the entries in Table 3 are expected to change with the acquisition of new data.

### 3.8. Distribution

The orbital distribution of the active asteroids may provide a clue as to the activity mechanisms. There is apparent clustering of active asteroids in Fig. 2 in the outer belt near

TABLE 3. Summary of mechanisms.

a  $\sim 3.1 \pm 0.1$  AU. Of the 13 active asteroids orbiting in the main belt, only two (P/2010 A2 and 311P) are located inside the 3:1 mean-motion resonance with Jupiter ( $a = 2.5$  AU), corresponding to  $\sim 15\%$  of the total, while for the asteroids as a whole, this ratio is  $\sim 35\%$ . However, the difference between these distributions is not significant. A Kolmogorov-Smirnov (K-S) test applied to compare the semimajor axes of the active asteroids and the first 500 numbered asteroids shows that the distributions have a 17% probability of being drawn from the same parent distribution and therefore are consistent. However, when the comparison is made between the distribution of the semimajor axes of active asteroids and of main-belt asteroids of comparable size, the difference instead becomes highly significant. Specifically, there is  $<0.1\%$  likelihood that active asteroids and main-belt asteroids with absolute magnitude  $H > 18$  are drawn from the same parent population, according to the K-S test. This different result occurs because of observational bias in magnitude-limited sky survey data, which strongly inhibits the detection of small asteroids in the outer belt. While the active asteroids are subject to this same bias, their detectability is also influenced by their activity, as is evident from the fact that many objects (e.g., P/2010 A2, 311P, P/2013 R3) were unknown before being discovered in an active state. We conclude that the relative paucity of active asteroids in the inner belt and the concentration near 3.1 AU are real, but larger samples from quantitative sky surveys will be important to better assess the biases. Clustering could suggest an origin as collisionally produced fragments of an ice-rich precursor (Novacović et al., 2012, 2014).

#### 4. DYNAMICS

Numerical simulations have been conducted to assess the long-term dynamical stability of many of the known active asteroids (e.g., Jewitt et al., 2009; Haghishipour, 2009; Hsieh et al., 2012a,b,c, 2013; Stevenson et al., 2012). This is of particular interest in the context of understanding whether ice-bearing main-belt comets are native to the asteroid belt or are implanted interlopers from the outer solar system. In most cases, while the median dynamical lifetime of short-period comets before ejection from the solar system or collision with the Sun was found to be  $\sim 5 \times 10^5$  yr (Levison and Duncan, 1994), active asteroids in the asteroid belt have been found to be stable over timescales of  $10^8$  yr or longer. 238P and 259P are notable exceptions, however, having been found to be unstable on timescales on the order of  $\sim 10^7$  yr (Jewitt et al., 2009; Haghishipour, 2009).

Fernández et al. (2002) forward-integrated the orbits of test particles representing the 202 Jupiter-family comets (JFCs) known at the time and several dynamical clones of each comet (using purely gravitational computations). None ended up on orbits with both low eccentricity and low inclination like that of 133P. Comet 503D/Pigott was seen to evolve onto a main-belt orbit, but with high inclination. Interestingly, we know now of active asteroids in the main belt with high inclinations (e.g., 259P and P/2010 R2), and so the possibility that these could be JFC interlopers cannot be excluded. In the same work, it was shown that detaching objects from the JFC population was possible with the inclusion of nongravitational forces in the simulations, but

such large forces were needed as to be unrealistic. The size dependence of nongravitational forces plays a role in this, since nongravitational forces should be far less effective for larger objects, while smaller objects may not be able to sustain such large nongravitational forces for very long without disintegrating or exhausting their volatile content.

The aforementioned simulations assume the modern-day architecture of the solar system. Some dynamical models of the early solar system suggest that planet migration could have resulted in the emplacement of icy outer solar system objects in what is now the main asteroid belt (e.g., Levison *et al.*, 2009; Walsh *et al.*, 2011), although probably not in low-inclination orbits like those of many active asteroids. Therefore, particularly when assessing the astrobiological significance of icy active asteroids as indicators of the composition of the inner protosolar disk, the possibility that these objects could have been implanted at early times must continue to be considered (see the chapter by Morbidelli *et al.* in this volume).

Several active asteroids are associated with collisional asteroid families and clusters. For example, four active asteroids (133P, 176P, 238P, and 288P) have been linked to the Themis family either currently or in the past (Tóth, 2000; Hsieh, 2009; Haghjipour, 2009; Hsieh *et al.*, 2012c), while P/2010 A2 and 311P are associated with the Flora family (Moreno *et al.*, 2010; Jewitt *et al.*, 2013c) and P/2012 T1 and 313P with the Lixiaohua family (Hsieh *et al.*, 2013, 2015b). The dynamical associations are consistent with photometry showing, for example, that the colors of 133P, 176P, and 238P are close to those of the Themis family (Licandro *et al.*, 2011a), while those of 311P are consistent with membership in the Flora family (Jewitt *et al.*, 2013c). However, dynamical associations are unsurprising, given that many asteroids are family members, and a causal relationship between family membership and activity cannot be assumed. The color relationships could also be coincidental, since S-types are common in the inner belt where P/2010 A2 and 311P are found, and C-types in the outer belt where 133P, 176P, 238P, and 288P orbit. However, several active objects have also been linked to much smaller, young asteroid clusters, including 133P [part of the <10-m.y.-old Beagle family (Nesvorný *et al.*, 2008)], 288P [part of a newly discovered  $7.5 \pm 0.3$ -m.y.-old cluster (Novaković *et al.*, 2012)], and P/2012 F5 [part of a  $1.5 \pm 0.1$ -m.y.-old cluster (Novaković *et al.*, 2014)]. In the case of active asteroids exhibiting sublimation-driven activity, membership in a young cluster suggests a natural mechanism by which ice could have been preserved over long timescales (i.e., within the interior of a larger parent body) and only recently exposed to more direct solar heating. In the case of objects exhibiting impact-induced activity, an associated young cluster could represent both a source of potential impactors (given that cluster members will share very similar orbits) and possibly a consequence of residing in a region of the asteroid belt characterized by high collision rates (e.g., Novaković *et al.*, 2014).

## 5. SURVEYS AND RATES

About 10 of the known active asteroids (Table 1) and  $\sim 10^6$  main-belt asteroids (Jedicke and Metcalfe, 1998) are larger than 1 km. The ratio of these numbers gives an active fraction, for all types of activity-driving mechanism,  $f \sim 10^{-5}$ . However, most asteroids fall near the limiting magnitudes of the surveys in which they are discovered and so are never effectively searched for dust emission. Therefore,  $f \sim 10^{-5}$  sets a strong lower limit to the active fraction, since many active objects must go undetected. Recent, dedicated surveys have attempted to remedy this situation by searching for comae in well-defined sky surveys. Unfortunately, most of these surveys are so small in scale that they detect no active objects [of the known active asteroids, only (118401) LINEAR (1999 RE<sub>70</sub>) was discovered as the result of a targeted survey], allowing  $3\sigma$  upper limits,  $f_{3\sigma}$ , to be determined. These include  $f_{3\sigma} \leq 54$  per million (Gilbert and Wiegert, 2009, 2010),  $f_{3\sigma} \leq 6000$  per million (Sonnett *et al.*, 2011), and  $f_{3\sigma} \leq 50$  per million (Waszczak *et al.*, 2013). These surveys were based on the attempted detection of spatially resolved coma. Cikota *et al.* (2014) instead used photometry to search for the brightening produced by the ejection of dust, finding five candidates from a search of  $\sim 75$  million observations of  $\sim 300,000$  asteroids. These candidates remain unconfirmed and it is not clear which method, resolved imaging vs. integrated photometry, offers the better sensitivity to mass loss.

Hsieh *et al.* (2015a) concluded from a sample of 30,000 objects observed near perihelion (giving two detections) that  $f \sim 100$  per million (in the outer belt), which we take as the best current estimate of the fraction of asteroids that are measurably active at any instant. This is still a lower limit to the true active fraction, in the sense that the surveys are sensitivity limited, and it is likely that more evidence for mass loss could be found by increasing the sensitivity. Sonnett *et al.* (2011) hint at this possibility by finding statistical evidence for comae in the averaged profiles of many asteroids, although not in any individual object. If real, their detection may point to electrostatic or gardening dust losses, or some other process acting broadly across the asteroid belt.

Of the present sample, at least four active asteroids are likely to be driven by outgassing (133P, 238P, 313P, and 324P), based on activity repeated in different orbits, corresponding to a fraction  $\geq 20\%$ . The fraction of sublimation-driven objects is therefore on the order of  $f \geq 20$  per million. The fraction of asteroids that contain ice,  $f_{ice}$ , could be much larger. We write  $f_{ice} = f/f_d$ , where  $f_d$  is the duty cycle, equal to the fraction of time for which the average asteroid loses mass. In the ice-excavation model described earlier,  $f_d$  is the ratio of the lifetime of an exposed ice patch to the interval between exposures (caused by boulder impacts?) on the same body. The present level of ignorance about  $f_d$  allows the possibility that  $f_{ice} = 1$ , meaning that potentially all asteroids could contain ice without violating the survey

limits. This surprising result indicates that the dividing line between comets and asteroids may be considerably less sharp than once supposed.

---

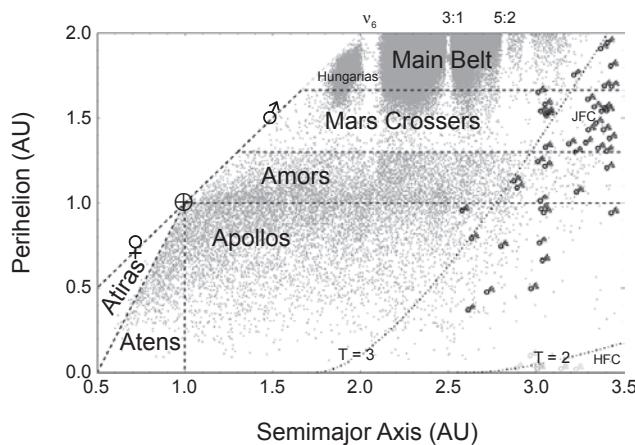

Near-Earth objects (NEOs) owe their origins to both the main-belt asteroids and comets. They include (by definition) precursors for all meteorite samples. Thus understanding NEO connections is central to the modern study of small bodies in our solar system and serves as the principal focus of this chapter. Herein we also briefly highlight how the proximity of near-Earth objects enables detailed study of the smallest known and most accessible natural objects in space, and we provide links to other chapters addressing these aspects more fully. The success of Japan's Hayabusa mission sample return yields a definitive link between the most common class of near-Earth asteroids and one of the most common meteorites, a watershed whose ground truth enables a deeper level of understanding and new questions. We can now investigate the near-Earth population to pinpoint specific main-belt source regions for broad taxonomic classes and specific meteorite types in addition to estimating the extinct comet contribution. Spectral properties combined with long-term orbital modeling reveal a strong role played by planetary encounters to resurface (and likely reshape) many objects. Outstanding puzzles remain for many of the newly revealed details; their resolution will generate new insights to the basic physical processes governing small bodies.

## 1. INTRODUCTION

Few topics within the field of asteroid studies garner more widespread attention than the near-Earth population. Many reasons motivate this attention, including: (1) These are the objects that (by definition) are capable of impacting Earth, thereby delivering meteorites (many times annually) and civilization-threatening impacts (centuries to geologic time-scales). (2) These are the most accessible spaceflight destinations for both robotic and human missions, including foreseeable in-space resource utilization. (3) The population is dynamic in terms of its ongoing resupply from both main-belt asteroid and comet sources, where such resupply must occur because planetary encounters have long ago depleted the initial population. (4) Individual objects, ranging from meter-scale to tens of kilometers (12 orders of magnitude in mass), find themselves susceptible to a diverse range of physical processes involving their response to external factors such as solar flux and impacts. (5) Their proximity to Earth observers allows a variety of observational techniques through which their resolved shapes, surface properties, and diverse physical configurations can be revealed.

In the most general terms, we refer to this population as near-Earth objects (NEOs) rather than near-Earth asteroids (NEAs) to recognize that both asteroid and comet origins are possible. NEAs is an applicable term when considering them as inert bodies (not outgassing), recognizing that a dormant or extinct comet can masquerade as an "asteroid." As discussed in the chapter by Jewitt et al. in this volume, the reality is likely a continuum of properties spanning from volatile-rich to volatile-poor objects for which defining their provenance may be extraordinarily complex (see the chapter by Morbidelli et al. in this volume). Thus the simple label of "asteroid" or "comet" is inadequate for the intricacy of the problem. Nevertheless, the opportunity remains wide open for ongoing descriptive investigations.

The basics, what one might call the ABCs of NEOs, are described in many sources (e.g., Binzel et al., 2002; Morbidelli et al., 2002; see the chapter by Morbidelli et al. in this volume). Here we summarize for convenience that the population is often subdivided in terms of its orbital properties (Shoemaker et al., 1979), where these orbital categories are depicted in Fig. 1. (Each category is typically named for one of the earliest discovered and named objects

**Fig. 1.** Orbital distribution of the near-Earth object population delineating the boundaries for traditionally named regions, defined in section 1. Symbols for the planets Venus, Earth, and Mars are plotted at their locations for circular orbits. Curved lines correspond to Tisserand parameter ( $T$ ) values equal to 2 and 3, respectively, for the case of zero orbital inclination. Symbols plotting near  $T = 3$  indicate low inclination ( $<10^\circ$ ) Jupiter-family comets (JFC), while those near  $T = 2$  are Halley-family comets (HFC). The main-belt and Mars-crossing objects plotted correspond to numbered objects, while all  $\sim 12,000$  presently known near-Earth objects are depicted. Additional labels along the top of the figure denote main-belt locations described in section 3 that may be source regions for the near-Earth population, including meteorites. (The  $v_6$  resonance location is for the case of zero orbital inclination.)

therein.) Earth's orbit serves as the dividing line among the categories, taking into account its 1.7% noncircularity (eccentricity,  $e$ ). Amor asteroids are those whose perihelia ( $q$ ) are greater than 1.017 AU but less than 1.3 AU, thus at all times orbiting beyond Earth. Apollo asteroids do intersect Earth's orbit by having semimajor axes ( $a$ ) greater than 1 AU with  $q \leq 1.017$  AU, noting the relationship  $q = a[1-e]$ . About 90% of all discovered NEOs are in the Amor and Apollo categories. Aten asteroids intersect with Earth's orbit from "the inside out" by having  $a < 1$  AU and aphelia ( $Q$ , where  $Q = a[1+e] > 0.983$  AU). For asteroids entirely interior to Earth's orbit (IEOs), the category "Atira" is often applied. Tholen and Whiteley (1998) originally called these "Apohelia" objects; the first discovered is now numbered and named (163693) Atira. One additional class, not yet discovered but possibly residing entirely interior to Venus' orbit, are called "Vatiras" by Greenstreet *et al.* (2012). Less strictly defined are the Mars-crossing asteroids, but generally denoted as objects having  $a > 1.3$  and  $1.3 \leq q < 1.665$  AU, where the larger value is roughly the aphelion distance of Mars.

Closer to home, "co-orbitals" is the name given to NEOs in similar orbits to Earth (having  $a \approx 1$ ), where the largest example object is (3753) Cruithne (Wiegert *et al.*, 1997). In a rotating coordinate frame (keeping the Earth-Sun line fixed),

co-orbitals appear to move in a "horseshoe-like" pattern relative to Earth. Occasionally these objects are temporarily captured as natural satellites of Earth, in which case they are colloquially called "mini-Moons" (Granvik *et al.*, 2012; Bolin *et al.*, 2014). To date only one object, 2006 RH<sub>120</sub>, is known to have been temporarily captured. Longer-term stability is possible near the Earth-Sun Lagrange points in a 1:1 orbital resonance with Earth, where 2010 TK<sub>7</sub> is the first (and at present only) known "Earth Trojan" (Connors *et al.*, 2011). Mainzer *et al.* (in this volume) describe the advantages of spacebased satellites for the ongoing discovery and characterization of Earth co-orbitals. As discussed by in the chapter by Abell *et al.* in this volume, the proximity and easy accessibility in terms of low rocket propulsion requirements make co-orbital objects of particular interest for future human exploration and possible space resource utilization.

In this chapter we focus on the ways in which the near-Earth population intersects with asteroid, comet, and meteorite studies in terms of compositional understanding. In particular, we investigate whether the current data provide a coherent picture for how meteorites link to NEOs, and in turn, how NEOs link to their main-belt and comet origins. In many cases over the past decade or longer, increasing the available data has seemed to confound the questions rather than illuminate their solution. Yet the successful near-Earth asteroid sample return by the Japanese Hayabusa mission (Nakamura *et al.*, 2011; see the chapter by Yoshikawa *et al.* in this volume) has been the singular most important achievement for advancing asteroid-meteorite connections in the last decade and for sharpening where significant questions remain. Table 1 presents a summary of the current status for a few of these overarching questions.

Our focus on the interrelationships of the near-Earth population leaves to other chapters many of the topics outlined at the top of this section. For example, impact hazards are addressed by in the chapter by Harris *et al.* in this volume, and the role of NEAs toward the future of human spacefaring is covered in the chapter by Abell *et al.* in this volume. Physical properties of NEOs, whose proximity makes them the currently available sample of observable solar system bodies at sizes below  $\sim 1$  km (and as small as a few meters), are addressed throughout this volume. Close range is an enormous advantage for the study of objects by radar, where the application of radar to asteroid science was pioneered by S. J. Ostro. As detailed in the fundamentals given by Ostro *et al.* (2002), the measured radar signal strength has a  $R^{-4}$  dependence, where  $R$  is the observer-to-target distance. As described in the chapter by Benner *et al.* in this volume, more than 500 members of the NEO population have been observed to date using radar (a total that has dramatically increased since the time of *Asteroids III*). Radar results corroborate the diversity of properties we describe here. Particularly interesting are indications that surface roughness (as measured by radar circular polarization ratios) shows some correlation with an asteroid's taxonomic class (Benner *et al.*, 2008).

Studies of the thermal properties of the smallest bodies observable among NEOs (see the chapter by Delbo *et al.* in

TABLE 1. Resolved and outstanding questions for linking the near-Earth object population.

Question	Status	Next Steps	Section
Do NEOs represent the main belt as their predominant source region?	Yes. Confirmed by comparing the distribution of taxonomic types and by specific mineralogical links to the main belt, including asteroid families.	Further investigate the delivery efficiencies of different main-belt regions and how they are reflected in the NEO population.	2.1, 3.1, 3.2, Fig. 2, Fig. 3, Fig. 5
Are the most common meteorites (ordinary chondrites) related to the most common S-type NEOs?	Yes. Confirmed by Hayabusa sample return.	Further investigate whether the H, L, and LL ordinary chondrite fall statistics can be reconciled with the observed NEO population.	2.2, 3.1, Fig. 3, Fig. 4
Does space weathering exist as a significant spectral alteration process on NEOs?	Yes. Confirmed by Hayabusa sample return.	Clarify the timescale for space weathering and how its effects depend on composition.	2.2, 2.3, Fig. 4
Are planetary encounters a major factor in NEO physical evolution?	Yes. Confirmed by spectral correlation with encounter probability.	Further advance the studies of geophysical and seismic responses to tidal and impact stresses in small bodies as a tool for deducing NEO internal structures. Further advance understanding of the role of thermal spin-up for frequent resurfacing.	2.3
Does our current census of the NEO population accurately account for the abundance of low-albedo objects?	Not yet. Results appear to be converging toward ~35% for the low-albedo proportion.	Future infrared surveys. Further analysis of the efficiency for delivery of bodies from the inner and outer asteroid belt. Full consideration of the effects of shock darkening.	3.2
Are extinct (inactive) comets present in the NEO population?	Likely, as evidenced by the apparently “primitive” (low-albedo and assumed carbon-rich) compositions dominating “asteroids” in comet-like NEO orbits.	Achieve sample returns from apparently primitive NEOs. Further advancements in spectral studies evaluating the volatile content of comet candidates.	3.4, Fig. 5
Can discovery surveys and fireball networks augment asteroid-meteorite and asteroid-comet links?	Almost certainly. One pre-atmospheric example to date: 2008 TC <sub>3</sub> yielded Almahatta Sita meteorites. Sutter Mill meteorite orbit similar to Jupiter-family comets.	Rapid telescopic reconnaissance response to future “incoming” discoveries in concert with dedicated meteorite recovery efforts. Further advance the debiased discovery of low-albedo NEOs to inform the comet fraction.	4

this volume) reveal their tendency to have relatively high thermal inertias. This increased thermal inertia (meaning a slower rate of surface temperature rise or fall) is attributed to the diminished ability to retain regolith in their lower-gravity regimes. (Ejection velocities of excavated material from cratering impacts easily exceed the low escape velocity.) Thus the increased thermal inertia results because the “bare rock” has more mass than any individual fine grain, and consequently requires a longer time to absorb enough solar energy to raise its temperature. The corresponding thermal reradiation to cool the surface (and reach an equilibrium temperature) has significant consequences for both the rotational and orbital evolution of small bodies (see the

chapter by Vokrouhlický et al. in this volume). In fact, the rotations and spin vectors of these smallest asteroids appear to be driven by thermal reradiation, where their maximum spin rate [the so-called “spin barrier” described by Pravec and Harris (2000); see the chapter by Scheeres et al. in this volume] is indicative of their limiting strength. What’s more, the rotational evolution history of experiencing a rapid rotation at some prior epoch appears to strongly influence the shape and configuration of small bodies. This is evidenced by the presence of equatorial ridges revealed by radar (see the chapter by Benner et al. in this volume) and the abundance of binaries within the NEA population (see the chapters by Margot et al. and Walsh and Jacobson in this volume).

## 2. OVERVIEW OF NEAR-EARTH OBJECT OBSERVATIONS

Asteroid studies have entered a new age since the epoch of *Asteroids III*, perhaps most profoundly exemplified by the order of magnitude growth in the discovered NEO population from ~1200 objects in 2001 to ~12,000 in 2015 (see the chapter by Jedicke et al. in this volume). Spacebased surveys have similarly shown their potential for the coming decades by yielding albedos and diameters for nearly 1000 NEOs (see the chapter by Mainzer et al. in this volume). The turn of the millennium also coincided with a turning point in astronomical instrumentation for measuring asteroids in reflected and thermally reemitted solar flux. This turning point includes the advent of near-infrared array spectrometers (for example, as developed by Rayner et al., 2003) with high quantum efficiency sensitivity over the range ~0.7–2.5 μm, the spectral region containing absorption bands diagnostic of pyroxene and olivine mineralogies common in asteroids and meteorites (see the chapter by Reddy et al. in this volume). The first broadscale outcome was the expansion and refinement of asteroid taxonomy that began with U, B, V filter photometry (Bowell and Lumme, 1979; *Asteroids*), continuing with eight-color filter photometry (Tholen and Barucci, 1989; *Asteroids II*), visible wavelength CCD spectroscopy (Bus et al., 2002; *Asteroids III*), and then extended to the near-infrared in the Bus-DeMeo taxonomy system (DeMeo et al., 2009; see the chapter by DeMeo et al. in this volume). A second major outcome ushered in by the availability of near-infrared measurements was the extensive application of mineralogical modeling and interpretation to the near-Earth asteroid population (e.g., Vernazza et al., 2008; Thomas and Binzel, 2010; Dunn et al., 2013). We review the taxonomic distribution of the NEO population in section 2.1 and describe the results and current challenges in their mineralogical modeling in section 2.2. The detector advances enabling ground-based and spacebased thermal flux measurements (yielding albedos and diameters) as a part of the “new millennium turning point” further illuminating our understanding of the NEO population are discussed in section 3.2 and detailed in the chapter by Mainzer et al. in this volume.

### 2.1. TAXONOMIC DISTRIBUTION OF THE NEAR-EARTH OBJECT POPULATION

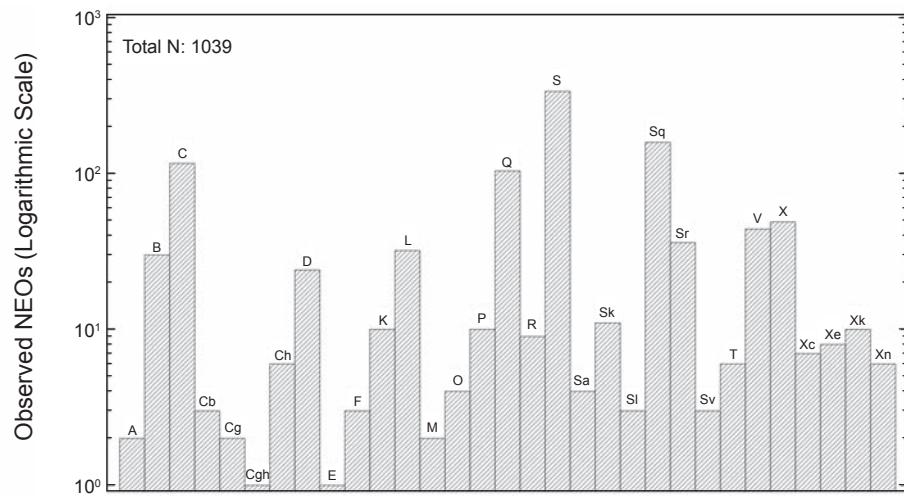

Apart from an asteroid’s measured brightness (see the chapter by Li et al. in this volume), the “color” of an asteroid is the most common physical parameter to be determined. For the near-Earth population, sufficient filter photometry or spectroscopic information is available to characterize about 10% of all currently catalogued objects, no small feat given the expanding rate of discovery (Galache et al., 2015). Binzel et al. (in preparation, 2015) summarize one of many spectroscopic survey efforts conducted using the NASA Infrared Telescope Facility (IRTF). They include in their tabulation results many other substantial characterization efforts focused towards NEOs (e.g., Tholen and Barucci, 1989;

Whiteley, 2001; Angeli and Lazzaro, 2002; Rivkin et al., 2005; Fevig and Fink, 2007; Licandro et al., 2008; de Leon et al., 2010; Lazzarin et al., 2008; Somers et al., 2010; Ye, 2011; Hasselmann et al., 2012; Hicks et al., 2012; Reddy et al., 2012; Sanchez et al., 2013; Kuroda et al., 2014; Thomas et al., 2014.). An online database of published NEO physical properties is maintained at <http://earn.dlr.de/neal/> and is an excellent resource for determining the original citation for specific characterization results. All totaled, more than 1000 taxonomic classifications are currently available, tripling the *Asteroids III* summary (Binzel et al., 2002). As discussed in the chapter by Reddy et al. in this volume, the taxonomic classification produced by these measurements is only a first step toward understanding an object’s composition. Herein we affirm that any compositional suggestion from taxonomy is an interpretation, not a certainty; taxonomy is not a substitute for detailed mineralogical analysis.

With this caveat, we first look at the observed distribution of NEO taxonomic classes and explore their potential sources. As depicted in Fig. 2, NEOs do in fact represent the full range of classes observed across the main belt, presenting the strongest circumstantial evidence for this transitional region of our solar system being the predominant supplier of the near-Earth population. The broad proportions of the NEO distribution matches the inner main-belt asteroids as well (Gradie and Tedesco, 1982), where in both cases the S-class asteroids are the most commonly observed. Including all the S-type subclasses, more than half of all measured NEOs fall into the broad “S-complex” (DeMeo et al., 2009). Other broad categories, the C- and X-complexes, account for ~15% and 10% of the observations. These latter values are surprisingly low proportions compared with the main belt, but this is due to observational bias that comes from magnitude-limited surveys: Higher-albedo objects are the easiest to detect and measure even if they are relatively small. Bias effects are discussed below.

The longstanding outlier between the main-belt and near-Earth populations is the Q-class, which to date remains rarely observed in the main belt (Mothé-Diniz and Nesvorný, 2008; Thomas et al., 2012). Initially recognized as unique to (1862) Apollo yet spectrally similar to the most commonly falling meteorites [ordinary chondrites (McFadden et al., 1985)], Q-class NEOs now comprise about 10% of the observed population. As discussed below (sections 2.2 and 2.3) and outlined in Table 1, the relative proportions of S- and Q-class asteroids and their meteorite relationship has been one of the longest-standing questions in asteroid science.

Essential to any discussion of an observed distribution (Fig. 2) is the question of what bias effects lurk within. For example, both discovery and spectroscopic surveys employ astronomical techniques and are thus magnitude limited. For the power-law distribution of asteroids (greater numbers with decreasing sizes; see the chapter by Bottke et al. in this volume), at any magnitude limit there are (for example) substantially more high-albedo S-type asteroids accessible for sampling than lower-albedo classes. For NEOs, the most direct consequence is the underrepresentation of C-type (and

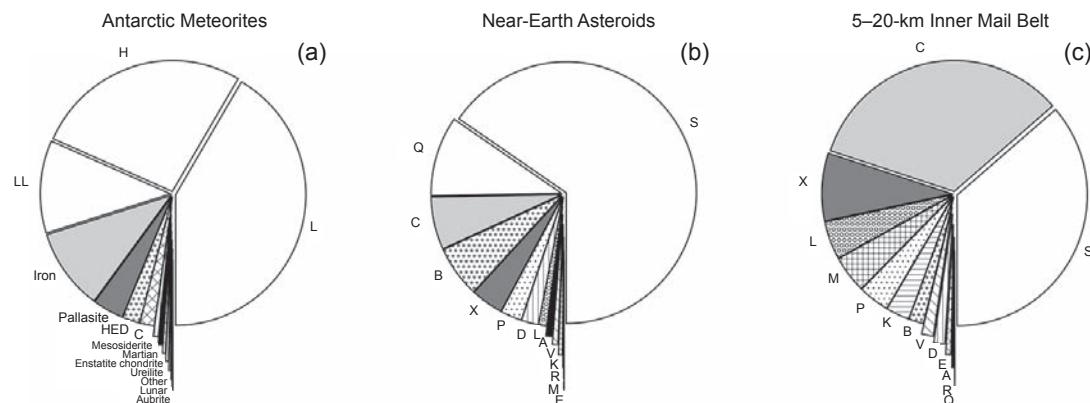

**Fig. 2.** Histogram distribution of taxonomic classes for more than 1000 near-Earth objects tabulated by Binzel et al. (in preparation, 2015) (see section 2.1 for contributing observers). Each and every one of the classes known to be present in the main belt is represented within the near-Earth population. (Note: The vertical scale is logarithmic.)

other low-albedo) asteroids in the known population. Here we attempt to overcome bias effects by considering mass distributions in the manner of DeMeo and Carry (2013). (A mass distribution provides a more debiased view owing to the fact that the largest, and most readily discovered, objects dominate the total mass of the sample; smaller members for which biased discoveries may be incomplete contribute minimal “weight” to the analysis.) Using the dataset from Binzel et al. (in preparation, 2015), we perform a mass distribution analysis of the NEO population with the results shown in Fig. 3. Compared with the mass abundance fraction of C-types in the inner main belt (DeMeo and Carry, 2014), both near-Earth asteroids and (their presumed analog) carbonaceous meteorites show considerably lower abundances. This underrepresentation of C-types among

NEOs has been previously realized (e.g., Luu and Jewitt, 1989; Stuart and Binzel, 2004) but is brought to focus by the unbiased nature of the mass distribution. We address this further in section 3.2.

## 2.2. Mineralogical Interpretation of Near-Earth Asteroids: Relationship to Meteorites

Establishing a correlation between the most commonly observed near-Earth asteroids (S-class) and the most common meteorites (ordinary chondrites comprise >80% of all falls; see the chapter by Borovička et al. in this volume) has been a vexing problem for decades (Wetherill and Chapman, 1988). Spectral interpretation of S-class asteroids and understanding their compatibility with the olivine/pyroxene mineralogy of

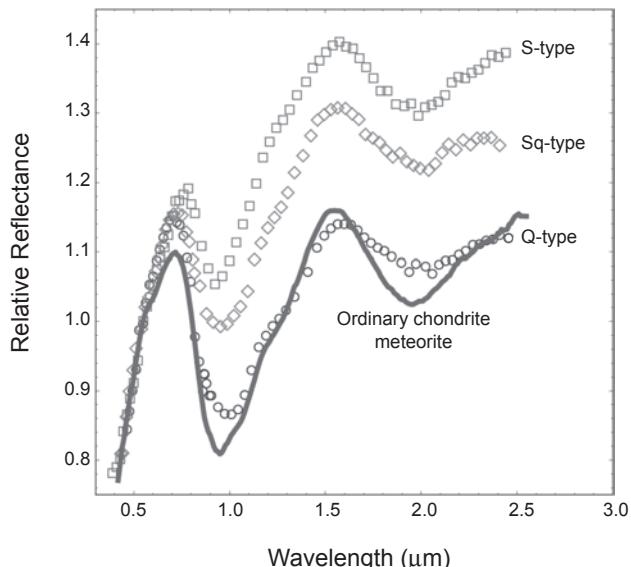

**Fig. 3.** Mass distribution for the near-Earth asteroids, Antarctic meteorites, and inner main asteroid belt. Asteroid data are from Binzel et al. (in preparation, 2015), Antarctic data are from the *Meteoritical Bulletin* database, and the comparably sized main-belt data are from DeMeo and Carry (2014). The two largest near-Earth asteroids, S-types (433) Eros and (1036) Ganymed, dominate the population mass and are not included.

ordinary chondrite meteorites has as its strongest roots the pioneering work by M. J. Gaffey (e.g., *Gaffey*, 1976; *Gaffey et al.*, 1993; see the chapter by Reddy et al. in this volume) as well as the underlying atomic structure revealed by R. G. Burns (*Burns*, 1970). In spite of discovering the mineralogical compatibility of these two groups, direct comparison of S-type asteroid spectra with laboratory spectra of ordinary chondrite meteorites shows a distinct mismatch owing to redder slopes and muted absorption bands displayed by the asteroids. Only the Q-type asteroids (*McFadden et al.*, 1985) (see section 2.1) display a compatible spectral match in slope and absorption band strengths. Finding that Q- to S-type spectral classes display a continuum in their transition [*Binzel et al.* (1996), updated in Fig. 4] bolstered the proposition that some sort of “space-weathering” process (see the chapter by Brunetto et al. in this volume) works to progressively disguise the spectral surface of a “fresh” ordinary chondrite asteroid. The Near-Earth Asteroid Rendezvous mission to the S-type asteroid (433) Eros (*Veverka et al.*, 2000) bolstered the space-weathering interpretation. Elemental abundance measurements of Eros (*Trombka et al.*, 2000) yielded evidence for its likely composition as an ordinary chondrite subject to space-weathering processes (*Chapman*, 2004). Certainly the mass distributions (Fig. 3) strongly support the S- and Q-type asteroid correspondence with ordinary chondrite meteorites. Ignoring the dominating mass of the two largest NEOs [(1036) Ganymed and (433) Eros are both S-types, and themselves make up 75% of the total mass], S- and Q-type asteroids account for 75%

of the NEO mass. In turn, ordinary chondrite meteorites (the sum of H + L + LL classes) are nearly identical in abundance at 80% of the total mass. Yet accepting this concordance as more than just a coincidence requires a definitive answer to the decades-old lingering question: Are some S-type (and Q-type) asteroids truly compositionally compatible with most ordinary chondrite meteorites?

The space engineering triumph of returning a sample from the S-type asteroid (25143) Itokawa by the Japanese Hayabusa mission (see the chapter by Yoshikawa et al. in this volume) cut the Gordian knot. Interpretation of telescopic spectra of Itokawa (then known by its provisional designation 1998 SF<sub>36</sub>) in advance of the “MUSES-C” mission (e.g., *Abell et al.*, 2007) included the specific prediction for Itokawa being a space-weathered LL ordinary chondrite (*Binzel et al.*, 2001). Hayabusa’s findings (*Nakamura et al.*, 2011) not only confirmed the 2001 prelaunch LL-chondrite prediction (see the chapter by Reddy et al. in this volume), but also revealed the details of the space-weathering process (*Noguchi et al.*, 2011) being due to nanophase iron, as predicted by *Pieters et al.* (2000).

Emboldened by this predictive success forged by Hayabusa’s ground truth link, mineralogical modeling of the near-Earth asteroid population has proceeded with new confidence. These models have taken differing approaches, including band area analysis (*Gaffey et al.*, 1993, 2002) and mixing models using optical constants for the constituent minerals (*Shkuratov et al.*, 1999). In an assuring way these approaches have yielded consistent, albeit surprising results. Most notably surprising, S-type near-Earth asteroid spectra (after correction for space weathering) are most often analogous to the LL subgroup of the ordinary chondrite meteorite population (*Vernazza et al.*, 2008; *Thomas and Binzel*, 2010; *de Leon et al.*, 2010; *Dunn et al.*, 2013). While this ordinary chondrite interpretation of asteroid spectra is overall consistent with the predominance of ordinary chondrites among all meteorite falls, the proportion is discordant. From highest-to-lowest metallic iron content, the fall percentages by mass for ordinary chondrite subgroups are H, 27%; L, 42%; LL, 12% of all meteorites (Fig. 3). Thus the epoch of *Asteroids IV* has its own new problem to solve: Why does the least-common subgroup of ordinary chondrites (LL) dominate the compositions interpreted by asteroid spectral analysis? Significant to the puzzle is that LL chondrites contain the highest proportion of olivine among the three classes, where olivine has a strong signature effect in broadening the absorption feature near 1 μm (see Fig. 4). Thus identifying and modeling olivine abundance from the spectral data would seem to be a secure art. Preferential delivery of the largest NEOs from the olivine-rich Flora region of the inner asteroid belt has been proposed as one explanation (*Vernazza et al.*, 2008) (see section 3). As addressed in the chapter by Reddy et al. in this volume, an explanation may also come through better modeling of space-weathering effects, better understanding of the role of impact shocks in altering spectral properties, or better understanding of temperature or phase-angle effects on asteroid spectra. These

**Fig. 4.** Asteroid reflectance spectral properties display an apparent continuum of increasing slope with decreasing absorption band depth as they transition between Q-, Sq-, and S-types, where this progression is thought to be consistent with the increasing effects of space weathering on ordinary chondrite-like asteroid surfaces. Figure adapted from *Binzel et al.* (2010).

noncompositional effects are particularly relevant because olivine-dominated LL chondrites are more likely to show space-weathering effects than L or H chondrites. In addition, significant work remains to be done to clarify space-weathering effects (and their consequences) across the full range of asteroid taxonomic classes and compositions (see the chapter by Brunetto et al. in this volume).

### 2.3. Linking Observable Properties to Planetary Encounters

With Hayabusa's returned sample demonstrating space weathering as both a real and significant process affecting asteroid spectra (most notably S-type spectra; see the chapter by Brunetto et al. in this volume), a key question is the timescale for this process. Near-Earth asteroids are particularly diagnostic because the population shows the full range from "fresh" to "weathered" objects (Fig. 4). Binzel et al. (2004; see their Fig. 7) proposed a size-dependence to explain this spectral range in terms of space weathering, where size is a proxy for the surface age. Their explanation: Smaller objects have shorter collision survival lifetimes and hence (on average) younger surface ages. By corollary, a smaller object could have its surface age reset more often as even more frequent significant (even if noncatastrophic) collisions could either recoat the surface with fresh regolith or seismically reset the surface entirely.

Under this collisional hypothesis, spectral studies turned to young asteroid families (e.g., Nesvorný et al., 2002; see the chapter by Nesvorný et al. in this volume) and the smallest (and hence youngest) measured main-belt objects (Nesvorný et al., 2005; Mothé-Diniz and Nesvorný, 2008; Thomas et al., 2012). Progressively these studies have found evidence for space weathering taking hold rapidly, with indications for the timescale being shorter than  $10^6$  yr (Vernazza et al., 2009). Such short timescales pose a problem for the near-Earth asteroid population: If space weathering is so rapid, how does one explain that 10% of NEAs (the Q-types; see section 2.1 and Fig. 4) appear completely unweathered? In other words, how and why do NEAs get resurfaced at a rate that occurs more frequently than in the main belt — especially when mutual collisions (if this is the responsible resurfacing mechanism) occur more often in the main belt?

Nesvorný et al. (2005) insightfully noted that NEAs undergo planetary encounters on a timescale that is even more frequent than their mutual collisions, such that in the face of rapid space-weathering timescales, encounters would play a more important role than collisions for resurfacing. For a sample of nearly 100 S- and Q-type NEAs, Binzel et al. (2010) treated the dynamical history of each object and its spectral properties as independent variables and found a distinct correlation: All fresh "unweathered" Q-types in the sample had the possibility of a recent (within the past  $10^5$  yr) Earth encounter, while weathered S-types (having no fresh resurfacing) fully populated the sample whose orbits had no recent Earth encounters. Thus telescopic measurements of near-Earth asteroids yield a geophysical and seismological in-

terpretation that planetary encounters induce tidal distortions and/or seismic shaking processes sufficient to resurface, if not fully reshape, Earth-close-encounter objects (Richardson et al., 1998; see the chapter by Scheeres et al. in this volume). The critical distance or "seismic limit" (residing somewhere beyond the Roche limit and perhaps reaching out to more than 10 Earth radii) at which planetary close encounters could possibly create a detectable surface changing effect remains uncertain: Binzel et al. (2010) interprets a further limit than that calculated by Nesvorný et al. (2010). Thus continuing studies represent a fruitful area for new insights into the bulk geophysical properties of small asteroids and their response to tidal forces (see the chapter by Murdoch et al. in this volume). For example, Binzel et al. (2010) advocate the detailed study (Rosetta-like reconnoitering) of the 2029 Earth encounter by (99942) Apophis at 6 Earth radii; substantial tidal torques altering its rotation are predicted (Scheeres et al., 2005). Yu et al. (2014) estimate that small-scale landslides may occur. However, the overall observable consequences (small scale or large scale) of the tidal effects remain highly uncertain. Here we reemphasize that the 2029 Apophis encounter is a grand experiment in asteroid seismology that *nature is performing for us*; no other currently foreseen naturally performed case study of asteroid interiors is availing itself so opportunistically. Looking for similar tidal effects beyond Earth, ongoing studies (DeMeo et al., 2014b) indicate that Mars encounters also appear effective. Venus encounters must be similarly effective, but our sample set of "Venus only" encountering objects is presently null owing to the limitations of our Earth-based vantage point for asteroid search programs.

Even with the apparent physical evidence for tidal effects in resurfacing, it remains an open question as to how the frequency of "seismic resurfacing" by planetary encounters compares with the frequency at which rapid spin-up due to thermal reradiation (e.g., Walsh et al., 2008; see the chapter by Vokrouhlický et al. in this volume) creates "refreshed" surfaces through mass shedding. What's more, it is possible that under the conditions of frequent tidal close encounters or thermal reradiation spin-up events, frequent overturn of the surface grains could effectively allow the grains to be "sautéed," i.e., fully "cooked" by space weathering on all sides. Thus there can be no guarantee that a given surface-shaking event will expose underlying fresh unweathered material.

## 3. SOURCE REGIONS FOR NEAR-EARTH OBJECTS AND METEORITES

With increasing numbers of NEOs and main-belt asteroids having compositional characterization, preliminary attempts at unraveling the source regions for the near-Earth population (including meteorites) are becoming possible. In this section we describe the "Asteroids IV Scenario," summarized in Table 2, as a framework to be augmented or refuted as future understanding evolves. Essential to this framework is the mineralogical modeling outlined in section 2.2 (see the chapter by Reddy et al. in this volume) and dynamical modeling for asteroid orbital evolution (see the chapter by

Morbidelli et al. in this volume). Here we particularly utilize the dynamical model developed by Bottke et al. (2002) that receives as input the current orbital elements for an individual NEO and evaluates the probability for its origin from each of five source regions: the  $v_6$  secular resonance with Saturn, the intermediate-source Mars-crossing region (IMC), the 3:1 mean-motion resonance at 2.5 AU, the outer belt region (OB) near the 5:2 resonance at 2.82 AU, and the Jupiter-family comet (JFC) region. (The sum of all model output probabilities for any set of input orbital elements is equal to unity.) Each of these locations is depicted in Fig. 1. Using this model, Bottke et al. (2002) predicted that ~61% of the NEO population comes from the inner main belt ( $a < 2.5$  AU), ~24% from the central main belt ( $2.5 < a < 2.8$  AU), ~8% from the outer main belt ( $a > 2.8$  AU), and ~6% from Jupiter-family comets.

In an attempt to reveal source regions for the NEO population, Binzel et al. (2004) evaluated the Bottke source prob-

abilities for ~400 NEOs and Mars-crossing (MC) objects for which visible and near-infrared spectra had been obtained. For their sample, they found the  $v_6$  resonance contributed 46% of NEOs, the IMC 27%, the 3:1 resonance 19%, the OB 6%, and the JFC 2%. The vast majority of measured objects (~90%) were classified as S-, Q-, X-, and C-complex bodies within the Bus and Binzel (2002) taxonomy. Figure 5 illustrates their results for correlating the taxonomic classes with source regions, where results for major classes are summarized below.

### 3.1. S-Types, Q-Types, and Ordinary Chondrite Meteorites

In comparing the histogram profiles (see Fig. 5) for S- and Q-types, both have very similar distributions across the inner main belt. (For “S-type” we specifically include in this discussion the related subclasses, such as Sq-types.) An

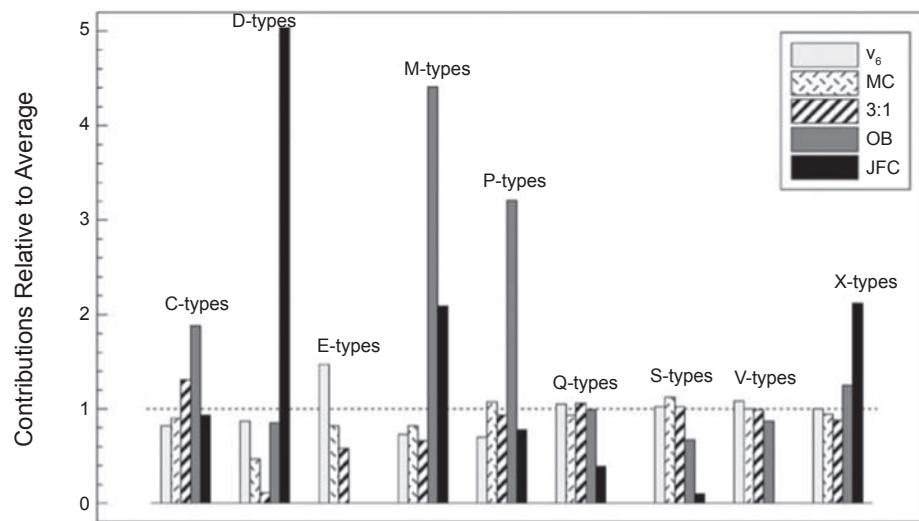

TABLE 2. Specifics for near-Earth object and meteorite sources: The *Asteroids IV* Scenario.

Link	Evidence	Key References
LL ordinary chondrites originate from the Flora region of the inner main belt.	Flora family shows similar olivine-rich compositions. Strong dynamical link of LL-compatible NEOs favor inner main belt source.	Vernazza et al. (2009); Dunn et al. (2013); section 3.1
H ordinary chondrites originate from the mid-region of the asteroid belt.	Hebe argued as a source, but compatible asteroid compositions are broadly abundant from the 3:1 region out to, and spanning, the 5:2 resonance. H-compatible NEOs show 3:1 and 5:2 resonance source region signatures.	Gaffey and Gilbert (1998); Thomas and Binzel (2010); Vernazza et al. (2014); Nedelcu et al. (2014); section 3.1.
Less certain, but emerging ideas for the L ordinary chondrites originating from the Gefion family in the outer main belt.	Gefion family spectra compatible with L chondrites. L-compatible NEOs favor 5:2 region source.	Nesvorný et al. (2009); Binzel et al. (2014, 2015); section 3.1
“Primitive” meteorite classes sample from the outer main belt. Unresolved is the contribution from inner belt C-types.	Interpreted primitive taxonomic C- and D-classes show outer main-belt source region signatures.	Brown et al. (2000); Hiroi et al. (2001); Binzel et al. (2004); Vernazza et al. (2013); section 3.2.
Most V-type NEOs linked to Vesta and to HED meteorites. Isotopically distinct HEDs (rare) and other achondrites indicate multiple differentiated source bodies.	Spectral and dynamical links to Vesta; Dawn <i>in situ</i> measurements. Other small basaltic asteroids in outer belt. Achondrite meteorites are diverse.	McCord et al. (1970); Cruikshank et al. (1991); Binzel and Xu (1993); Lazzaro et al. (2000); Scott et al. (2009); Prettyman et al. (2012); Lucas and Emery (2014); section 3.3
Enstatite achondrites (aubrites) originate from the Hungaria region of the inner main belt.	E- and Xe-type asteroids are spectrally distinct. They show strong orbital and dynamical links to the inner main belt.	Gaffey et al. (1992); Binzel et al. (2004); section 3.3
Extinct Jupiter-family comets reside in NEO orbits having Tisserand ( $T$ ) values $< 3$ .	$T < 3$ indicates dynamical link to Jupiter; dominated by low-albedo objects.	Wetherill (1988); Fernandez et al. (2001); DeMeo and Binzel (2008); Kim et al. (2014); section 3.4

identical source region signature for both is not unexpected due to the relationship between the two groups [e.g., S-types are believed to be weathered Q-types as discussed in section 2.2 (Binzel et al., 1996)]. As discussed in section 2.2, mineralogic analyses of S- and Q-type NEAs have most often found their spectral properties to be similar to LL chondrites. Vernazza et al. (2008) suggested that the olivine-rich Flora family (near the  $v_6$  resonance) was the source region for the subset of S- and Q-type NEOs whose spectral analysis yielded results most similar to LL compositions; de León et al. (2010) independently find the same result. Dunn et al. (2013) also calculated mineralogies from individual NEO spectra to analyze the source regions based on the Bottke et al. (2002) probability models. For their sample of 47 NEOs with ordinary chondrite spectral parameters, LL chondrites again showed their familiar predominance (60% of the sample), while 15% and 10% had H- and L-chondrite mineralogies, respectively. (The remaining 15% had mineralogies that could not easily be distinguished between L or LL chondrites.) For 75% of the Dunn et al. (2013) sample, the  $v_6$  resonance was the most probable source region and the LL-chondrite mineralogies were preferentially derived from there, similarly consistent with Vernazza et al. (2008) as originating in the nearby Flora family. Results from Dunn et al. (2013) did not establish a distinct source region for NEOs with H- or L-chondrite mineralogies. While these first steps toward definitive correlations are emerging, caution is still warranted as the role of shock effects in altering spectral properties, with possible consequences for mineralogical interpretations, remains an open and emerging area for study (see the chapter by Reddy et al. in this volume).

As an example, a fruitful result of considering shock effects may be the compositional diversity displayed among members of the Baptistina asteroid family; Reddy et al. (2014) suggests them to be the source of shock-darkened LL chondrites.

Thomas and Binzel (2010) used modified Gaussian modeling (MGM) (Sunshine et al., 1990) to determine meteorite analogs and source region probabilities (model of Bottke et al., 2002) and found NEAs most closely matching H chondrites have a higher-than-average delivery preference through the 3:1 mean-motion resonance. A 3:1 resonance source preference for H-chondrite-like NEAs persists in the substantially larger sample presented by Binzel et al. (2014), with the 5:2 resonance also showing a signature for being a strong contributor of the H chondrites. The 3:1 resonance being a source for the H chondrites is consistent with Gaffey and Gilbert (1998), who suggested that asteroid (6) Hebe, which is located adjacent to the  $v_6$  and 3:1 resonances, is the parent body of the H chondrites. Vernazza et al. (2014) note that abundant main-belt asteroids having H-chondrite-like spectral properties are common in the 3:1 region, consistent with this provenance for H chondrites, but also lessening any requirement for linking specifically to Hebe. Similarly, Vernazza et al. (2014) find the provenance for H chondrites extends from the 3:1 to 5:2 resonance, spanning across the 5:2 resonance as well. Nedelcu et al. (2014) and Sanchez et al. (2015) also illustrate the case of an “H chondrite-like” NEA (2007 PA<sub>8</sub>) being derived from the 5:2 resonance, although this same object is interpreted to have an L-chondrite-like composition by Fornasier et al. (2015) (consistent with

**Fig. 5.** Histogram distribution for source regions of near-Earth asteroids based on the orbital evolution model of Bottke et al. (2002). Each ratio is relative to the overall flux from each source, thus any significant deviation from unity indicates a strong signature (or relative deficiency) for that source region contributing objects in that taxonomic class to near-Earth space. Figure adapted from Binzel et al. (2004).

the L-chondrite discussion below). Thus the current evidence (see the chapter by Vernazza et al. in this volume) indicates the source region for the H-chondrite meteorites may be broad across the central region of the main belt involving both the 3:1 and 5:2 resonances.

L chondrites are increasingly being pinpointed toward an outer belt (5:2 resonance) source region, as proposed by Nesvorný et al. (2009) based on dynamical considerations for the origin of the Gefion family located nearby. Spectral interpretation of Gefion family asteroids has been found to be consistent with L chondrites (Blagén, 2012). Supporting this result is the analysis of the largest datasets for NEAs (Binzel et al., 2014; Binzel et al., in preparation, 2015) finding an outer belt preference for objects whose spectral properties are interpreted as being most similar to L chondrites. We do not consider any conclusion regarding the L chondrites to be definitive at this time: Confirming or refuting a link of L chondrites to the outer belt remains an area of active current investigation.

### 3.2. C-Types and Carbonaceous Chondrite Meteorites

As described in section 2.1, accurately quantifying the abundance of C-type NEOs has been a long-standing problem owing to the difficulty of their detection through surveys relying on visible reflected light. This difficulty is the same for all asteroid classes having low albedos, such as D- and P-types (noting that for this discussion “C-type” includes the subclasses such as B-types). As we discuss below, and as extensively addressed in the chapter by Mainzer et al. in this volume, surveys operating in the thermal infrared overcome this bias as a consequence of dark surfaces having higher relative temperatures (absorbing rather than reflecting nearly all sunlight).

As shown in Fig. 3c, the inner main belt is now more clearly revealed to have an abundance of low-albedo members [roughly 40% by mass are C-, D-, and P-types (DeMeo and Carry, 2014; DeMeo et al., 2014a)]. Yet a sharp discordance remains: These low-albedo classes comprise scarcely 20% among characterized NEOs (Fig. 3b). While this 20% value is by mass, and *should* be less subject to bias than raw discovery statistics (see section 2.1), spectroscopic reconnaissance is nonetheless subject to the same magnitude-limiting effects as visible-light discovery surveys. Thus we can have confidence that the characterized NEO population of 20% low-albedo objects represents a lower limit. As noted immediately above, reconciliation may be emerging from thermal infrared surveys that are yielding ~35% as the low albedo fraction (see Fig. 3 of the chapter by Mainzer et al. in this volume).

As work on this topic progresses in the future, there is an orbital distribution factor that might account for an ongoing deficit remaining for the abundance of low-albedo NEOs relative to the overall main belt. Specifically, the inner edge of the main belt ( $v_6$  secular resonance and the Mars-crossers evolving deeper in to near-Earth space) may overwhelmingly dominate the total NEO flux. As shown

by DeMeo and Carry (2014; see their Fig. 4), the  $v_6$  inner edge is itself dominated by S-types. Thus if the  $v_6$  inner edge specifically dominates the NEO flux, then C-types (for example) do not have equal access to this highly efficient “resonance escape hatch” for delivery into the inner solar system. This effect may be presenting itself in the source region histograms for C-types shown in Fig. 5, where the 3:1 resonance does show a stronger contribution than the  $v_6$  resonance. Overall, this figure shows a distinctly clear signature for C-type NEOs being delivered from the outer main belt, where this class most thoroughly dominates.

The minuscule fraction of carbonaceous chondrite meteorite falls (~2% in Fig. 3a) remains an enigma compared to any assessment (20–35%) for the low-albedo NEO population. Historically this factor of 10 underrepresentation of carbonaceous chondrite falls compared with the NEO population is attributed to a strong selection effect against surviving atmospheric entry (Baldwin and Sheaffer, 1971; Sears, 1998). The canonical explanation is that the lower-strength carbonaceous materials have a lower likelihood of surviving (at sizes larger than dust) and yielding recoverable fragments (Love and Brownlee, 1993; Taylor et al., 2000; Love and Alton, 2006).

Finally, when reconciling the low-albedo population of NEOs relative to the main belt and meteorite fractions, there is a reemerging consideration of a process that may be significantly important to the census: shock darkening of asteroid regoliths due to impacts. While the fundamental work revealing this process was performed more than two decades ago (Britt and Pieters, 1991, 1994), it has been brought back to the foreground by extensive studies of the Chelyabinsk meteorite (Kohout et al., 2014; Reddy et al., 2014; see the chapter by Reddy et al. in this volume). Shock darkening could factor into the equation if a significant fraction of low-albedo NEOs or main-belt objects are not carbonaceous in composition, but are instead shock-darkened ordinary chondrites. This reemerging consideration presents a possible paradox and certainly an opportunity for ongoing study.

### 3.3. Other Asteroid Classes and Possible Meteorite Source Relationships

Near-Earth asteroids having Vesta-like (V-type) spectra among the NEOs were first reported by Cruikshank et al. (1991). Examining the V-type source region histogram in Fig. 5 shows a particularly flat distribution for their origin among all inner main-belt sources, with equal preference between the  $v_6$  and 3:1 resonances. This equal source distribution mimics the broad extent of the Vesta family across the inner belt (see the chapter by Masiero et al. in this volume), yielding the conclusion that the NEO source for V-types is consistent with an origin from (4) Vesta (McCord et al., 1970; Cruikshank et al., 1991; Binzel and Xu, 1993). *In situ* elemental abundance characterization of Vesta by the Dawn mission (Prettyman et al., 2012) provides the “golden spike” for the connection between Vesta, the V-type asteroids, and the howardite-eucrite-diogenite (HED) meteorites (Consolmagno and Drake, 1977; Binzel, 2012). As a mark

of progress, it is now recognized that Vesta is likely not the only source for HED meteorites. Apart from what might be called the “main-group HEDs” is a small set (approximately five known) of isotopically anomalous meteorites that likely originated on another parent body (Scott et al., 2009). V-type asteroids that are dynamically independent of Vesta in the outer main belt (Lazzaro et al., 2000; Moskovitz et al., 2008) and perhaps 100 parent bodies being represented by iron meteorites are consistent with the previous existence of other differentiated asteroids with Vesta as a unique “intact” survivor (see the chapter by Scott et al. in this volume).

D- and X-types show source region signatures (Fig. 5) indicating they are predominantly derived from the outer belt and Jupiter-family comets, as discussed below in section 3.4. These X-types most likely have low albedos, in which case their ambiguous X classification would be resolved to being labeled as P-types. The taxonomically rare A- and E-types are uncommon in the overall NEO population (<1%), but are more common among observed Mars-crossing objects (5%). Sanchez et al. (2014) found no distinct link between known A-type asteroids and an asteroid family. Binzel et al. (2004) suggested that this was indicative of slow diffusion into Mars-crossing orbits from the Flora or Hungaria regions. Such an origin is also consistent with previous observations by Gaffey et al. (1992), who linked E-type Apollo asteroid (3103) Eger to the Hungaria region.

### 3.4. Cometary Contribution to the Near-Earth Object Population

Identifying potential cometary objects in the NEO population is in some ways more straightforward and in other ways more enigmatic than linking to main-belt source regions and to specific meteorite types. As noted in section 1, the label of “asteroid” or “comet” can be a hindrance to the problem as clearly there is a continuum in the distribution between volatile-rich and volatile-poor objects in the solar system. What’s more, the volatile-free characteristics of an object’s surface can belie the nature of a possibly volatile-rich interior. We sidestep the issue in the following way: We consider an object to be “cometary” in the sense that it is interpreted to have a “primitive” (low-albedo and carbonaceous-chondrite-like) composition and a dynamical origin from the outer belt or beyond, most notably being in an orbit similar to Jupiter-family comets (Wetherill, 1988). A superb and convincing illustration of the comet contribution to the NEO population was made by Fernandez et al. (2001, 2005), who found that “asteroids” having Tisserand values less than 3 (an orbital parameter indicating a gravitational link to Jupiter that is common to all Jupiter-family comets) display comet-nucleus-like low albedos. Outer-belt and Jupiter-family-comet links for presumed “primitive” C-, D-, and P-type asteroids are also clearly revealed in the source region analysis performed by Binzel et al. (2004) and illustrated here in Fig. 5. Follow-on analyses that have sought to quantify the currently contributed fraction of cometary material to the inner solar system (DeMeo and Binzel, 2008; Kim et al., 2014) have adopted

the same low-albedo and taxonomic criteria. DeMeo and Binzel (2008) estimate that  $8 \pm 5\%$  of the NEO population is contributed by comets, not inconsistent with the estimate of 4% given by Fernandez et al. (2005). In their recent work, Kim et al. (2014) find some cases of higher-albedo objects in the “comet-like” orbits, which they attribute to possible Yarkovsky drift of “asteroids” into those dynamical states. If Yarkovsky mixing proves to be a significant factor in pushing “asteroids” into comet-like orbits, that must lower the estimates for the comet contribution to NEOs that have relied on orbital properties as a discriminating parameter. Ongoing discoveries of the low-albedo component of the near-Earth population (see the chapter by Mainzer et al. in this volume) promise to provide the most critical new constraints for the comet fraction.

## 4. SUMMARY

In this concluding section, we attempt to “put it all together” and to look at the path ahead by pointing to our summaries in Tables 1 and 2 for the current status of key questions for the NEO population and the current scenarios for our understanding of myriad interrelationships. Exposing gaps and critical new details in all these areas — and most especially, revealing the flaws in our current thinking — should be the goal of every new student venturing into this corner of the field. Most traditionally, making advancements implies devising new observational strategies or computational models. We particularly emphasize that ongoing laboratory work using meteorites as “ground truth” is one of our field’s greatest strengths.

Ongoing advancements will certainly come through the link between remote sensing measurements (available for thousands of objects) to laboratory analysis of returned samples. As conceptualized in the pyramid of planetary exploration (Binzel, 2012), spacecraft exploration and sample return are the most specialized opportunities that maximize their yield when designed toward addressing specific and highly refined science questions. Understanding the nature of primitive C-complex asteroids and their meteorite link(s) are the goals for the Hayabusa-2 (Abe et al., 2012) and Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) (Lauretta et al., 2015) sample return missions.

As discovery surveys advance in their detection thresholds and cadence, future “incoming” object discoveries are sure to occur as presaged by the detection of 2008 TC<sub>3</sub> and the recovery of its fragments as Almahata Sitta meteorites (Jenniskens et al., 2010). Alas, this first example of discovering a body in space prior to its “free” sample collection proves the difficulty of remote sensing interpretation: The rare class of ureilite meteorites to which Almahata Sitta belongs has nearly featureless spectral reflectance characteristics (Cloutis et al., 2010). If not discovered prior to arrival, the detailed tracking of the entry trajectories for arriving meteorites can also enable estimates of their orbits (and source regions). Recent examples of the Sutter Mill [CM

carbonaceous chondrite (*Jenniskens et al.*, 2012; also see the chapter by Jenniskens in this volume)] and Chelyabinsk [LL ordinary chondrite (*Reddy et al.*, 2014)] recovered falls point to possible Jupiter-family comet and inner-main-belt (Baptistina family) origins. Direct samples, of course, have the enormous advantage of obviating the difficulties of mineralogic interpretation from remote sensing.

The scientific riddles and rewards offered by NEO studies, coupled with the pragmatic motivations for their investigation arising from impact hazards and exploration potential, all point to a propitious path ahead. In many ways, they all point toward the same path. Optimizing the synergies between science, human exploration, and resource utilization is the ultimate grand challenge *and opportunity* for asteroids in the twenty-first century (*Binzel*, 2014). Abundant knowledge of the population, achieved through discovery, characterization, and unraveling their interrelationships, is the enabling pathway to convergence that will deliver the most productive future for all stakeholders having interests in near-Earth objects.

**Acknowledgments.** Preparation of this chapter was supported by the National Science Foundation under Grant No. 0907766 (R.P.B.) and the NASA Near-Earth Object Observations Program grant NNX14AL06G (V.R.). We are grateful to B. J. Burt and T. H. Burbine for assistance with the figures and to J. de Leon and J. Masiero for their careful reviews. The authors unanimously acknowledge the scientific progress in asteroid spectroscopy that has been enabled by the dedicated staff of the NASA Infrared Telescope Facility and its commitment to advanced instrumentation, exemplified by the SpeX instrument (*Rayner et al.*, 2003).

# Small Near-Earth Asteroids as a Source of Meteorites

Jiří Borovička and Pavel Spurný

*Astronomical Institute of the Czech Academy of Sciences*

Peter Brown

*University of Western Ontario*

Small asteroids intersecting Earth's orbit can deliver extraterrestrial rocks to Earth, called meteorites. This process is accompanied by a luminous phenomena in the atmosphere called bolides or fireballs. Observations of bolides provide pre-atmospheric orbits of meteorites, physical and chemical properties of small asteroids, and the flux (i.e., frequency of impacts) of bodies at Earth in the centimeter to decameter size range. In this chapter we explain the processes occurring during the penetration of cosmic bodies through the atmosphere and review the methods of bolide observations. We compile available data on the fireballs associated with 22 instrumentally observed meteorite falls. Among them are the heterogeneous falls Almahata Sitta (2008 TC<sub>3</sub>) and Benešov, which revolutionized our view on the structure and composition of small asteroids; the Příbram-Neuschwanstein orbital pair, carbonaceous chondrite meteorites with orbits on the asteroid-comet boundary; and the Chelyabinsk fall, which produced a damaging blast wave. While most meteoroids disrupt into fragments during atmospheric flight, the Carancas meteoroid remained nearly intact and caused a crater-forming explosion on the ground.

## 1. INTRODUCTION

Well before the first asteroid was discovered, people unknowingly had asteroid samples in their hands. Could stones fall from the sky? For many centuries, the official answer was no. Only at the end of the eighteenth century and the beginning of the nineteenth century did the evidence that rocks did fall from the sky become so overwhelming that this fact was accepted by the scientific community. It was the German scientist Ernst Chladni who first recognized their extraterrestrial origin in 1794. Nevertheless, it took some time before his idea became accepted (see, e.g., Lauretta and McSween, 2006).

The stones that fell from the sky are distinct from all terrestrial rocks. They are called *meteorites*. Meteorites are classified into many different types according to their mineralogical composition. The two basic classes are stony and iron meteorites, although a mixture of these chemistries (stony-iron meteorites) exists as well. Iron meteorites are composed of metallic iron with an admixture of nickel and some traces of other elements. Stony meteorites are mostly composed of silicates such as olivine and pyroxene, with some metallic iron also present in many cases. The elements and most of minerals found in meteorites are known from terrestrial rocks, but their ratios in meteorites are different. The most common type of stony meteorites, called chondrites, contains millimeter-sized spherical structures called chondrules. Such structures are not present in any terrestrial rock. More detailed classification of meteorites is given in the chapter

by Binzel et al. in this volume. The study of meteorites is a well-developed scientific field and rich literature is available (e.g., Dodd, 1981; Papike, 1998; Hutchison, 2004; Lauretta and McSween, 2006).

According to the circumstances of their recovery, meteorites can be divided into *finds* and *falls*. Finds are meteorites found on ground (by chance or by dedicated searches), but the date of their fall is unknown. Falls are meteorites, whose fall was witnessed — either the meteorite was seen (or heard) to hit the ground or the fireball caused by the ablation of the parent meteoroid in the atmosphere was observed and the meteorites were found later. *Meteoroid* is a term for the original body that dropped the meteorite(s). In fact, there is no strictly defined boundary between large meteoroids and small asteroids. For the purpose of this chapter, we will call meteoroids all bodies smaller than 10 m and larger than 50 µm. Bodies smaller than 50 µm are called *dust particles*. A dust particle, when entering the atmosphere, may not give rise to the phenomenon called a meteor, depending on its initial speed. *Meteor* is the radiation, and associated phenomenon (heat, shock, ionization), caused by the entry of a meteoroid in the atmosphere. Dust particles are sufficiently small that they may decelerate before they start to evaporate, so they do not produce meteors. They gradually sediment through the atmosphere and finally reach the ground.

The vast majority of meteoroids are destroyed in the atmosphere and do not produce any macroscopic meteorites. Parts of them may not be evaporated completely and can reach the ground as dust or *micrometeorites* (objects smaller

than  $\sim 1$  mm). To produce a meteorite, the meteoroid must be large enough and mechanically strong enough, and must have a relatively low entry velocity. The initial velocities of meteoroids at entry to the terrestrial atmosphere in bound heliocentric orbits are between 11 and  $71 \text{ km s}^{-1}$ . The chance of surviving the passage through the atmosphere strongly decreases with increasing velocity. As a rough empirical rule (for which there are many exceptions), a meteoroid of stony composition with a low entry velocity ( $\sim 20 \text{ km s}^{-1}$ ) can produce meteorites with a total mass of 5–10% of the initial (pre-atmospheric) mass of the meteoroid (Halliday *et al.*, 1989a; Popova *et al.*, 2011).

A meteor brighter than stellar magnitude –4 (i.e., brighter than the planet Venus) is called a *fireball* or *bolide*. The term *superbolide* is used for meteors brighter than magnitude –17 (Ceplecha *et al.*, 1999). Meteorite falls are always in the bolide or superbolide category. Nevertheless, it is not true that the brighter the bolide, the larger the meteorite. There are fluffy meteoroids of cometary origin, which produce bright bolides but are completely destroyed high in the atmosphere (e.g., Borovička and Spurný, 1996; Madiedo *et al.*, 2014a).

Meteorites, as extraterrestrial samples, have much scientific value. However, to fully exploit the information they contain, it is necessary to know where they come from. Early researchers thought that meteorites came from interstellar space (see, e.g., the discussions of Öpik, 1950; Fessenkov *et al.*, 1954). It was the Příbram meteorite, which fell in the former Czechoslovakia in 1959 and whose trajectory, impact position, and orbit was determined rigorously for the first time from bolide photographs, that placed meteorites in the context of the solar system (Ceplecha, 1961). Since bolides are rare events and occur unexpectedly, it is necessary to systematically monitor large territories to obtain observational data. For that reason, dedicated arrays of cameras, called fireball networks, were put into operation in several countries. One of their goals was to assist with meteorite recovery and, at the same time, provide orbits of the meteorites (Ceplecha, 1986). In more modern times, when various types of still and video cameras became widespread among the public, casual instrumental records of bolides have become common. These records, after careful calibration (Borovička, 2014) and often laborious computation, also provided some meteorite orbits, although with lower precision than dedicated bolide cameras. As of 2014, there are 22 meteorites with reliably (i.e., instrumentally determined) known pre-impact orbit (see section 5). The orbits confirm that most meteorites are fragments of asteroids, although a cometary origin of a small fraction of meteorites cannot be fully excluded. In addition, it was found that some meteorites, according to their composition, must originate from the Moon and some others from Mars, although no orbits for lunar or martian meteorite falls are yet documented.

It is estimated that about 4500 meteorite falls dropping more than 1 kg of total meteorite mass occur annually on Earth (Halliday *et al.*, 1989b). Only in one case has the meteorite fall been predicted in advance: A small interplanetary object designated as 2008 TC<sub>3</sub> was discovered on October 7,

2008, when approaching Earth, and it was predicted to enter the atmosphere the next day over Sudan. Its remnants were later recovered as the Almahata Sitta meteorites (Jenniskens *et al.*, 2009). On January 1, 2014, another object, 2014 AA, was discovered on an Earth-approaching orbit but the impact point was poorly constrained. There are indications that the impact occurred in the Atlantic Ocean (Chesley *et al.*, 2015).

The observations of bolides, with or without an associated meteorite fall, provide information about the orbital distribution, physical properties, and (when accompanied with spectral observation) composition of fragments of asteroids (and comets) intersecting Earth's orbit. They are therefore a complementary tool to the astronomical and *in situ* studies of asteroids. They also provide direct information on the effects of impacts on Earth. Large bodies generate a strong blast wave in the atmosphere, which can have damaging effects on the surface, as was the case for the Tunguska event over Siberia in 1908 (e.g., Vasilyev, 1998) and Chelyabinsk in 2013 (Brown *et al.*, 2013a; Popova *et al.*, 2013). Even small meteoroids can occasionally cause an impact crater, as was the case for the Carancas impact in 2007 (e.g., Tancredi *et al.*, 2009).

This chapter provides an overview of what is known about bolides producing meteorite falls. Special attention is devoted to instrumentally observed meteorite falls. These are the events with the most complete information available (analysis of both the bolide and the corresponding meteorite). We note that these phenomena are not restricted to Earth. Meteorites (Fairén *et al.*, 2011), fresh impact craters, and crater strewn fields (Daubar *et al.*, 2013) were discovered on the surface of Mars and superbolides have now been observed in the atmosphere of Jupiter (Hueso *et al.*, 2013). On the atmosphereless Moon, flashes caused by the direct impact of meteoroids on the surface can be observed (Suggs *et al.*, 2014).

## 2. METEOROIDS IN THE ATMOSPHERE

In this section we describe in more detail the penetration of large ( $>10 \text{ cm}$ ) meteoroids thorough the atmosphere. The understanding of these processes is important for the derivation of meteoroid properties from bolide observations, for assessment of the hazard connected with meteoroid/asteroid entry, and for improving the efficiency of meteorite recoveries.

In the upper layers of the atmosphere, at heights  $>130 \text{ km}$ , individual atoms and molecules directly impact the meteoroid surface. This leads to gradual heating of the meteoroid surface. Under some circumstances, the collision with atmospheric molecules can lead to the release of a meteoric atom from the surface. This process, called *sputtering*, is a form of slow mass loss at low temperatures (Rogers *et al.*, 2005). It is efficient only at meteoroid velocities larger than  $30 \text{ km s}^{-1}$  (Popova *et al.*, 2007). Intense mass loss starts only when the meteoroid surface is heated to its melting temperature of about 2000 K (Ceplecha *et al.*, 1998). The molten surface layer partly evaporates and is partly lost in the form of liquid droplets, which then continue to evaporate in the hot plasma surrounding the meteoroid in a process

called *thermal ablation*. The hot envelope of heated air and meteoric vapors around the meteoroid is the main source of bolide radiation. The plasma temperature and composition can be studied by the methods of meteor spectroscopy. The typical temperatures are 4000–5000 K (e.g., Borovička, 2005). At these temperatures, the main contributors to the bolide radiation in visible light are meteoric metals, in particular Fe, Mg, Na, Ca, Cr, and Mn. They radiate in the form of atomic emission lines. The atmospheric species (N, O) and some meteoric species (notably Si, S, and C) have no bright lines in the visible range. As a result, their abundance is difficult to determine. Moreover, the composition of meteoric vapors usually does not fully reflect the composition of the meteoroid as some refractory elements, notably Al, Ca, and Ti, are not evaporated completely during thermal ablation, particularly at heights above 30 km (Borovička and Spurný, 1996; Borovička, 2005). Nevertheless, bolide spectroscopy can be used to distinguish the main types of meteoritic material (chondrites, achondrites, irons) in the cases where no meteorite is recovered. There is also a component of higher temperature (~10,000 K) observed in bolide spectra (Borovička, 1994a). The strength of this second component (represented mainly by the lines of Ca<sup>+</sup>, Mg<sup>+</sup>, and Si<sup>+</sup>) increases rapidly with bolide velocity and is not seen in slow bolides. The high-temperature region is probably formed in front of the body, where the interaction of the ablated material and the air flux is the strongest.

In the denser atmospheric layers, atmospheric molecules do not directly impact the meteoroid surface. The *free molecular regime* changes into the *continuous flow* (Popova, 2004), which can be treated within the framework of gas hydrodynamics. A shock wave forms at the boundary between the envelope protecting the meteoroid and the incoming flow of the atmosphere. According to models, the temperature of the shock-heated air can reach tens of thousands of degrees (Artemieva and Shuvalov, 2001).

The interaction with the atmosphere leads to loss of mass, deceleration, and, in many cases, fragmentation of the meteoroid. The classical meteor equations describe the deceleration and mass loss (ablation) of a single (non-fragmenting) meteoroid (Bronshcen, 1983; Ceplecha et al., 1998). In this treatment, the meteoroid with mass m, cross-section S, moving with a velocity v, encounters atmosphere of mass Spvdt, where p is the density of atmosphere and dt is the considered time interval. The momentum of the encountered atmosphere is Spv<sup>2</sup>dt and the kinetic energy is  $\frac{1}{2}Spv^3dt$ . From the conservation of momentum, we have the *drag equation* describing deceleration of the meteoroid

$$m \frac{dv}{dt} = -\Gamma Spv^2$$

where  $\Gamma$  (sometimes written as  $C_D/2$ ) is the *drag coefficient*. The energy is consumed in mass loss according to the *ablation equation*

$$\frac{dm}{dt} = -\Lambda Spv^3/2Q$$

where  $\Lambda$  is the *heat transfer coefficient* and Q is the energy necessary to ablate a unit mass of the meteoroid. These equations are usually rewritten by introducing the *shape factor*  $A = Sm^{-2/3}\delta^{2/3}$ , where  $\delta$  is the bulk density of the meteoroid, and the *ablation coefficient* is  $\sigma = \Lambda/2Q\Gamma$ , the latter of which can be directly inferred from observations. More details and the analytical integrals of the above equations (assuming constant coefficients) can be found in Ceplecha et al. (1998). Theoretical models of meteoroid ablation were discussed by, e.g., Baldwin and Schaeffer (1971), Biberman (1980), Svetsov et al. (1995), Golub' et al. (1996), and Nemtchinov et al. (1997).

The single-body approach is rarely applicable for the entirety of the bolide's flight. Meteoroid fragmentation in the atmosphere is a complex process that is not possible to predict exactly but is ubiquitous. It depends on the structural properties of each individual meteoroid and occurs in various forms, i.e., chipping off a small part of the body, disruption into two or more fragments of similar sizes, catastrophic disruption into large numbers of small fragments, etc. Fragmentation is often a multi-stage process, whereby fragments arising from early fragmentation episodes disrupt again later. If this process has some regularity, it is called *progressive fragmentation*. The term *quasicontinuous fragmentation* refers to a process when small fragments (dust) are released from the main body almost continuously. This is the dominant fragmentation mode for a kind of weak millimeter-sized population of meteoroids of cometary origin (Borovička et al., 2007).

For a given bolide velocity, the structurally weaker is the meteoroid, the higher in altitude the fragmentation starts. Some types of fragmentation can be induced thermally; nevertheless, in most cases (especially when large fragments are involved or when catastrophic disruption occurs) the breakup is likely due to aerodynamic loading. In this process, the dynamic pressure acting at the front surface of the meteoroid is  $p = \Gamma p v^2$ , while the pressure at the rear side is zero, and the difference in the pressures causes structural failure of the meteoroid. Fragmentation occurs when p exceeds the strength of the meteoroid [see Holsapple (2009) for various definitions of strength]. In estimating the dynamic pressure at breakup, the factor  $\Gamma$ , on the order of unity, is often neglected and the meteoroid strength is estimated as  $pv^2$ . The velocity, v, is easily measurable from meteor data, but the determination of the fragmentation height (and thus the corresponding atmospheric density, p) is often difficult. This can be done by a number of methods (geometric, photometric, dynamic, acoustic), depending on the type of available data and the type of fragmentation (Ceplecha et al., 1993; Trigo-Rodríguez and Llorca, 2006; Popova et al., 2011).

The radiation of the bolide is assumed to be proportional to the instantaneous loss of kinetic energy, as expressed by the luminosity equation

$$I = -\tau(\frac{1}{2}v^2 \frac{dm}{dt} + mv \frac{dv}{dt})$$

where I is the radiative output and  $\tau$  is the *luminous efficiency* (which may depend on meteoroid velocity, mass, composition,

and height in the atmosphere). For cases including fragmentation, the total output is the sum of contributions of all fragments. When a large number of fragments is released, a sudden increase in brightness, called a *flare*, occurs due to the increase of the meteoroid total cross-section.

Thermal ablation stops when the meteoroid velocity decreases below about  $3 \text{ km s}^{-1}$ . The end of the bolide therefore occurs when either all mass has been ablated and no macroscopic fragments remain or the velocity of all fragments decreases below this ablation limit. In the latter case, the fragments continue to fall during a period called *dark flight*. Their surface gradually cools and no light is emitted (except perhaps a faint infrared glow at the beginning). Typically, the velocity drops below the ablation limit at a height somewhere between 10 km and 30 km, depending mainly on the initial meteoroid mass and its fragmentation in the atmosphere. The deceleration continues during dark flight. The fragments follow a ballistic trajectory that turns into a nearly vertical fall, influenced by atmospheric winds (Ceplecha, 1987). When they reach the ground, the fragments are called *meteorites*. Typical impact speeds are in the range  $10\text{--}100 \text{ m s}^{-1}$  for meteorites of  $0.1\text{--}100 \text{ kg}$ . Fresh meteorites are characterized by a dark fusion crust representing a resolidified layer of molten material acquired during the latter stages of ablation (Genge and Grady, 1999). Sometimes a part of the fusion crust is missing, suggesting that fragmentation continues to occur during the dark flight.

In rare cases of large, strong meteoroids, the deceleration may not be sufficient to convert the flight into free fall. If the body hits the ground with a velocity larger than about  $0.5\text{--}1 \text{ km s}^{-1}$ , it generates a shock wave in the ground resulting in crater formation. An *impact crater* much larger than the impactor is then formed (Holsapple, 1993).

The radiation is not the only demonstration of meteoroid flight through the atmosphere. The supersonic flight generates a cylindrical *blast wave*, which can be heard on the ground and, if the amplitude and the seismic characteristics of the ground are appropriate, seismic waves may be excited (Edwards et al., 2008). Meteoroid fragmentation events can generate spherical blast waves. These waves travel in the atmosphere with the speed of sound ( $\sim 300 \text{ m s}^{-1}$ ), so they reach the ground tens of seconds to minutes after the bolide, depending on the range of the bolide. Non-audible sound waves of low frequency, termed *infrasound*, attenuate particularly slowly in the atmosphere and can be detected with special detectors over large distances, in some cases for tens of thousands of kilometers (Ens et al., 2012).

Eyewitnesses of bolides sometimes report another type of sound (variously described as a hissing, popping, or crackling) heard simultaneously with the bolide. The origin of these *electrophonic sounds* is not well understood but they are believed to be transmitted as very low frequency/extremely low frequency (VLF/ELF) electromagnetic waves and converted into audible sound by the vibration of objects in the vicinity of the observer (Keay, 1992). Recently, radio emissions at frequencies 20–40 MHz were reported from fireball trails (Obenberger et al., 2014).

Bolides, but also quite faint meteors, produce *ionization trails* in the atmosphere. The lifetimes of the trails vary from a fraction of second to many minutes. They reflect electromagnetic radiation, which is used for the detection of meteors by radars (Ceplecha et al., 1998; Jones et al., 2005). High-power, large-aperture (HPLA) radars are able to detect the plasma that forms in the vicinity of tiny meteoroids (Close et al., 2007). For larger bodies, this so-called *head echo* can also be detected by normal meteor radars (Brown et al., 2011).

### 3. FIREBALL OBSERVATIONS

In this section we provide a brief overview of bolide observations and the basic methods of data analysis.

#### 3.1. Observation Methods

Bolides, and particularly superbolides, are conspicuous phenomena on the sky (Fig. 1) and often draw the attention of the public. They can also be detected by various instruments — optical cameras, photoelectric sensors, radars, acoustic and seismic detectors, or satellite-based sensors. Optical imaging cameras provide the most straightforward data about the bolide trajectory, velocity, and luminosity. The bolide must be imaged from at least two widely separated (optimally about 100 km apart) sites to reconstruct the trajectory. Inspired by success with the Příbram bolide, whole networks of cameras have been established to capture similar events and to characterize the population of large meteoroids. The network, which started in Czechoslovakia in 1963 (Ceplecha and Rajchl, 1965) and was joined by Germany in 1968 (Ceplecha et al., 1973; Oberst et al., 1998), formed the European Fireball Network (EN), which remains in operation today. The network originally used low-resolution all-sky mirror cameras recording on photographic film. The Czech portion has been modernized in several stages following the advancement of technology: Mirrors have been replaced by fish-eye lenses providing

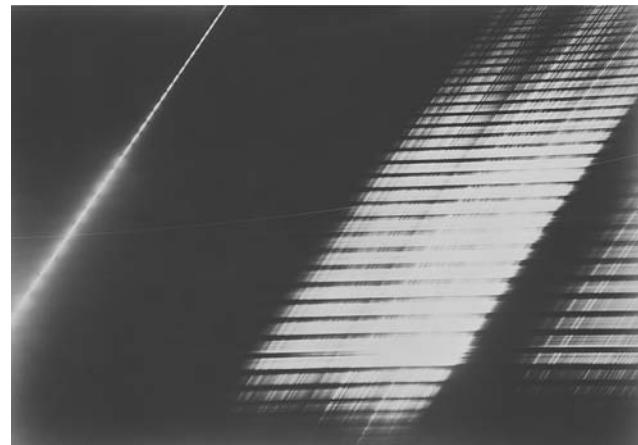

**Fig. 1.** Image of a very bright bolide EN 210199 taken by the photographic all-sky camera at Lysá hora, Czech Republic. Stars form circles around the North Pole during a long exposure. Only part of the all-sky image is shown.

higher resolution after 1975 (*Ceplecha*, 1986), manually operated cameras were replaced by Autonomous Fireball Observatories (AFO) beginning in 2001 (*Spurný et al.*, 2007), and film versions are currently being replaced by digital versions (the Digital AFO, or DAFO). The Australian Desert Fireball Network, which has operated since 2005 (*Bland et al.*, 2012), also uses AFO. The Prairie Network operated in the United States (U.S.) from 1963 to 1975 and used batteries of high-resolution photographic cameras (*McCrosky and Boeschenstein*, 1965). This was also the case for the Meteorite Observation and Recovery Project (MORP) in Canada, which was active from 1971 to 1985 (*Halliday et al.*, 1978, 1996). The three early networks were compared by *Halliday* (1973). The Tajikistan Fireball Network operated in 2009–2012 (two stations have been in operation since 2006 until now) and used manually operated fish-eye film cameras together with digital cameras (*Kokhirova et al.*, 2015). There are also networks based on video cameras, either all-sky versions used in the Southern Ontario Meteor Network, operated in Canada since 2004 (*Brown et al.*, 2010); in the NASA fireball network operated in the U.S. since 2008 (*Cooke and Moser*, 2012), and in the Slovak Video Meteor Network, which started with two stations in 2009 (*Tóth et al.*, 2012), or various types of wide field cameras. The latter is the case of the Spanish Meteor Network dating back to 1997 (*Trigo-Rodríguez et al.*, 2001) and the Polish Fireball Network operated since 2004 (*Olech et al.*, 2006). The video-based networks provide lower resolution and thus lower precision of data than photographic networks. Video cameras are usually more sensitive and capture fainter meteors, while bright bolides are saturated and hardly measurable. The quality and reliability of the data critically depends on the quality of the astrometric procedures. Amateur astronomers in many countries now operate video cameras optimized for fainter meteors (e.g., *Molau and Rendtel*, 2009; *SonotaCo*, 2009). The International Meteor Organization (<http://www.imo.net>) plays an important role in coordinating and popularizing these activities. Occasionally, faint-meteor cameras also capture meteorite falls, as was the case for the Slovenian and Croatian Meteor Networks (*Spurný et al.*, 2010; *Šegon et al.*, 2011) and the professional Cameras for Allsky Meteor Surveillance (CAMS) system in California (*Jenniskens et al.*, 2014).

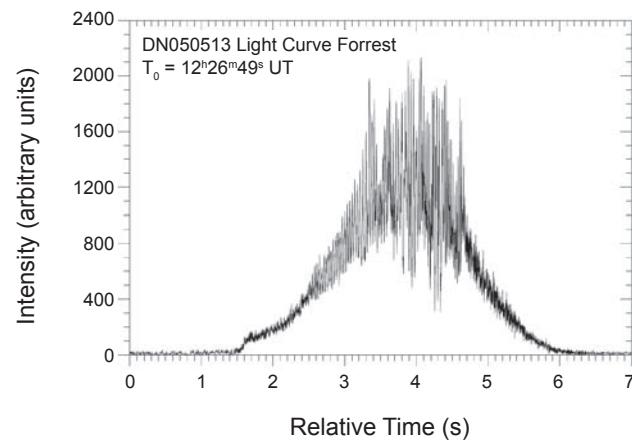

Optical cameras can be used as meteor spectrographs by putting a diffraction element (prism or grating) in front of the lens. Such objective spectrographs do not need any slit, since meteors are line objects and their monochromatic images form the spectrum. Large-format photographic film cameras with rather long focal length have been used to obtain high-resolution spectra of bright bolides (Fig. 2). The description and analysis of such detailed spectra, containing more than 100 emission lines, was published in a number of papers (e.g., *Halliday*, 1961; *Ceplecha*, 1971; *Borovička*, 1993, 1994b). High-resolution photographic spectrographs are still in use at Ondřejov Observatory. A more sensitive charge-coupled-device (CCD) spectrograph (but having a smaller field of view) was used during the Leonid campaign

(*Jenniskens*, 2007). The Spanish Meteor Network uses video cameras to obtain low-resolution spectra of bolides (*Madiedo et al.*, 2013a,b, 2014a).

Detailed light curves of bolides can be studied by radiometers, i.e., photoelectric or semiconductor devices, which do not image the bolide, but measure the total scattered sky light as a function of time (Fig. 3). Radiometers are part of AFOs and DAFOs in central Europe and of AFOs in Australia and

**Fig. 2.** Photographic grating spectrum of a lower part of the Benešov bolide EN 070591. The spectrum was taken from the Ondřejov Observatory, Czech Republic. The zero order (direct image) is on the left, the first order and part of the second order are on the right. The fireball flew from the top to the bottom. The exposure was interrupted by a rotating shutter. See *Borovička and Spurný* (1996) for more detailed description of the spectrum. Benešov is the only bolide with both recovered meteorites and recorded spectrum.

**Fig. 3.** Radiometric light curve of bolide DN 050513 taken by the Autonomous Fireball Observatory at Forrest station in Australia. The sampling rate was 500 Hz. The high amplitude and high frequency variations during the bright phase are real. The amplitude of the noise was much lower, as can be seen at the edges of the curve. DN 050513 was a type I meteorite-dropping bolide (meteorites landed in an inaccessible area and were not recovered).

provide the light curves with either 500 or 5000 samples per second (*Spurný and Ceplecha*, 2008). Radiometric light curves of superbolides are also detected globally as a by-product of satellite-based systems constructed for different purposes. These systems provide global detection of superbolides, with radiometric measurements establishing bolide time and radiant power (*Tagliaferri et al.*, 1994). The total energy of the event may also be estimated under a number of assumptions. A complimentary system provides estimates of the location and in some cases the velocity/altitude or fragmentation height of superbolides. Meteorological and scientific satellites have also detected bolides in flight or their remnant dust/aerosol clouds (*Borovička and Charvát*, 2009; *Klekociuk et al.*, 2005; *Rieger et al.*, 2014).

In addition to systems exploiting the electromagnetic emission of bolides, the atmospheric shock waves produced by fireballs may be detected (*Edwards*, 2010). At large distances from the bolide, these shocks are detectable as infrasound, which is sound below  $\sim$ 20 Hz. Bolide infrasound is detectable by microbarographs, which are instruments able to record coherent pressure amplitudes as low as one part in  $10^8$  of the ambient atmospheric pressure. When three or more such sensors are deployed within a region on the order of 1 km in size, the resulting sensor array can efficiently distinguish coherent sources from noise based on cross-correlation of the pressure signals and measured signal arrival direction and elevation (*Christie and Campus*, 2010). Since approximately 2000, the International Monitoring System (IMS) of the Comprehensive-Test Ban Treaty Organization (CTBTO) has operated infrasound arrays on a global scale. As of 2014, some 47 stations (of a projected network of 60) are operating and provide nearly global detection capability for kiloton-scale superbolides.

In contrast to infrasound observations, which directly detect the very small pressure perturbation from bolides at ranges of thousands of kilometers, seismographs respond to the bolide air waves coupled to the solid Earth. The low efficiency of seismo-acoustic coupling implies that airwaves are normally only directly detectable seismically within a few hundred kilometers of a bolide. For very energetic bolides, surface-coupled waves may also be produced (*Edwards et al.*, 2008). The principle advantage of seismic bolide measurements are the tens of thousands of seismic stations operated globally that provide dense coverage in some areas, sometimes allowing multiple seismo-acoustic detections of a single bolide, which can provide information on trajectory and fragmentation points (e.g., *Borovička and Kalenda*, 2003; *Pujol et al.*, 2006).

Radar may also be used in several modes to characterize bolides. Direct detection of the radar head echo associated with the fireball, whereby radio waves are reflected off electrons in the region of the fireball head, can be used to estimate the velocity of the bolide as well as compute its trajectory (*Brown et al.*, 2011) and, in principle, its mass. The main limitation of this observational mode is the large power aperture (or large radar cross section) needed to detect such head echoes, which effectively limit detectability to small

regions in the atmosphere near the radar (*Kero et al.*, 2011). The ionization trail left behind from a bolide is more easily detected than the corresponding head echo (*Ceplecha et al.*, 1998) — this provides some limited information on the location of the bolide and may be used to place constraints on its ablated mass.

Recently, weather radars (*Fries and Fries*, 2010) have been shown to be effective at detecting the debris plume from a bolide in the form of material in dark flight. These Doppler radars are able to detect macroscopic-sized fragments as well as finer dust drifting to Earth, typically at altitudes  $<$ 20 km (and in some instances at altitudes as low as just a few kilometers) after a bolide. They provide a means to confirm the deposition of meteorites on the ground together with fall location as they probe the terminal stages of dark flight.

### 3.2. Data Analysis

Once analyzed, optical data from fireball networks provides fireball trajectories, velocities, and light curves. The first very important step is astrometric reduction of wide-field or all-sky images (*Borovička et al.*, 1995). In most cases, bolide trajectories can be considered to be straight. The triangulation from two or more stations can be done either with the plane intersection method (*Ceplecha*, 1987) or the straight least-squares method (*Borovička*, 1990; *Gural*, 2012). The trajectories of long-duration, nearly horizontal bolides are nonnegligibly curved by Earth's gravity and special procedures are needed to reconstruct the trajectories of such so-called Earth-grazing fireballs (*Ceplecha*, 1979; *Borovička and Ceplecha*, 1992).

To measure bolide velocities on long-exposure photographic records, the cameras are equipped with a shutter periodically interrupting the exposure (with frequencies on the order of 10 Hz). By measuring the positions of the shutter breaks or individual video images, the fireball position (length along the trajectory or height) as a function of time is obtained. This information forms the basis of dynamic analysis, i.e., determination of bolide velocity and deceleration as a function of time and, consequently, other parameters such as ablation coefficient and *dynamic mass* of the meteoroid. The parameters can be obtained by fitting the integral solution of the drag and mass loss equations first obtained by *Pecina and Ceplecha* (1983). The method assumes a single-body meteoroid, i.e., no fragmentation. The method of *Gritsevich* (2009) is an equivalent treatment. In reality, however, fragmentation is a very common and important process. A more general method allowing the determination of one fragmentation point from bolide dynamics was developed by *Ceplecha et al.* (1993). For a review, see *Ceplecha et al.* (1998).

Another method of estimating the meteoroid mass is derived from the bolide light curve. The mass obtained by the integration of the luminosity equation is called the photometric mass. The crucial parameter is the luminous efficiency, which unfortunately is not well known. It has been discussed in a number of papers (e.g., *Ceplecha and*

*McCrosky, 1976; Pecina and Ceplecha, 1983; Hill et al., 2005; ReVelle and Ceplecha, 2001; Weryk and Brown, 2013*). In general, it appears that luminous efficiency increases with meteoroid velocity and mass. It is also expected on theoretical grounds that the luminous efficiency depends on height of flight and on flow regime. These dependencies are not as important for large meteoroids because they affect mostly the beginning of the bolide. Theoretical estimates of luminous efficiency were published by *Golub' et al.* (1996) and *Nemtchinov et al.* (1997).

In addition to the differential luminous efficiency found in the luminosity equation, an integral luminous efficiency is defined as the ratio of the total energy radiated by the bolide to its initial kinetic energy. The integral luminous efficiency also increases with meteoroid energy (*Brown et al.*, 2002a). To give a rough value, in a typical meteorite fall (velocity  $\sim 15 \text{ km s}^{-1}$ , initial mass  $\sim 100 \text{ kg}$ ), both integral and differential luminous efficiency of large fragments are about 5%.

A major issue that is not explainable by uncertainties in the luminous efficiency is the large difference found between the dynamic and photometric masses of meteoroids. The underlying physical reason for these order-of-magnitude disparities is meteoroid fragmentation, which was not properly taken into account in early treatments. To obtain self-consistent meteoroid mass and other properties of the meteoroid, modeling its atmospheric flight including fragmentation using both dynamic and photometric data (and, if possible, other data as well such as direct observation of fragments) is desirable. One such attempt was done by *Ceplecha and ReVelle* (2005). A somewhat different approach was used by *Borovička et al.* (2013a) when analyzing the Košice meteorite fall.

Besides optical data, the energy of the fireball can also be estimated from acoustic data. The information available for acoustic energy estimation is the pressure amplitude and dominant period of the pressure waveform from infrasound measurements. Due to the complex, changing nature of the atmosphere, it is not generally possible to theoretically determine initial source energy from infrasound measurements alone. Instead, empirical estimates are made using calibrations from explosive sources with known energy. As pressure amplitude is most modified in atmospheric propagation, the signal period tends to be most robust in estimating source energy. Using data derived from simultaneous infrasound and satellite measurements of bolides, *Ens et al.* (2012) found that bolide source energies  $E$  (in tons of TNT equivalent energy) could be related to average infrasound periods (in seconds) via  $E = 3.16\tau^{3.75}$ .

These bolide-specific energy relations are nearly identical to those derived from nuclear weapon tests. These period energy estimates become less certain at small energies (small periods) and more reliable as more stations are used to provide average period estimates. Amplitude-based yields are similarly calibrated from ground explosions and bolides, but are less robust, show wide scatter, and are highly sensitive to stratospheric winds. Amplitude-based yields become increasingly unreliable at large ranges or large source ener-

gies (above  $\sim 1 \text{ kt}$  TNT). Hence at short ranges and small energies, amplitude-based energy estimates are preferred, while for large ranges and large energies periods become more reliable.

The bolide observations can also be used to estimate the terminal mass, i.e., the mass of fragments that survived the flight and landed as meteorites (if any). The mass of an individual well-observed fragment can be computed from the atmospheric density,  $\rho$ , velocity,  $v$ , and deceleration,  $dv/dt$ , at the end of the luminous trajectory using the drag equation

$$m_E = (\Gamma A)^3 \rho^3 v^6 \delta^{-2} (dv/dt)^{-3}$$

where the drag coefficient,  $\Gamma$ , shape factor,  $A$ , and meteorite density,  $\delta$ , must be assumed (for a sphere,  $A = 1.21$ ;  $\Gamma \sim 0.6$  at the relevant heights and velocities). The landing point can be estimated by the numerical integration of the objects motion during dark flight (*Ceplecha, 1987*) without knowing its mass — just the direction of flight, and last observed height, velocity, and deceleration are needed as initial values. The largest uncertainty in this landing point estimate arises from the error in the deceleration (which is not observed directly but must be computed from the observed length as a function of time over some part of the trajectory) and also in the uncertainty in the high-altitude winds, which can shift the meteorite by many kilometers (e.g., *Spurný et al.*, 2012a). Note, however, that in some cases small, not directly observable fragments can form the bulk of the fall mass (e.g., *Borovička et al.*, 2013a; *Spurný et al.*, 2014). Their presence may be revealed when modeling the light curve. Large numbers of meteorites make the recovery more likely, even if they are small ( $\ll 1 \text{ kg}$ ).

Meteorites usually represent only a small part of the initial mass of the meteoroid. In some cases quite a large fraction of the total mass is deposited in the atmosphere in the form of micrometer-sized dust particles that avoid complete vaporization (*Klekociuk et al.*, 2005; *Borovička and Charvát*, 2009). This dust slowly sediments out of the atmosphere over timescales of months and can spread over large geographical areas (*Gorkavyi et al.*, 2013). In addition, part of the vaporized material may recondense, forming nanometer-sized meteoric smoke (*Borovička and Charvát*, 2009) that is distributed globally (*Megner et al.*, 2008).

Early data from fireball networks showed that there are enormous differences in fireball end heights even if the initial conditions (velocity, mass, slope of the trajectory) are similar. This is most readily interpreted as differences in physical strength among meteoroids within the fireball population. On this basis, *Ceplecha and McCrosky* (1976) created the PE criterion (which derives from the symbol  $\rho_E$ , representing the atmospheric mass density at the end point of the fireball) and classified bolides into four types based on physical strength: namely, types I, II, IIIA, and IIIB. A typical meteorite-dropping bolide, which *a priori* is expected to be near the high end of all meteoroid physical strengths, is of type I and was associated by *Ceplecha and McCrosky* (1976) with stony meteoroids of densities  $> 3000 \text{ kg m}^{-3}$ .

Meteoroid densities are not directly measurable from bolide data; nevertheless, statistical arguments led Ceplecha and McCrosky to the conclusion that type II bolides correspond to carbonaceous chondrites of densities  $\sim 2000 \text{ kg m}^{-3}$ , and IIIA and IIIB are two types of cometary material of densities of about  $750 \text{ kg m}^{-3}$  and  $300 \text{ kg m}^{-3}$ , respectively (Ceplecha, 1988). The latter two types disintegrate high in the atmosphere and do not provide meteorites.

The bolide end height is easily measurable and the PE criterion is still used today. A complementary method of classification uses the apparent ablation coefficient of the fireball. It is obtained by fitting the bolide dynamics without considering fragmentation. Typical values are 0.014, 0.042, 0.1, and  $0.21 \text{ s}^2 \text{ km}^{-2}$  (or  $\text{kg MJ}^{-1}$ ) for fireball types I, II, IIIA, and IIIB, respectively (Ceplecha, 1988; Ceplecha *et al.*, 1998). However, as shown by Ceplecha and ReVelle (2005), if fragmentation is taken into account, the obtained *intrinsic ablation coefficient* is nearly the same for all four types and is quite low, about  $0.005 \text{ s}^2 \text{ km}^{-2}$ . This suggests that the composition of the material is similar in all cases (mostly silicates) and the main differences are in the bulk density, porosity, and mechanical strength, which determines the degree of meteoroid fragmentation. Note that iron meteoroids are not considered in this scheme, since they are quite rare and we do not have enough bolide data to characterize them as a population. In fact, iron meteoroids are not easily recognizable without spectral observation or recovered meteorites. They have a higher density than stony meteoroids ( $\sim 7800 \text{ kg m}^{-3}$ ) and probably also have a larger intrinsic ablation coefficient because of lower melting temperature and higher thermal conductivity (ReVelle and Ceplecha, 1994).

Finally, if discrete fragmentation points are identified on the fireball trajectory, the dynamic pressure acting on the meteoroid at that point can be used to classify the meteoroid. The fragile IIIB bodies often disrupt catastrophically at pressures of several to several tens of kilopascals accompanied by conspicuous flares (Borovička and Spurný, 1996; Borovička *et al.*, 2007; Madiedo *et al.*, 2014a). The type I bodies usually fragment into macroscopic pieces, often several times consecutively, at pressures from a few tenths to a few megapascals (Ceplecha *et al.*, 1993; Popova *et al.*, 2011).

The heliocentric orbit of the meteoroid can be computed from the time of entry, direction of flight (radian coordinates), and velocity. The corrections to Earth gravity and Earth rotation must be applied. The corrected radiant and velocity are called *geocentric*. An analytical method of orbit computation was presented by Ceplecha (1987). Clark and Wiegert (2011) presented a computationally more demanding numerical method and showed that Ceplecha's formulation remains valid except in rare particular cases.

#### 4. METEORITE ANALYSES RELEVANT TO FIREBALL STUDIES

Meteorites, when recovered, are subject to detailed mineralogical, chemical, physical, and isotopic analyses in the

laboratory. Some of them are directly relevant to fireball studies because they provide either independent estimates of some parameters or supplementary information.

In interplanetary space, meteoroids are bombarded by energetic particles of solar and galactic cosmic rays. The interaction of cosmic rays with atoms in the meteoroid leads to the formation of atomic nuclei that are otherwise only rare or absent in the meteoric material, namely noble gases and short-lived radionuclides (Verchovsky and Sephton, 2005; Eugster *et al.*, 2006). Cosmic rays penetrate a few meters inside the meteoroid. The measurement of the concentration of selected nuclides, in particular  $^{60}\text{Co}$ ,  $^{10}\text{Be}$ ,  $^{21}\text{Ne}$ , and  $^{22}\text{Ne}$ , can be used to estimate the pre-atmospheric radius of the meteoroid and the depth of the measured sample inside the meteoroid. Note, however, that the calculations are model dependent and rely on derived nuclide production rates (Leya and Masarik, 2009). The correspondence with the fireball-determined pre-atmospheric mass of the meteoroid is not always good (Popova *et al.*, 2011).

The cosmogenic nuclides can be also used to estimate the *cosmic-ray exposure* (CRE) age of the meteoroid. This is the time for which the meteoroid was exposed to cosmic rays, i.e., the time elapsed since the meteoroid was excavated from a deeper depth in its parent body. Lunar meteorites and carbonaceous chondrites have the shortest CRE ages (about 1 m.y. on average), while the CRE ages of iron meteorites are the longest (hundreds of million years) (see Eugster *et al.*, 2006).

The measurement of physical properties of meteorites is also important for modeling the meteoroid flight in the atmosphere. Densities and porosities of meteorites of various types were published in a series of papers (Macke *et al.*, 2011, and references therein). Thermal conductivities (Opeil *et al.*, 2012) and heat capacities (Consolmagno *et al.*, 2013) were also measured. Other measurements of these quantities were obtained by Beech *et al.* (2009) and their application to meteor physics was discussed. The measurements of tensile and compressive strengths of meteorites are still rare because a destructive analysis is needed. Published values were compiled by Popova *et al.* (2011) and Kimberley and Ramesh (2011).

#### 5. INSTRUMENTALLY OBSERVED METEORITE FALLS

Instrumental observations of fireballs that produce meteorite falls and finds are of great scientific interest and importance because meteorites provide us with a surviving physical record of the formation of our solar system, and a direct link to their parent bodies. But most meteorites are also unique — as geological materials — in that they come with virtually no spatial context to aid us in interpreting that record. Reliable orbital information for meteorite falls is known for only 22 cases. This is a tiny fraction of the tens of thousands of meteorites that are known. For this reason, every new fireball with precise orbital data that produces a meteorite gives us invaluable information.

Similarly important is the study of processes accompanying the atmospheric flight of the meteoroid producing a meteorite fall. From every new instrumentally documented fall we learn much to help refine our methods and models. On the other hand, the known properties of the meteorite, such as density, mass, shape, composition, structure, etc., facilitate reverse calibration of other data from fireballs that do not produce meteorites. This provides information on the physical properties of meteoroids not likely contained in our meteorite collections.

Basic data about all instrumentally documented meteorite falls (22 cases so far) are shown in Tables 1–3, where details about their orbital data, atmospheric trajectory data, and meteorite data are collected. When comparing the data, it must be realized that the data were obtained under various circumstances (day/night, different ranges to the bolide) and by widely different techniques. The techniques are listed in the last column of Table 1. Only in a minority of cases (eight) was the fireball trajectory fully determined from professional photographic or video networks aimed at fireball observations. In seven cases, only casual videos and photographs were available. In four cases, a combination of the two or video cameras aimed at fainter meteors were used. Tagish Lake and Almahata Sitta fireballs were not imaged in flight from the ground at all; instead, satellite data and dust cloud images were used. In the case of Almahata Sitta, the orbit was precisely known from pre-impact observation of the meteoroid. To some extent the atmospheric trajectory could be determined from that data as well.

It is difficult to link specific meteorites with individual parent asteroids with some certainty. The orbit measured for any particular meteorite-producing fireball is heavily evolved from the original orbit of the parent asteroid. As a result, linking individual fireballs with specific asteroids is generally not possible. Rather, classes of meteorites and source regions in the main asteroid belt can be statistically associated using the orbit distribution of many meteorites and models of main-belt to near-Earth asteroid (NEA) delivery (*Bottke et al.*, 2002a).

We tried to evaluate the quality of various aspects of fireball data in the thirteenth column of Table 1. The trajectory (direction of flight, geographical coordinates, heights), dynamics (deceleration along trajectory), photometry (absolute brightness, shape of the light curve), and heliocentric orbit (dependent on the precision of the radiant, initial velocity, and time of the fireball) were evaluated on scale of 1–5 (1– means between 1 and 2, etc.). Overall, Tagish Lake, Buzzard Coulee, and Sutter’s Mill have less-reliable data.

The number of digits for orbital elements in Table 1 is given so that the published error is on the last digit. Most orbits are Apollo-type; only one is an Aten-type. The inclinations are mostly low (the median value is about 5°) but go up to 32°. All aphelia lie within the orbit of Jupiter, although the Tisserand parameters ( $T_J$ ) of Maribo and Sutter’s Mill are lower than 3. These two fireballs had the largest entry velocity ( $V_\infty$  in Table 2). The other values given in Table 2

are the observed terminal velocity ( $V_E$ ), the best estimate of the initial mass of the meteoroid ( $m_\infty$ ), the maximal absolute magnitude of the fireball ( $M_{\max}$ ), the slope of the trajectory (the slope is changing along the trajectory due to Earth’s curvature, so only rough values are given), the observed beginning height ( $H_B$ ), the height of maximum brightness ( $H_{\max}$ ), the terminal height ( $H_E$ ), the total length of the trajectory ( $L$ ); the duration of the fireball ( $T$ ), the total energy ( $E$ ) in kilotonnes of TNT (1 kt TNT =  $4.185 \times 10^{12}$  J), and the maximal encountered dynamic pressure ( $P_{\max}$ ). The observed beginnings of the fireballs (and thus also the lengths and durations) strongly depend on the technique and, in the case of casual records, also on pure chance. We therefore also list in some cases values from visual observations. The terminal heights are affected by observation effects to a lesser extent because the drop of brightness at the end is usually steeper.

It can be seen that meteorites were observed to fall from meteoroids of a wide range of masses, causing fireballs that are different by orders of magnitude in terms of energy and brightness. At the lower end, there were meteoroids of initial masses of only a few dozens of kilograms causing fireballs of absolute magnitude of about –10 or slightly more. Some meteorite falls were produced by large (>meter-sized) meteoroids associated with superbolide events, which occur globally every two weeks (*Brown et al.*, 2002a, 2013a). As a result, only a very small number of these events have detailed atmospheric flight observed. Our sample includes several superbolides with good dynamic and photometric data (such as Benešov, Košice, and Chelyabinsk). In these instances we can obtain insight into the internal structure of the pre-atmospheric meteoroid, for comparison with the physical structure of asteroids as determined from other kinds of observations. One of the measurable values is the mechanical strength expressed by the dynamic pressure at fragmentation. The enlarged sample confirms the conclusions of *Popova et al.* (2011) about the low strengths of interplanetary meteoroids and small asteroids. The relatively large value for Chelyabinsk (18 MPa) concerns only a very minor part of the body. The majority of the material was, in fact, destroyed under 1–5 MPa (*Borovička et al.*, 2013b).

Data on types and masses of recovered meteorites are compiled in Table 3. Some of the large meteoroids disrupted heavily in the atmosphere and produced large numbers of small meteorites. This was the case for not only all three carbonaceous chondrite meteorites (which were made of relatively weak rock) and two mineralogically heterogeneous bodies (Almahata Sitta and Benešov), but also for ordinary chondrite bodies like Košice. The opposite example is Carancas, discussed in the next section. But there are bodies also in our sample that did not fragment very heavily (e.g., Morávka, Příbram, and, in particular, Neuschwanstein). Chelyabinsk fragmented extensively; nevertheless, one large (600 kg) piece survived intact to the ground.

In the next section, we discuss in greater detail some particularly notable meteorite falls that were caused by large meteoroids.

\* Quality coefficient describes the achieved reliability in determination of the atmospheric trajectory (T), dynamics (D), light curve and photometry (P), and heliocentric orbit (O); 1 = best, 5 = worst.  
 † Instrumental techniques used for the data acquisition: P = dedicated photographic network, V = casual video, S = seismics, Sa = seismic, I = infrasound, T = telescope (pre-atmospheric observation of the meteoroid), RD = weather Doppler radar, CP = casual photograph, CTP = causal trail photograph.

\* The most precise orbit thanks to the pre-atmospheric observations; however, very limited precision in the atmospheric trajectory, dynamics, and photometry determination.

All angular orbital values are in J2000.0 equinox.

## 6. NOTABLE METEORITE-PRODUCING FIREBALLS

### 6.1. Almahata Sitta (2008 TC<sub>3</sub>) and Benešov: Heterogeneous Falls

The Almahata Sitta meteorite fall (*Jenniskens et al.*, 2009) is unique in many aspects. It was the first meteorite fall that was predicted in advance — still the only case of this kind. The corresponding meteoroid/asteroid, designed 2008 TC<sub>3</sub>, was discovered 19 hr before it entered the terrestrial atmosphere. During that time interval, numerous astrometric observations were made from various observatories around the world. Thanks to these data, a precise orbit was computed and the impact trajectory was predicted over the Nubian Desert in the Sudan with a precision of better than 1 km. Moreover, photometric and spectroscopic observations of 2008 TC<sub>3</sub> were also made and helped to characterize the body before the atmospheric entry.

There was not enough time to set up any fireball cameras in the region of impact. Consequently, available data for the actual fireball are scarce. Nevertheless, the data clearly showed that the meteoroid was a fragile body and disrupted relatively high in the atmosphere. In accordance with this, a large number (~600) of mostly small (0.2–379 g) meteorites were recovered, but no large meteorite was found. Quite surprisingly, the meteorites were of various mineralogical types. This fact completely changed our paradigm that one meteorite fall produces meteorites of one type and that (undifferentiated) asteroids have a certain mineralogical composition, although polymict meteorite breccias were previously known (*Bischoff et al.*, 2010).

*Shaddad et al.* (2010) described over 600 recovered meteorites. Their total mass was 10.7 kg; the individual masses ranged from 0.2 to 379 g. The locations of all meteorites were carefully documented but only a few of the meteorites were analyzed in detail. Of the classified meteorites, the majority were ureilites, i.e., a relatively rare type of achondrite. However, enstatite chondrites and ordinary chondrites were found as well. *Kohout et al.* (2010) measured magnetic susceptibility of 62 meteorites from that sample. In 25 cases, he found anomalous values suggesting that the meteorites are not ureilites. *Bischoff et al.* (2010) analyzed a different sample of 40 meteorites from undocumented locations within the Almahata Sitta strewn field and found many different types. The mineralogical measurements of 110 meteorites by various authors were summarized by *Horstmann and Bischoff* (2014). Of these, 75 were ureilites or ureilite-related, 28 were enstatite chondrites (both EH and EL), 5 were ordinary chondrites (H, L, LL), one was a carbonaceous chondrite (CB), and one was a previously unknown type of chondrite related to R chondrites. Such a variety of meteorite types within one fall is unprecedented. Naturally, the question arises if all meteorites were really part of 2008 TC<sub>3</sub> and did not come from unrelated meteorite fall(s) with overlapping strewn fields. The main arguments for common origin are as follows: (1) All meteorites are

similarly fresh looking. (2) There is no indication that the non-ureilitic meteorites were located in a specific part of the strewn field (*Shaddad et al.*, 2010). (3) The presence of short-lived radionuclides in two non-ureilitic meteorites is evidence for a recent fall, consistent with the association with 2008 TC<sub>3</sub> (*Bischoff et al.*, 2010). (4) The analysis of noble gases and radionuclides in two other non-ureilitic meteorites provided the same pre-atmospheric radius and the same CRE age (20 m.y.) as for ureilitic meteorites (*Meier et al.*, 2012). So, although not definitely proven, it is very likely that most, if not all, of the various meteorite types really belonged to the same fall and that 2008 TC<sub>3</sub> was therefore a highly heterogeneous body. Although the ureilitic lithology was prevailing, completely different lithologies were present as well. It is worth noting that none of the foreign lithologies was found to be directly embedded within the ureilitic meteorites. It therefore seems that the chondritic material was only loosely bound within the asteroid.

From the foregoing it may seem that asteroid 2008 TC<sub>3</sub> was a rubble pile, i.e., a conglomerate of rocks bound together only by mutual gravity. However, other data do not support that view. *Scheirich et al.* (2010) and *Kozubal et al.* (2011) determined the shape and rotation of 2008 TC<sub>3</sub> from pre-impact photometry. The asteroid was an elongated body with axial ratio of approximately 1:0.54:0.36. It was in an excited rotation state with period of rotation of 99.2 s and period of precession of 97.0 s. The absolute dimensions are uncertain due to uncertainties in albedo. The V-band albedo of selected meteorites was measured as  $0.046 \pm 0.005$  by *Jenniskens et al.* (2009) and as 0.11 by *Hiroi et al.* (2010). The asteroid dimensions can, in principle, be determined from its mass and density as well. The mass can be inferred from bolide energy, since the entry velocity is well known. The bolide energy was estimated as  $(6.7 \pm 2.1) \times 10^{12}$  J from infrasound detection in Kenya (*Jenniskens et al.*, 2009). The radiated energy measured by U.S. government sensors was  $4 \times 10^{11}$  J (*Jenniskens et al.*, 2009), which translates to a total energy  $(2.7\text{--}5.1) \times 10^{12}$  J, depending on the value of luminous efficiency (*Borovička and Charvát*, 2009). The densities of most of the 45 meteorites measured by *Shaddad et al.* (2010) were around  $2800 \text{ kg m}^{-3}$ , but values as high as  $3430 \text{ kg m}^{-3}$  and as low as  $1590 \text{ kg m}^{-3}$  were found. The bulk density of the asteroid could in principle be even lower if significant macroporosity was present. Combining the possible range of all values, *Kozubal et al.* (2011) concluded that the most probable mean size was 4.1 m, mass 50,000 kg, albedo 0.05, and bulk density  $1800 \text{ kg m}^{-3}$ . They did not use the shape model of *Scheirich et al.* (2010). *Kohout et al.* (2011) found a mean density of five Almahata Sitta ureilites of  $3100 \text{ kg m}^{-3}$ . Considering the higher albedo values of *Hiroi et al.* (2010) as more reliable and assuming significant macroporosity, they concluded that the mass of 2008 TC<sub>3</sub> was only between 8000 and 27,000 kg. *Welten et al.* (2010) estimated the radius × density on the basis of radionuclide measurements to  $3000 \pm 300 \text{ kg m}^{-2}$ . We consider the following parameters as the most likely: size  $6.6 \times 3.6 \times 2.4$  m, volume  $22 \text{ m}^3$ , mean radius 1.74 m, mass 40,000 kg, bulk density  $1800 \text{ kg m}^{-3}$ ,

porosity almost 50% [using grain density  $3500 \text{ kg m}^{-3}$  from *Kohout et al.* (2011)], albedo 0.049, bolide energy  $3.1 \times 10^{12} \text{ J}$ , and integral luminous efficiency 13%. This implies that the albedo of *Hiroi et al.* (2010) and the energy derived from infrasound estimates were overestimated. The higher albedo would lead to a smaller mass and thus an even higher conflict with infrasonic energy. On the other hand, if that energy were true, the resulting asteroid density would be too high in comparison with some of the meteorites, and considering the atmospheric behavior of the body or an unrealistically low albedo would be needed.

The fast rotation of 2008 TC<sub>3</sub> means that the centrifugal force at the surface exceeded self-gravity, and therefore 2008 TC<sub>3</sub> was not a classical rubble pile held together only by gravity. Nevertheless, as shown by *Sánchez and Scheeres* (2014), a cohesive strength of only 25 Pa would be sufficient to bind the body together. Such strength could be provided by van der Waals forces between constituent grains (*Sánchez and Scheeres*, 2014). However, such a small mechanical strength would lead to the disintegration of the body just at the beginning of atmospheric entry at heights above 100 km. The bolide observations by U.S. government sensors revealed that the bolide exhibited three flares; that in the middle was the brightest and occurred at a height of 37 km (*Jenniskens et al.*, 2009). The Meteosat satellite data confirmed the maximum at 37 km and revealed two earlier flares at 45 km and 53 km (*Borovička and Charvát*, 2009). Finally, the distribution of meteorites is consistent with their release at a height of 37 km (*Shaddad et al.*, 2010). So the major disruption of 2008 TC<sub>3</sub> occurred at a height of 37 km under the dynamic pressure 0.9 MPa. This pressure is within the lower range as compared to other bodies of similar sizes (see Table 2), confirming the fragile nature of 2008 TC<sub>3</sub>, but it is still much higher than the expected strength of rubble piles. The actual structure of this body remains unclear. In any case, the recovered meteorites of various physical and mineralogical properties represent only a tiny fraction of the original mass, namely the fraction that was the strongest. They were probably embedded within a matrix that mostly disappeared during atmospheric entry. The matrix could be similar to the meteorites with the lowest measured densities, i.e., the porous fine-grained ureilites (*Bischoff et al.*, 2010).

The reflectance spectrum of 2008 TC<sub>3</sub> was taken in the wavelength range 550–1000 nm (*Jenniskens et al.*, 2009). The spectrum was flat and featureless and 2008 TC<sub>3</sub> was classified as F type. *Jenniskens et al.* (2010) searched for asteroids of similar spectra. They were not able to identify an asteroid family as the source of 2008 TC<sub>3</sub>. A similar search was performed by *Gayon-Markt et al.* (2012), who also discussed the origin of 2008 TC<sub>3</sub> and concluded that it is highly improbable that the heterogeneous structure was formed by low-velocity impacts in the current asteroid belt. *Horstmann and Bischoff* (2014) proposed that the material was formed in the early solar system by a four-stage process: (1) heating and partial melting on the ureilite parent body (UPB), including basaltic magmatism; (2) an impact event that resulted in the catastrophic disruption of the UPB;

(3) rapid cooling of the released mantle material; and (4) reaccretion into smaller daughter asteroids, forming ureilitic “second-generation” asteroids. The foreign (chondritic) fragments were more likely incorporated into them at the fourth stage rather than by subsequent impacts. Finally, 2008 TC<sub>3</sub> separated from one of the second-generation ureilitic bodies at 20 Ma. More recently, *Goodrich et al.* (2015) argued that the proportion of foreign clasts in 2008 TC<sub>3</sub> was not larger than in other polymict ureilites and that the same selection of materials as in other polymict ureilites was present. They hypothesized that the immediate parent of 2008 TC<sub>3</sub> was also the immediate parent of all other ureilitic meteorites. In contrast to *Horstmann and Bischoff* (2014), *Goodrich et al.* (2015) considered it more likely that the foreign fragments were accreted by the 2008 TC<sub>3</sub> parent body over long periods of time.

Almahata Sitta is not the only heterogeneous meteorite fall. The second confirmed case is Benešov, a fall instrumentally observed and very well documented in 1991 (*Spurný*, 1994), including a rich bolide spectrum. The search for meteorites was unsuccessful at that time; nevertheless, several papers were devoted to the bolide analysis (e.g., *Borovička and Spurný*, 1996; *Borovička et al.*, 1998). In the spring of 2011, after a complete reanalysis of all available records (*Spurný et al.*, 2014), the meteorite search was resumed with a revised strategy — not looking for big pieces but for small ones produced in large amounts from the disruption at a height of 24 km. The new strategy was successful and four weathered meteorites with masses in the predicted range were found with metal detectors exactly in the predicted area (*Spurný et al.*, 2014). Surprisingly, one meteorite was an H chondrite, one was an LL chondrite, and one was an LL chondrite with an embedded achondritic clast (the fourth meteorite could not be classified because of its small size and weathering stage). The size and location of all four meteorites exactly in the predicted area for corresponding masses, the same degree of weathering and composition consistent with the bolide spectrum, and the extremely low probability of two coincidental falls in the given area means that all the meteorites almost certainly came from the Benešov bolide. The heterogeneous nature of the Benešov meteoroid is supported by its early separation into smaller bodies during atmospheric flight (*Borovička et al.*, 1998).

These findings can shed new light on some old meteorite finds. The Galim meteorite fall contained both LL and EH specimens (*Rubin*, 1997). Other examples of meteorites of different types found close to each other can be found in the Meteoritical Database, e.g., Hajmah (ureilite + L), Gao-Guenie (H + CR), and Markovka (H + L). These meteorites were traditionally classified separately, e.g., as Hajmah (a), Hajmah (b), but may in fact come from the same body. Of course, chance alignment in these non-observed falls is also possible. Studies of the surprisingly rich Franconia strewn field, which contains various meteorite types, concluded that they fell at various times (*Hutson et al.*, 2013). On the other hand, there are some meteorites containing foreign clasts on a microscopic scale. The most prominent example

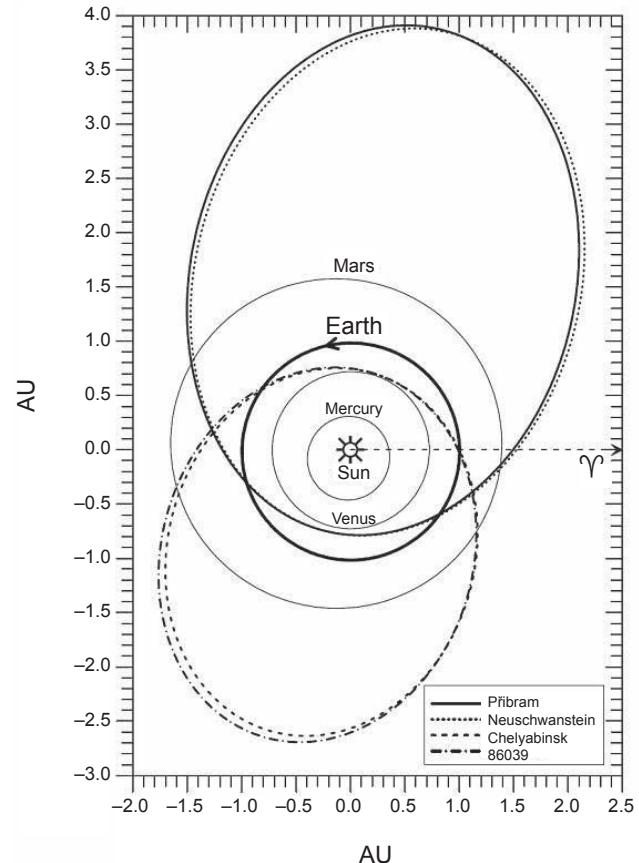

is the polymict microbreccia Kaidun, which contains materials of many different meteorite types in millimeter-sized clasts (Zolensky and Ivanov, 2003). Other cases have been summarized by Bischoff *et al.* (2010).

## 6.2. Příbram and Neuschwanstein Meteorite Pair

The Příbram meteorite fall has a special status among instrumentally recorded falls. This is not only because of the fact that it was the first such case in history (it fell on April 7, 1959) and that it represents the first time that recovered meteorites were directly linked with asteroids, but also because it was the first time when the so-called dark flight (first use of this term, which was invented by Z. Ceplecha) was rigorously computed for individual meteorite trails seen on the photographs (Ceplecha, 1961). This method was crucial for the future recovery of several subsequent events and it also played a fundamental role in the recovery of the second predicted meteorite fall in Europe, Neuschwanstein. Coincidentally, this other extraordinary case actually increased the original significance of the historic Příbram fall. The spectacular Neuschwanstein bolide was recorded by the all-sky cameras of the EN over Austria and Germany exactly 43 years after the Příbram fall. Based on the analysis of EN photographic records, three meteorites of corresponding masses were found exactly in the predicted area (Spurný *et al.*, 2003). However, the uniqueness of this case is not in the successful recovery of meteorites, but in the fact that the heliocentric orbits of both Příbram and Neuschwanstein meteoroids were almost identical, with  $D_{SH} = 0.025$  (Fig. 4). Such close similarity of orbits for two independent meteorite falls with recovered meteorites is unknown among the other 20 meteorite falls having known orbits. Only in the case of Innisfree and Ridgedale (presumed fall) meteorite falls observed in the MROP Canadian fireball network (Halliday, 1987) has a similarly close orbital pair been observed; unfortunately, meteorites were found only for the Innisfree fall. Nevertheless, this case generated the idea of the existence of meteorite streams (Halliday *et al.*, 1990), a notion strongly supported by the unique orbital similarity of the Příbram–Neuschwanstein pair. On the other hand, Příbram and Neuschwanstein falls differ in meteorite composition (Příbram is H5 while Neuschwanstein is EL6) and in CRE ages (Příbram is 12 m.y. while Neuschwanstein is 48 m.y.). Therefore this case has generated wide discussion as to whether the apparent orbital connection between these two meteoroids is real (e.g., Tóth *et al.*, 2011) or only coincidental (Pauls and Gladman, 2005). This question is not yet reliably solved; it seems from other recent instrumental observed falls such as Almahata Sitta or Benešov that the compositional difference should not be a decisive argument against the Příbram and Neuschwanstein connection.

## 6.3. Carbonaceous Chondrites: The Weakest Meteorites

Three instrumentally recorded fireballs resulted in carbonaceous chondrite meteorite falls. These three falls (Tagish Lake,

**Fig. 4.** The orbits of Příbram, Neuschwanstein, and Chelyabinsk meteorites and asteroid (86039) 1999 NC<sub>43</sub>, projected into the plane of ecliptic. The arrow with symbol points to vernal equinox. The orbital similarity of Příbram–Neuschwanstein and Chelyabinsk–1999 NC<sub>43</sub> is evident.

Maribo, and Sutter's Mill) have several common characteristics: They were all large (multi-meter-sized) initial objects and they all showed flight characteristics (early fragmentation, high end heights relative to their mass and speed) indicative of a very fragile structure. While the orbit for Tagish Lake (a C2 ungrouped unusual meteorite) is solidly asteroidal (with  $T_J = 3.7$ ), the orbits for Maribo and Sutter's Mill (both CM2 chondrites) are on the borderline between Jupiter-family comets and asteroids. Intriguingly, Maribo and Sutter's Mill have very similar orbits, suggesting both a common and relatively recent origin on the basis of short CRE ages (Jenniskens *et al.*, 2012). Moreover, these two meteorite falls appear to be associated with fireballs having initial speeds in excess of  $28 \text{ km s}^{-1}$ . This is substantially higher than the next fastest recovered fall (Morávka, at  $22.5 \text{ km s}^{-1}$ ). As surviving mass from ablation  $\propto \exp(-v^2)$ , even a small increase in initial speed result in large increases in ablation. This is even more remarkable as these are friable carbonaceous chondrites. The large size of the initial objects and the high altitude of the breakup allowing fragments to decelerate gradually appears to have been critical in survival of a small terminal mass in all three cases. For Tagish Lake, the estimated mass survival

fraction was <2% (*Hildebrand et al.*, 2006), while for Sutter's Mill it is <0.001% (*Jenniskens et al.*, 2012). While the orbits of Maribo and Sutter's Mill suggest a very recent, common origin, the CRE age of Sutter's Mill of 0.082 Ma (*Nishiizumi et al.*, 2014) places it in the 0.1–0.3-Ma CRE age grouplet of predominantly CM2 meteorites (*Caffee and Nishiizumi*, 1997), while the CRE age of Maribo at 0.8–1.4 Ma (*Haack et al.*, 2012) suggests they are not immediately related.

#### 6.4. Carancas: A Rare Monolithic Meteoroid

The Carancas meteorite fall occurred near noon local time on September 15, 2007, in the Andes Altiplano of Peru near the border with Bolivia. Remarkably, this fall produced an impact crater some 14 m in diameter, apparently the result of the hypersonic impact by a stony meteorite (*Tancredi et al.*, 2009). If the impact velocity is low, the size of the formed structure (impact pit/crater) is comparable to the impactor size (e.g., *Petaev*, 1992; *Mukhamednazarov*, 1999), whereas for high-velocity impacts the size of the crater is much larger than the impactor. The prevalence of low-velocity meteorite impacts emphasizes the ubiquity of fragmentation during ablation of stony meteoroids. This is a well-known feature of most meteorite-producing fireballs, which show breakup at altitudes indicating that the mean strength of the parent meteoroid is on the order of 0.1–1 MPa (*Popova et al.*, 2011). No optical recordings of the Carancas fireball were obtained, but airwaves from the fireball were recorded by an infrasound station located less than 100 km from the crater. From analysis of near-field infrasound, *Le Pichon et al.* (2008) and *Brown et al.* (2008) independently derived constraints on the trajectory of the associated fireball suggesting a steep (>45°) entry angle and radiant azimuth located to the east. Using the constraint that the orbit is unlikely to be transjovian and hence placing limits on the entry speed given the infrasonically estimated radiant, *Brown et al.* (2008) and *Borovička and Spurný* (2008) independently estimated that the associated meteoroid experienced >15 MPa ram pressure during flight and was initially most likely a few meters in size. Presuming that the crater formed because the meteoroid did not undergo significant fragmentation during flight (highly unusual for a stony meteoroid), this suggests the initial object was largely devoid of cracks and well described as a monolith. This result emphasizes the fact that meteoroid strengths and physical properties vary significantly, a conclusion well summarized as indicating there is no “average” meteoroid (e.g., *Ceplecha et al.*, 1998). The Carancas impact demonstrates that contrary to entry models, which predict that stony meteoroids require in excess of 10 MT of mass to produce high-velocity impact craters on the ground (*Bland and Artemieva*, 2006), in rare cases much smaller stony objects can impact Earth's surface hypersonically. As Carancas is the only known example of such a small stony meteorite producing a high-velocity impact crater, it is unclear how common strong (>10 MPa) monolithic meter-sized stony meteoroids are among the NEA population. The energy of formation of the crater was

estimated to be 2–3 t of TNT equivalent ( $10^{10}$  J) based on proximal blast effects (*Tancredi et al.*, 2009) as well as interpretation of the infrasonic signals (*Le Pichon et al.*, 2008; *Brown et al.*, 2008). The crater-forming impact generated a surface wave seismically detected some 50 km from the crater. Based on the estimated crater yield and equivalent seismic magnitude of the surface wave the impact coupling was approximately 0.1%, the first direct measure of crater seismic coupling from an impact (*Tancredi et al.*, 2009).

#### 6.5. Chelyabinsk: The Largest Well-Documented Impact

The Chelyabinsk meteorite fall, which occurred in Russia on February 15, 2013, was an event in a fundamentally different category than any other meteorite fall in recent history. It was preceded by an extraordinarily bright superbolide, brighter than the Sun, and accompanied by damaging blast wave. The analysis of the infrasonic, seismic, and satellite data showed that the total energy was ~500 kt TNT, i.e.,  $2 \times 10^{15}$  J (*Brown et al.*, 2013a; *Popova et al.*, 2013). This energy is ~30× larger than the energy of the Hiroshima atomic bomb. Although the explosion of an asteroid near the Tunguska River in Siberia in 1908 had much larger energy, estimated to be 5–20 Mt TNT (*Vasilyev*, 1998; *Boslough and Crawford*, 2008), no meteorites were recovered. Moreover, only limited data exist about the Tunguska event, which occurred over a very remote region. The Chelyabinsk event, on the other hand, was casually recorded by many video cameras and represented a unique opportunity to study the entry of a body larger than 10 m in size into the atmosphere. From the known energy, entry velocity, and density of the meteorites, the effective diameter of the Chelyabinsk was estimated to be 19 m and the mass was 12,000 t.

For such a large initial mass, the mass of material surviving as meteorites was quite small. There was only one large meteorite, which landed in Lake Chebarkul and was later recovered from the lake bottom, having a mass of ~600 kg (*Popova et al.*, 2013). All other meteorites were smaller than 30 kg. Only a few meteorites larger than 1 kg were recovered, although the number of small meteorites was enormous. The total recovered mass is unknown but was probably not larger than 2 t. The percentage of initial mass, which landed as macroscopic (>~1 cm) fragments, was much smaller than in a typical meteorite fall. It was also smaller than theory predicted for an impacting asteroid of such size (*Bland and Artemieva*, 2003, 2006).

The analysis of the atmospheric fragmentation revealed that severe destruction of the asteroid occurred between heights 39–30 km, under dynamic pressures of 1–5 MPa. At this early stage 95% of the mass was ablated and converted into dust and small (<1 kg) fragments. The remaining 5% of the initial mass continued ablating in the form of meter-sized boulders that fragmented again at lower heights, under pressures of 10–18 MPa. The only large piece (mass ~2 t) that emerged withstood a maximum pressure of 15 MPa (*Borovička et al.*, 2013b), comparable in strength to the

Carancas meteoroid, although representing less than 0.01% of the initial mass.

These fragmentation pressures are in the same range as found for smaller meteoroids based on observations of the associated fireballs (Popova et al., 2011). This confirms that there is no clear size-strength correlation among stony NEAs over the size range of centimeters to tens of meters. Since the actual strength and thus atmospheric behavior varies from case to case, we do not expect that Chelyabinsk will be representative of all bodies of similar size. Nevertheless, larger bodies are less decelerated, so they are subject to larger pressures when reaching denser atmospheric layers, which may lead to more destructive fragmentation.

Some asteroids are believed to be rubble piles/gravitational aggregates with a small strength of  $\sim 25$  Pa due to van der Waals forces between constituent grains (Sánchez and Scheeres, 2014). *A priori*, we expect rubble-pile meteoroids to separate into their constitutional parts at the very beginning of their atmospheric entry, under pressures of tens to hundreds of pascals. There is no evidence that such a separation occurred in the Chelyabinsk case. Nevertheless, significant loss of mass in the form of dust, probably from the surface layers, started early in flight at heights of  $>70$  km, as demonstrated by the extent of the dust trail deposited in the atmosphere (Borovička et al., 2013b; Popova et al., 2013).

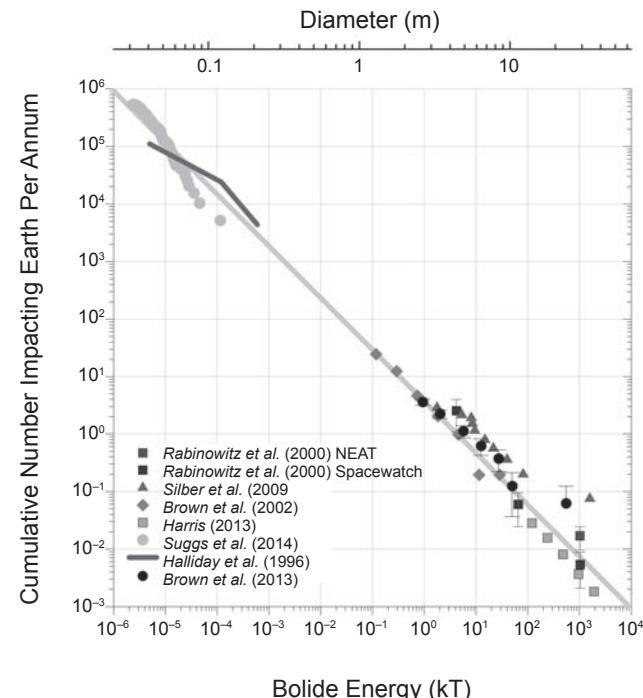

The Chelyabinsk case also vividly demonstrates the damage potential of small (tens of meters) NEAs. Although no significant damage was caused by the ground impact, the cylindrical blast wave originating at heights of 25–35 km (Brown et al., 2013a) caused structural damage (one collapsed roof, about 10% of windows broken, many large doors of factory halls fallen). The flying glass and other objects injured 1600 people (Popova et al., 2013).

## 7. STATISTICS OF FIREBALLS AND SMALL ASTEROID IMPACTS

The number of meter-sized objects colliding with Earth as a function of energy has been estimated from several independent techniques, as shown in Fig. 5.

Halliday et al. (1996) used data from the MORP fireball network to construct a clear-sky survey, the only controlled flux survey of in-atmosphere fireball detections. The survey provided impact rates for meteoroids between a few tens of grams and a few tens of kilograms with a total area-time product roughly equivalent to one full day of global coverage. Notably, he found that roughly 40% of all fireballs in this size range were associated with meteor showers and that the proportion of asteroidal (as opposed to cometary) meteoroids increased toward the top of the size range in the survey, rising to 70% of all meteoroids having masses of a few kilograms. A pronounced change in the slope also occurs at masses of a few kilograms, and is probably associated with changes in meteoroid population/origin. The primary limitation of this survey is uncertainty in conversion of fireball brightness to meteoroid mass, although most masses are likely accurate to a factor of several.

Independent confirmation of these flux estimates has recently been provided by Suggs et al. (2014), who examined lunar impact flashes. Compared to Halliday et al. (1996), they find absolute flux numbers to be a factor of several lower in the kilogram range and the proportion of shower meteoroids to be  $>60\%$ , although most of their data are in

**Fig. 5.** Observational estimates of the terrestrial cumulative impact flux (ordinate) as a function of impact energy (abscissa). The light gray line cutting through the plot represents the power-law fit from Brown et al. (2002a) based on satellite impact flash observations (diamonds) approximately representing the interval 0.1–10 kT where data is most complete. The solid circles are an update to these data as given by Brown et al. (2013a) with better statistics at larger sizes for energies  $>1$  kT. Error bars (where shown) represent counting statistics only. These data consist of debiased estimates of the telescopic near-Earth asteroid population and assumed average impact probabilities as given by Rabinowitz et al. (2000) (dark gray squares) from the NEAT survey and Spacewatch (black squares) surveys, where diameters are determined assuming an albedo of 0.1. The LINEAR values at smaller sizes are normalized to early work that established the absolute population for diameters  $>100$  m (Stuart, 2001). Also shown are the estimated impact rate from infrasonic measurements of bolide airbursts from the Air Force Technical Application Centre (AFTAC) acoustic monitoring network as reanalyzed by Silber et al. (2009) (triangles). More recent telescopic debiased estimates from data compiled from all surveys by Harris (2013) are shown as light gray squares. The circles are the equivalent impact rate for Earth as determined from lunar flashes taking into account gravitational focusing (Suggs et al., 2014). Finally, the dark gray line at the top represents the impact rate from the photographic Meteorite Observation and Recovery Project (MORP) clear sky survey as described by Halliday et al. (1996).

the tens of grams mass range, below the level where the *Halliday et al.* (1996) survey is complete. A larger difference is apparent at the smallest sizes, but the uncertain mass scale in both surveys may be the cause.

Due to the rarity of meter-sized impacts (which occur roughly once every two weeks over the entire Earth), groundbased optical systems are not efficient at recording large enough numbers of such events to estimate fluxes. *Brown et al.* (2002a) used data from spacebased systems to detect impacts on a global scale of multi-meter-sized meteoroids over an eight-year period. Total impact energies were available for 300 events, although individual speeds were not. The resulting cumulative number of impacts per year ( $N$ ) as a function of energy ( $E$ ) — in units of kilotons of TNT =  $4.18 \times 10^{12}$  J — was found to follow a power law of the form  $N = 3.7 E^{-0.9}$ . This fit is appropriate to energies of 0.1–10 kt or diameters ranging from 1–6 m. An extension to this survey by *Brown et al.* (2013a) found similar values at these energies, but evidence for fluxes above the power-law curve at larger sizes. *Silber et al.* (2009) used acoustic records of impacts over a 14-year period to independently estimate fluxes in a similar size range. Their fluxes are systematically higher than the power-law curve from *Brown et al.* (2002a) but in agreement within uncertainty with the revised values at larger sizes (>6 m) from *Brown et al.* (2013a).

At sizes above 10 m diameter, telescopic population estimates are widely used to estimate flux. These estimates generally agree well with the extrapolated *Brown et al.* (2002a) power law, although are somewhat lower than the small-number statistic-limited estimates from bolide impacts at these larger sizes. The telescopic survey impact values have underlying uncertainties due to unknown population-wide collision probabilities at smaller sizes and poorly known albedo distribution of smaller NEAs. Given the widely differing sources of uncertainties across all the surveys shown in Fig. 5, the degree of agreement is good. We note that fluxes may also be derived from counting smaller lunar impact craters, and such estimates (e.g., *Werner et al.*, 2002) agree well with the telescopically determined flux curve (*Harris*, 2013). We chose not to include the estimated flux from small lunar craters due to the controversy surrounding the role and importance of secondary craters at such small sizes (e.g., *McEwan and Bierhaus*, 2006).

Orbital information from telescopic data is only available in quantity for NEAs larger than ~10 m. Unlike the population in the centimeter to tens of centimeter size range, NEA “streams” appear to be non-existent (*Schunová et al.*, 2012), emphasizing both the longer collisional lifetimes of larger NEAs and a probable lack of cometary material among multi-meter-sized bodies. Of the several dozen meter-class impacts recorded in Earth’s atmosphere with orbital and/or physical information about the strength of the impactor, the majority appear to be stony objects, with only a small number of probable, weak cometary bodies. Only 10% of this impacting population had Tisserand values below 3, emphasizing the likely dominance of asteroidal objects

at these larger sizes. Among the 22 meteorite-producing fireballs, eight appear to have been meter-sized or larger prior to impact. None of these had clearly cometary orbits, although Maribo and Sutter’s Mill (both CM2 carbonaceous chondrites) have orbits similar to 2P/Encke.

## 8. OPEN QUESTIONS

We have shown that bolide observations provide information about physical and chemical properties of asteroidal and cometary fragments in the decimeter to decameter size range; about the processes occurring during their interaction with the atmosphere, including potentially hazardous effects; and about the size-frequency distribution of such events. The obtained pre-impact heliocentric orbits enable the study of likely source regions of meteorites. Nevertheless, there are still open questions that need to be answered by further observations and modeling. In this final section of this chapter, we discuss some of these questions.

### 8.1. Meteorites from Comets

The question of whether some meteorites come from comets has been discussed for a long time (e.g., *Öpik*, 1968; *Padevět and Jakeš*, 1993; *Campins and Swindle*, 1998; *Lodders and Osborne*, 1999; *Gounelle et al.*, 2008). Some of the earlier studies were motivated by the apparent difficulty of transferring meteoroids from the asteroid belt to Earth, a problem that has now been solved [by orbital resonances and the Yarkovsky effect (see *Morbidelli et al.*, 2002; *Bottke et al.*, 2002b)]. Nevertheless, it was proposed that cometary nuclei may also contain — in addition to ice and dust — macroscopic boulders similar to carbonaceous asteroidal material, e.g., in the “icy-glue” model of *Gombosi and Houpis* (1986). Although other cometary models seem to be more probable (*Weissman and Lowry*, 2008), the presence of chondrule-like material in the samples of Comet 81P/Wild 2 returned by the Stardust mission (*Nakamura et al.*, 2008) suggests that material that formed meteorites is present in comets as well, at least in small samples.

None of the known meteorite orbits is clearly cometary, although the orbits of Maribo and possibly also Sutter’s Mill are close to the transition between cometary and asteroidal orbits. The carbonaceous chondrites, in particular types CI and CM, would be the primary candidates for cometary origin. These meteorites have been hydrated, while cometary dust is anhydrous, but *Gounelle et al.* (2008) argued that hydration can occur in cometary interiors. *Gounelle et al.* (2006) computed the orbit of the Orgueil CI1 meteorite, which fell in France in 1864, and concluded that the aphelion probably lay beyond the orbit of Jupiter. As determination of the orbit was based on visual observations and there is no direct velocity information available, the assumptions about the orbit cannot be completely trustworthy. *Trigo-Rodríguez et al.* (2009) observed a deeply penetrating fireball (no meteorites were found) and concluded that the orbit was similar to that

of Comet C/1919 Q2 Metcalf. Their paper, however, contains a numerical error in orbit computation. When corrected, the orbit is no more similar to the orbit of Comet Metcalf, although the aphelion still lies beyond Jupiter. However, the orbit is highly sensitive to the value of initial velocity, which was difficult to measure in that particular case. A small change of velocity will make the orbit completely asteroidal. So there remains no clear, unambiguous example of a cometary meteorite fall.

## 8.2. Meteorites from Meteor Showers

Meteor showers are caused by meteoroids of a common origin, in most cases cometary. For many showers, the meteorite survival is hampered by high entry velocity. Until recently,  $30 \text{ km s}^{-1}$  was considered a practical upper velocity limit for the occurrence of a meteorite fall (Ceplecha et al., 1998). The fact that the Maribo meteorite almost reached this limit and was made from a soft material suggests that the actual limit may be higher. Some of the low-velocity meteor showers, like the  $23.5 \text{ km s}^{-1}$  Draconids originating from Comet 21P/Giacobini-Zinner, contain, however, such fragile material that survival is excluded (Borovička et al., 2007). On the other hand, the Taurid meteor shower (entry speeds  $\sim 26\text{--}30 \text{ km s}^{-1}$ ) contains both fragile and strong bodies, some of which seem to be capable of producing meteorites (Brown et al., 2013b). The principal parent body of Taurids is supposed to be Comet 2P/Encke, a comet on a peculiar orbit completely inside Jupiter's orbit. Both Taurids and Comet 2P/Encke may be part of a broader "Taurid complex," which also contains several other showers and possibly several NEAs (see Jenniskens, 2006). Because of this it may be difficult in individual cases to link bolides directly with Comet 2P/Encke.

The Geminid shower, on the other hand, is well defined and is one of the most active annual showers. The entry speed is  $36 \text{ km s}^{-1}$  and the parent body is (3200) Phaethon, which orbits in the inner solar system and closely approaches the Sun ( $q = 0.14 \text{ AU}$ ,  $a = 1.27 \text{ AU}$ ,  $i = 22^\circ$ ). Recently it has been classified as an active asteroid (Jewitt, 2012; Jewitt et al., 2013). Based on the reflectance spectroscopy, asteroid (2) Pallas was identified as the likely parent body of Phaethon (de León et al., 2010). Geminid meteoroids have been known to be relatively dense and strong (e.g., Babadzhanov, 2002; Brown et al., 2013b), but only recently has it been demonstrated that a meteorite-dropping Geminid could occur, although the meteorite was not found (Spurný and Borovička, 2013; Spurný et al., in preparation). Madiedo et al. (2013b) presented similar observations concerning Geminid meteorite survival, but their data were less robust. The recovery of a meteorite originating from Phaethon would undoubtedly be a major milestone.

## 8.3. Meteorite Streams

The very close similarity of orbits of the Příbram and Neuschwanstein meteorites (Spurný et al., 2003) suggested

that they may have a common origin and be part of a meteorite stream. A similar pairing was proposed earlier for the Inisfree meteorite and the Ridgedale bolide (Halliday, 1987). The idea of meteorite streams was also discussed from another perspective by Lipschutz et al. (1997). Meteorite streams are potentially formed by asteroidal collisions. The orbit of Chelyabinsk meteorites was found to be similar to the orbit of asteroid (86039) 1999 NC<sub>43</sub>, suggesting that the Chelyabinsk body could have been ejected from 1999 NC<sub>43</sub> by a collision (Borovička et al., 2013b). In that case, a meteorite stream could exist in Chelyabinsk orbit. However, the typical decoherence time of meteoroid streams in the near-Earth region is only  $10^4\text{--}10^5 \text{ yr}$  (Pauls and Gladman, 2005), while the estimated collisional lifetime of asteroids is much longer (Bottke et al., 2005). Meteorite streams should be therefore rare, although some may be expected to exist (Jones and Williams, 2008). In the Příbram-Neuschwanstein case, the search for a related shower of fainter meteors was negative (Koten et al., 2014), implying that the stream, if it exists, contains only large bodies. For Chelyabinsk, the reflectance spectra of the meteorites and 1999 NC<sub>43</sub> do not match well, so the association seems to be unlikely (Reddy et al., 2015). Direct evidence of a meteorite stream or an association of a meteorite with its immediate parent body is therefore still missing.

Near-Earth asteroids have been also associated with (often unconvincingly) meteor showers or individual fireballs, not necessarily meteorite dropping (e.g., Babadzhanov et al., 2012; Madiedo et al., 2014b, and references therein). If some of these associations are real, they may indicate that the respective NEAs are in fact extinct comets and the stream was formed by cometary activity.

## 8.4. Structure of Meteoroids and Details of Their Interaction with the Atmosphere

The internal structure of meteoroids and their bulk densities are still difficult to infer from bolide observation. Data interpretation is complicated by the fact that the values of luminous efficiencies are not reliably known and the process of meteoroid ablation and fragmentation is not understood in detail. In particular, the structure and frequency of mixed-type meteoroids like Almahata Sitta and Benešov is unknown. There are also unexplained phenomena like periodic variations and high-frequency flickering on fireball light curves (Spurný and Ceplecha, 2008) (see also Fig. 3), large lateral velocities of fragments (Borovička and Kalenda, 2003; Borovička et al., 2013b; Stokan and Campbell-Brown, 2014), and jet-like features on fireball images at high altitudes (Spurný et al., 2000).

# Meteoroid Streams and the Zodiacal Cloud

Peter Jenniskens

*SETI Institute and NASA Ames Research Center*

In the last decade, considerable progress has been made in charting meteoroid streams at Earth and in understanding the mechanisms of meteoroid stream formation and evolution that ultimately result in the formation of the zodiacal cloud. This has led to the realization that episodic disruption plays a key role in the decay of comets and primitive asteroids. Several ongoing disruption cascades manifest as multiple meteoroid streams at Earth. Evidence is mounting that the recently released meteoroids also fall apart, on timescales of 100–10,000 yr, into smaller meteoroids that survive for another  $10^5$ – $10^6$  yr to form the zodiacal cloud. The first dynamical models of the zodiacal cloud are being developed to explore the relative importance of the various sources. These show that main-belt asteroids contribute only a small fraction to the cloud. Ironically, the infall to Earth of freshly ejected meteoroids, dominated by the larger meteoroid streams, is currently in significant part from primitive asteroid (3200) Phaethon.

## 1. INTRODUCTION

All asteroids and comets in our solar system are gradually falling apart into meteoroids. These meteoroids move at a high relative speed to other objects in the solar system and are therefore an impact hazard to satellites, a cause of asteroid surface weathering, and create meteors when impacting a planetary atmosphere. Streams of meteoroids provide a history of parent body activity and can warn us about the presence of potentially hazardous objects.

Interplanetary matter falls to Earth at a rate of 10,000–40,000 tons per year, mostly in the form of  $\sim$ 150- $\mu\text{m}$  (10  $\mu\text{m}$ –1 mm)-sized meteoroids (Love and Brownlee, 1993; Ceplecha et al., 1998). They produce the neutral-atom-debris layer (and trails) in our atmosphere, responsible for the sodium airglow (Plane, 2003), and the meteoric smoke particles that condense the ice of noctilucent clouds (Hervig et al., 2012). They are responsible for the interplanetary dust particles (IDP) collected in Earth’s atmosphere, and deliver to Earth’s surface micrometeorites (e.g., Rudraswami et al., 2014), solar wind-implanted  $^3\text{He}$  (e.g., Farley, 2001), platinum-group elements (Peucker-Ehrenbrink, 2001), and the meteoric iron that enables life in the iron-depleted southern oceans (Plane, 2012). In the past, meteoroids may have supplied origin-of-life organics, directly from surviving organics as well as through impact-induced chemistry in the atmosphere (e.g., Chyba et al., 1990; Maurette, 1998; Jenniskens, 2001; see also Chapter 34 in Jenniskens, 2006).

Meteoroids with sizes on the order of the wavelength of light (also called interplanetary dust) scatter light efficiently and cause the visible zodiacal cloud (Leinert et al., 1998).

They are also strong emitters of infrared light when heated (e.g., Levasseur-Regourd and Lasue, 2010; Maris et al., 2011; Krick et al., 2012; Ade et al., 2014). It is these meteoroids that make the presence of minor planets in other solar systems detectable (e.g., Nesvorný et al., 2010; Morlok et al., 2014; Bonsor et al., 2014; Ballering et al., 2014).

Larger >1-mm meteoroids are often only detected when they enter Earth’s atmosphere and cause phenomena collectively called a “meteor.” They cause the ionization trains in radio-detected meteors, the bright lights that are our naked-eye observed meteor showers, as well as the occasional fireballs that produce airbursts and meteorites.

The largest >1-m meteoroids are the topic of the chapter by Borovicka et al. in this volume. The manner in which these larger meteoroids break in the atmosphere probes the physical properties of small near-Earth asteroids (NEAs), while the surviving meteorites sample their material properties.

This chapter is mostly concerned with how active asteroids and the now dormant comets created the meteoroid streams that manifest as meteor showers on Earth and how that matter contributes to the zodiacal cloud and sporadic meteors.

Numerous papers on these topics since the 2002 *Asteroids III* volume and the 2001 review papers on interplanetary dust in Grün et al. (2001a) can be found in conference proceedings of meetings on interplanetary dust by Krueger and Graps (2007); on meteoroids by Trigo-Rodríguez et al. (2008), Cooke et al. (2010), and Jopek et al. (2014); on asteroids, comets, and meteors by Lazzaro et al. (2006); and in abstracts from the Asteroids, Comets, and Meteors (ACM) 2008 meeting in Baltimore, the ACM 2012 meeting in Niigata, and the ACM 2014 meeting in Helsinki, as well

as in the annual Proceedings of the International Meteor Conference. This chapter builds upon, and expands on, an earlier synopsis presented in *Jenniskens* (2006).

## 2. NOMENCLATURE

When discussing the role of asteroids in the production of meteoroids, it is important to understand what is meant by “asteroid.” From an observer’s point of view, that can include both objects from the asteroid main belt and the dormant or mostly inactive comets that originated in the Kuiper belt and Oort cloud (*Levison*, 1996).

It is the instantaneous rate of mass loss and its nature, especially the meteoroid size and size distribution, that determine a telescopic observer’s distinction between an asteroid (star-like) and a comet (fuzzy object). This appearance can change over time. An asteroid can have an associated stream of meteoroids from a period of activity in the past.

A “meteoroid” is defined as “a solid object moving in interplanetary space, of a size considerably smaller than an asteroid and considerably larger than an atom or molecule” (*Millman*, 1963).

At what point an “asteroid” becomes a “meteoroid” is not clear. The definitions approved by the International Astronomical Union in the 1960s are now outdated and efforts are underway to come to terms with this. For example, it is custom these days to also use the term “meteoroid” for the object when it no longer moves through space but through Earth’s atmosphere to cause the meteor. The boundary with asteroids is varyingly put at 1 m or 10 m. However, some researchers protested the use of “asteroid” for the 20-m-sized meteoroid responsible for the Chelyabinsk airburst (*Popova et al.*, 2013), as it had not been seen in space prior to impact, while the small boulders seen in space near Comet 103P/Hartley 2 by the telescopic cameras of NASA’s Deep Impact mission are considered “meteoroids” rather than “asteroids” (*A’Hearn et al.*, 2011).

## 3. INTERPLANETARY DUST PARTICLES

A review of the properties of the IDPs and micrometeorites collected on Earth is given in the chapter on asteroidal dust in the previous *Asteroids III* book (*Dermott et al.*, 2002a). In summary, ~75% of IDPs collected in Earth’s atmosphere are unequilibrated, fine-grained mixtures of thousands to millions of mineral grains and amorphous components with close to chondritic abundances. The compositions of micrometeorites are similar to CM- and CR-type carbonaceous chondrites, but they are 2× richer in carbon. Some hydrous IDPs are extensively altered by liquid water inside a parent body. However, most are anhydrous, with the pyroxene-rich particles that are complex admixtures of 0.1–5-μm-diameter single-mineral grains (most commonly enstatite and Fe-Ni sulfides), amorphous material, carbonaceous material, and submicrometer spheroidal grains of silicate glass with embedded metal and sulfides (GEMS). Some have very large D/H ratios and other isotopic anomalies, and contain presolar grains.

Clearly, interplanetary dust is dominated by relative primitive materials, not by dust from the ordinary chondrites that are recovered from most meteorite falls. Back in 2002, these materials were thought to be the result of prolonged mechanical mixing in the deep regolith of asteroidal rubble piles in the outer main belt (*Dermott et al.*, 2002a).

This view has changed dramatically in recent years with the study of the small cometary dust particles collected from Jupiter-family comet (JFC) 81P/Wild in 2004 during the Stardust mission (e.g., *Zolensky et al.*, 2006; *McKeegan et al.*, 2006; *Hanner and Zolensky*, 2010). This dust proved to consist of the expected fine-grained (submicrometer-sized) loosely bound aggregates with a bulk chondritic composition. However, most aggregates also contained large individual crystals of (most commonly) olivine (33%), low-calcium pyroxene (24%), mixtures of these (10%), and other minerals (33%), mostly Fe-Ni sulfides, formed or altered at temperatures of 1600–2000 K (*Zolensky et al.*, 2012). The cometary dust was even found to have calcium-aluminum-rich inclusions (CAIs) and small chondrule fragments (*Nakamura et al.*, 2008; *Joswiak et al.*, 2014), suggesting that high-temperature inner solar system materials reached the young Kuiper belt. Some magnesium-calcium carbonates and a single occurrence of orthorhombic cubanite even suggested that transient liquid water may have existed within the nucleus or in the inner solar system parent bodies from which this dust originated (*Mikouchi et al.*, 2007; *Berger et al.*, 2011; *Zolensky et al.*, 2012).

These materials are not unlike those found in primitive carbonaceous chondrite meteorites. Indeed, the recent “Grand Tack” planet-formation models suggest that primitive asteroids and Kuiper belt (JFC) comets could both have initially formed beyond the birth region of the giant planets (*Walsh et al.*, 2011; *Morbidelli et al.*, 2011; *Briani et al.*, 2011; *Raymon and Morbidelli*, 2014; see also the chapter by Morbidelli et al. in this volume).

Are meteoroids from primitive asteroids and JFC-type comets different? *Kikwaya et al.* (2011) measured similar densities from meteor lightcurves. CM-type meteorites are likely from a main-belt asteroid source (*Jenniskens et al.*, 2012), although the eccentric orbits of CM-type Maribo and Sutter’s Mill resemble that of JFC 2P/Encke (*Haack et al.*, 2011). The CI-type carbonaceous chondrite Orgueil (also aqueously altered) had an even wider JFC-like pre-atmospheric orbit, but based on the 1864 visual observations of the fireball (*Gounelle et al.*, 2006).

How these materials manifest as IDPs in Earth’s atmosphere and micrometeorites on the ground is determined by changes while in the interplanetary medium and the physical conditions during entry (*Rietmeijer*, 2007). In the interplanetary medium, grains are exposed to solar wind and galactic cosmic rays, causing amorphitization of minerals and polymerization of carbon (e.g., *Rietmeijer*, 2011).

During atmospheric entry, the level and rate of heating is a function of entry speed. This changes the meteoroid density and porosity (*Kohout et al.*, 2014). Because of admixtures of large grains, even the IDPs with nonchondritic

abundances could originate from primitive bodies, with frail aggregate material more easily lost during atmospheric entry (Rietmeijer, 2008).

#### 4. METEOROID STREAMS

Meteoroid streams provide a historic record of dust formation, and still identify their sources. These sources are not necessarily the active comets we can study today, long known to be a source of meteoroid streams and the zodiacal cloud (Shiparelli, 1867; Whipple, 1950, 1967). Instead, the meteoroid input can be dominated by discrete massive disruption events that happened some time ago or, alternatively, by a large population of objects that each contribute small amounts of meteoroids that are hard to measure.

##### 4.1. Formation and Evolution of Meteoroid Streams

Meteoroid streams are observed as meteor showers on Earth and, in some cases, as dust trails in infrared emission (Davies *et al.*, 1984; Sykes *et al.*, 1986). Significant progress was made in recent years in systematically charting meteoroid streams at Earth (e.g., Brown *et al.*, 2008a,b, 2010; Younger *et al.*, 2009; Jenniskens *et al.*, 2011).

Around the time when the *Asteroids III* book came out in 2002, there was a watershed in understanding the mechanisms of meteoroid stream formation and evolution. Many relevant mechanisms were proposed earlier, but only now

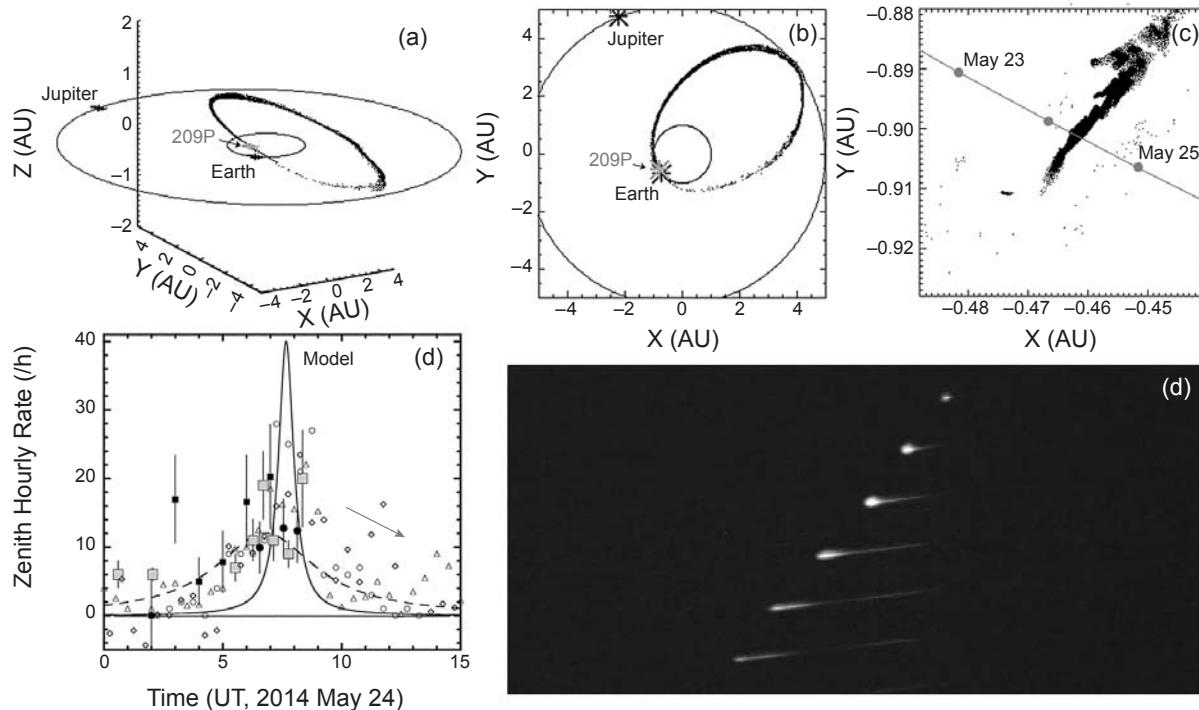

were theoretical predictions validated and refined by observations, such as shown in Fig. 1 (see reviews by Jenniskens, 2006; Williams, 2011).

Meteoroid streams are principally first created by small differences in the orbital period of the ejected particles, which cause a comet dust coma to return as a meteoroid stream after one orbit, creating the one-revolution dust trail (Pravec, 1955).

Ejection of meteoroids from parent bodies can occur via gas drag from sublimating ices (Whipple, 1950), parent body disruptions (with collisions, spinup, or other causes), impacts by meteoroids on surfaces, centrifugal forces from Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) spinup of the parent body, and even from electrostatic levitation (e.g., Walsh *et al.*, 2008).

All common mechanisms tend to result in small relative ejection speeds compared to the heliocentric velocity of the parent body. The hemispherical direction of ejection can either be toward the Sun or be isotropic. Models of ejection from active asteroids follow those for comets (e.g., Whipple, 1950; Crijo and Rodionov, 2000; Vaubaillon *et al.*, 2005; Kelley *et al.*, 2014).

The shorter or longer orbital period resulting from the ejection process will cause the particle to return correspondingly sooner or later in future returns (two-revolution, three-revolution, etc., orbit), spreading the trail along the parent body orbit and creating a meteoroid stream (Fig. 1), but not broadening it (Kondrateva and Reznikov, 1985; McNaught

**Fig. 1.** Meteoroid stream model for how the 1903 AD ejecta from weakly active comet 209P/Linear are distributed on May 24, 2014 (top); dust from AD 1803–1924 will be in Earth's path (bottom, left). From Berárd and Vaubaillon (2013). In the bottom left panel, the predicted activity (solid line, scaled down by factor of 10) is compared to the observed activity (dashed line), with different symbols representing different video (right), visual, and radio-MS data. From Jenniskens (2014).

and Asher, 1999; Lyytinen, 1999). Solar radiation pressure tends to increase the orbital period of the meteoroids relative to that of the comet on average, delaying the return of the meteoroids somewhat (Kresak, 1976).

Planetary perturbations act differently on different parts of the trail, with Jupiter and Saturn changing in position relative to the node of the stream from year to year (Jenniskens, 1997; Lyytinen and Jenniskens, 2003). As a result, the dust trails move relative to Earth's orbit, causing meteor outbursts in some years, but not in others (Kondrateva and Reznikov, 1985; Jenniskens, 1997; McNaught and Asher, 1999).

Mean-motion resonances can keep sections of the dust trail stable (e.g., Asher et al., 1999; Jenniskens, 2006). Close encounters with the planets will distort the trails more dramatically, creating gaps, kinks, or a scattering of meteoroids over a wider region around the orbit of the parent body (e.g., Vaubaillon et al., 2005; Jenniskens, 2006).

If close-encounter perturbations by Jupiter and mean-motion resonances are not dominant, then secular perturbations will gradually rotate the nodal line. For parent bodies on orbits that pass inside Earth orbit, this rotation of the nodal line will ultimately result in a stream crossing Earth's orbit (Babadzhanov and Obrubov, 1992; Jenniskens, 2006). When the inclination is higher than 20°, secular perturbations create large oscillations of inclination and perihelion distance, called Kozai cycles (Kozai, 1962).

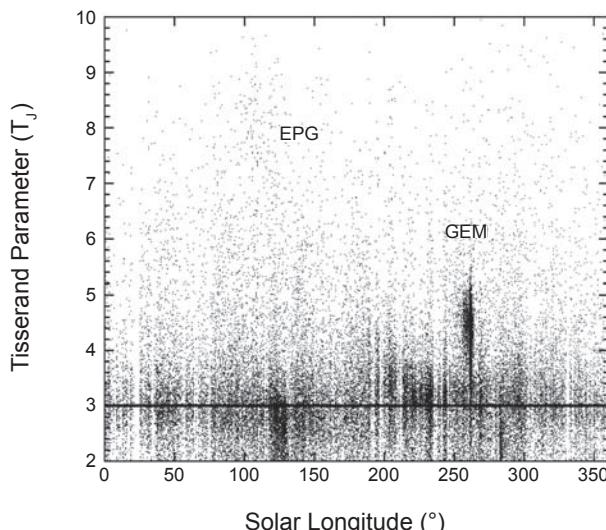

#### 4.2. Main-Belt Asteroids as a Source of Meteoroid Streams

Main-belt asteroids create meteoroid streams when primitive asteroids have comet-like activity, such as observed for the Geminid shower parent asteroid (3200) Phaethon (see the chapter by Jewitt et al. in this volume), or when rubble-pile asteroids spin up by YORP and fall apart by centrifugal forces (Walsh et al., 2008), if not prevented by cohesion forces (Rozitis et al., 2014).

These events could produce dust trails detectable by the Infrared Astronomical Satellite (IRAS) and Spitzer at mid-infrared (IR) wavelengths for much longer periods of time than the cometary activity. Two such low-inclined and low-eccentricity dust trails may have originated from relatively recent, <100-k.y.-old, collisional breakups of small <10-km-diameter main-belt asteroids (Nesvorný et al., 2006a).

Main-belt asteroids can create meteoroid streams at Earth when such disruptions happen while the asteroid is in a near-Earth orbit. These streams still would have the Tisserand parameter with respect to Jupiter  $T_J \gg 3$  close to that of the parent asteroid (Levison, 1996).

Very few of our meteor showers appear to originate from main-belt asteroids. To illustrate this, Fig. 2 shows  $T_J$  as a function of time in the year for ~1-g (1-cm) meteoroids observed by the Cameras for All-sky Meteor Surveillance (CAMS) project (Jenniskens et al., 2011) between October 2010 and March 2013. The graph covers the range of  $T_J$  for main-belt asteroids and JFCs. Solar longitude is a measure of time throughout the year. Meteoroid streams show up as

**Fig. 2.** Tisserand parameter of CAMS-observed meteors as a function of solar longitude (time of the year). Note the lack of high  $T_J$  orbits. GEM = Geminids; EPG = ε Pegasiids.

clumps in a narrow range of solar longitude. Measurement errors in meteoroid speed account for some of the diffusion of the  $T_J$  values.

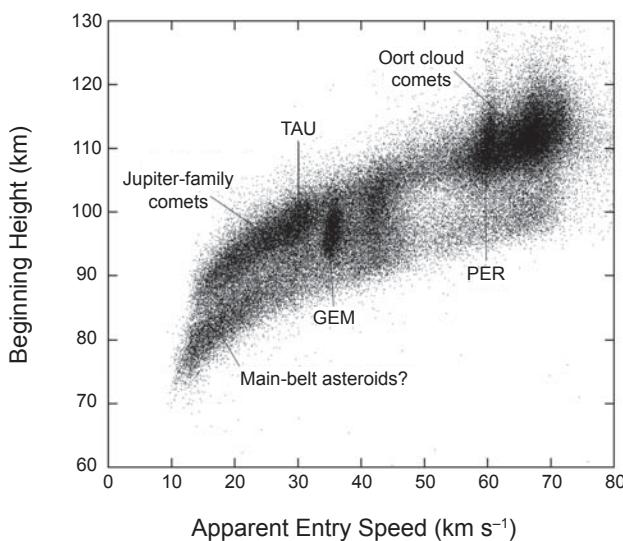

The Geminids (GEM) move in distinctly asteroidal  $T_J \sim 4.4$  orbits (Fig. 2). These meteoroids also have a relatively high meteoroid density, resulting in unusually low meteor beginning heights (Fig. 3). Meteor flares are rarely observed.

The Phaethon parent body is rapidly decaying into streams and remaining fragments. The streams (Geminids and Daytime Sextantids) are still in close proximity to their associated parent bodies (Phaethon and 2005 UD, respectively) in terms of the direction of their nodal line. The Geminids are thought to be only ~1000 yr old (Jones and Hawkes, 1986; Jenniskens, 2006). If (3200) Phaethon originated from the Pallas asteroid family (de Leon et al., 2010), then there must be a more rapid pathway from family to the orbit of Phaethon than proposed, which is possible via the 5:2 resonance with Jupiter.

The Geminids account for 15% of present-day mass influx in the form of meteoroid streams detected by CAMS from the nighttime sky (Jenniskens et al., 2015a). Only 2% of mass is contributed by main-belt asteroidal sources other than the Geminids ( $T_J > 3.2$ ).

This activity will not last. The shower is expected to increase in intensity until about 2050 AD, but then decrease and be gone by 2100 AD (Jenniskens, 2006). Because of this, the dominant role of the Geminids is perhaps not representative for the zodiacal cloud as a whole. On the other hand, individual meteoroid orbits with  $T_J \gg 3$  are commonly measured in CAMS data (Fig. 2) and in photographed meteoroid orbits.

Many asteroidal streams were identified in the past (perhaps unjustified) from only pairs of similar meteoroid orbits from photographed fireballs (Terent'eva, 1990). One example is the pair of similar orbiting Neuschwannstein and Pribram meteorites, which are of EL6 and H6 type, respectively. Such pairings are now mostly thought to be

**Fig. 3.** Beginning heights of CAMS-detected meteors. GEM = Geminids; TAU = Taurids; PER = Perseids.

accidental (Koten *et al.*, 2014).

Asteroidal streams are also detected in radar surveys of small meteoroids, such as the Canadian Meteor Orbit Radar (CMOR) (Brown *et al.*, 2008a,b, 2010), in particular pertaining to high-inclination showers (Table 1).

So far, no new meteor showers rich in  $T_J > 4$  meteoroids have been identified from CAMS data. Few of the established CMOR showers with  $T_J > 4$  show a concentration in the CAMS orbital-element diagrams, possibly because they are rich in faint meteors. Table 1 lists only those CMOR-derived streams for which some meteoroids were detected by CAMS ( $N$  being the number of meteoroid orbits). These include the  $\epsilon$  Pegasids (#326, EPG), the  $\beta$  Equuleids (#327, BEQ), and the  $\alpha$  Lacertids (#328, ALA). The  $\epsilon$  Aquilids (#151, EAU) were detected earlier by the Harvard Meteor Radar (Sekanina, 1976). In later work, CMOR also detected a shower called the July  $\beta$  Pegasids (#366, JBP) (Brown *et al.*, 2010). Only the  $\epsilon$  Pegasids stand out well in Fig. 2.

It is possible that these high-inclination short-semimajor-axis showers are not from main-belt asteroids at all. No main-belt asteroid parent bodies have been identified yet, despite the fact that 9.3% of all 11,853 known NEAs have inclinations  $>30^\circ$ , and as much as 25% of the bright  $H \leq 18$  mag NEAs. Instead, old age and Poynting-Robertson (P-R) drag may have decreased the semimajor axis of initial JFC- or Halley-type-comet-derived dust, without fully dispersing the meteoroids.

Many CAMS-detected meteoroids have orbits that straddle the border of asteroids ( $T_J \geq 3$ ) and JFC ( $T_J = 2-3$ ) domains (Fig. 2). The Taurid Complex showers in November, associated with large but weakly active comet 2P/Encke, have  $T_J \sim 3.2$  on average, well into the asteroidal domain, but these meteoroids are fragile, with beginning heights similar to JFCs, higher than those of the Geminids (Fig. 3).

Whipple (1940) first proposed that Comet 2P/Encke is the parent body of the Southern Taurids (#2, STA) and the Northern Taurids (#17, NTA). From the widely dispersed longitude of perihelion, these streams are thought to be at least 20–30,000 yr old. One rotation of the nodal line takes about 5900 yr, explaining the twin showers, as well as the associated daytime  $\beta$  Taurids (#173, BTA) and  $\zeta$  Perseids (#172, ZPE) (Whipple, 1940; Steel and Asher, 1996).

After more asteroids were discovered in Taurid-like orbits, it was proposed that there existed a Taurid complex with a hard-to-understand wide range of semimajor axes ( $a = 1.66-2.57$  AU), proposed to be fragments from a 20-km-sized comet that broke apart 20–30,000 yr ago (Clube and Napier, 1984; Asher *et al.*, 1993; Steel and Asher, 1996).

However, a tally made in 2006 concluded that all proposed members up to that point, with the exception of 2P/Encke, had reflection properties typical of S- or O-class asteroids (Jenniskens, 2006, pp. 462–464). It is now thought that these originally proposed objects are instead asteroids that originated from the inner main belt by ejection from the  $v_6$  resonance, a known source of S-class asteroids.

More recently, the picture is dramatically changing with both more near-Earth objects (NEOs) being discovered in orbits that resemble 2P/Encke in semimajor axis and more

TABLE 1. High  $T_J$  showers.

# IAU	N (AU)	a (AU)	q (°)	i (°)	$\omega$ (°)	Node	$T_J$

Median orbital elements for  $N$  = number of CAMS-observed meteors:  $a$  = semimajor axis;  $q$  = perihelion distance;  $i$  = inclination;  $\omega$  = argument of perihelion; Node = longitude of the ascending node.

clarity about the Taurid stream being composed of multiple streams (*Porubcan et al.*, 2006).

A recent analysis of CAMS data shows that the Taurid showers are composed of at least 19 individual streams, 7 of which were assigned to parent body asteroids. Importantly, these streams are not twins, having separate values of the longitude of perihelion, but similar to that of their parent bodies. This implies that individual streams fade rapidly, presumably due to meteoroids falling apart, before their node can significantly rotate away from the parent body (*Jenniskens et al.*, 2015b).

Unlike the Taurid complex asteroids proposed in the past, these asteroids all have a narrow range of semimajor axis ( $a = 2.20\text{--}2.35$  AU). Of the 17 known asteroids with semimajor axis in this range and with a Taurid (and related  $\chi$ -Orionid) shower's longitude of perihelion  $\Pi = 130^\circ\text{--}185^\circ$ , 9 can be associated with one of the Taurid and  $\chi$ -Orionid stream components, most in the 0.3–1-km size range. The current completeness of NEO detections in this size range is about 64%, in good agreement (*Jenniskens et al.*, 2015b).

Another example of a complex of comet fragments, each meteoroid stream detected at Earth still having a nodal line similarly oriented to that of the comet fragments, is the complex of comets and meteoroid streams associated with Comet 96P/Machholz (*Sekanina and Chodas*, 2005; *Jenniskens*, 2006; *Jenniskens et al.*, 2015b).

## 5. THE ZODIACAL CLOUD

How important are main-belt asteroids in the formation of the interplanetary dust cloud as a whole? In the *Asteroids III* chapter on asteroidal dust (*Dermott et al.*, 2002a), much focus was given to the zodiacal dust bands at  $2^\circ$  and  $10^\circ$  ecliptic latitude, because these features can be used to estimate the contribution of dust from asteroids to the zodiacal dust cloud.

At the time, the dust bands were thought to be produced in the Eos, Koronis, and Themis families, but a few problems with this interpretation were already noted in *Grogan et al.* (2001). This perception has changed completely in the past decade. Now, the three main bands are believed to sample an ongoing collisional cascade among the smallest fragments in three recently formed families: Karin, Veritas, and Beagle, which represents collisions between asteroids only 6–8 m.y. ago (*Nesvorný et al.*, 2006a,b, 2008; *Kehou et al.*, 2007; *Vokrouhlický et al.*, 2008; *Espy et al.*, 2009).

Based on the earlier proposed source regions, and assuming that all asteroids contribute similar amounts of meteoroids, *Kortenkamp and Dermott* (1998) estimated that >75% of infalling matter on Earth originated from main-belt asteroids, and later increased this estimate to as high as 90% (*Grogan et al.*, 2001; *Dermott et al.*, 2002a,b). With some holdouts, this perception has also completely changed in recent years. Now, dynamical models put this fraction at less than 5% (*Wiegert et al.*, 2009; *Nesvorný et al.*, 2010). That also agrees better with the fact that satellites with dust detectors passing through the asteroid belt have never detected

a significant increase of impact rates of small meteoroids (*Gruen et al.*, 2001b; *Landgraf et al.*, 2002).

Nevertheless, *Ipanov et al.* (2008) still assigned 30–50% to main-belt asteroids, while the “model A” by *Rowan-Robinson and May* (2013) found 22.2% of meteoroids from asteroids originating in the main belt and 7.5% from an isotropic source proposed to be interstellar dust.

### 5.1. DORMANT COMETS AS THE SOURCE OF ZODIACAL DUST

The first dynamical models of the zodiacal cloud were inspired by insight from meteor observations and were made possible by advances in computing techniques, which now make it possible to follow the complex dynamical evolution of clouds of meteoroids. The advance in computing capabilities also has greatly aided the ongoing development of new meteor and meteoroid observing techniques, and has resulted in a better understanding of the observing biases and the astronomical interpretation of meteor observations (e.g., *Taylor and McBride*, 1997; *Galligan and Baggaley*, 2004, 2005; *Campbell-Brown*, 2008; *Close et al.*, 2007).

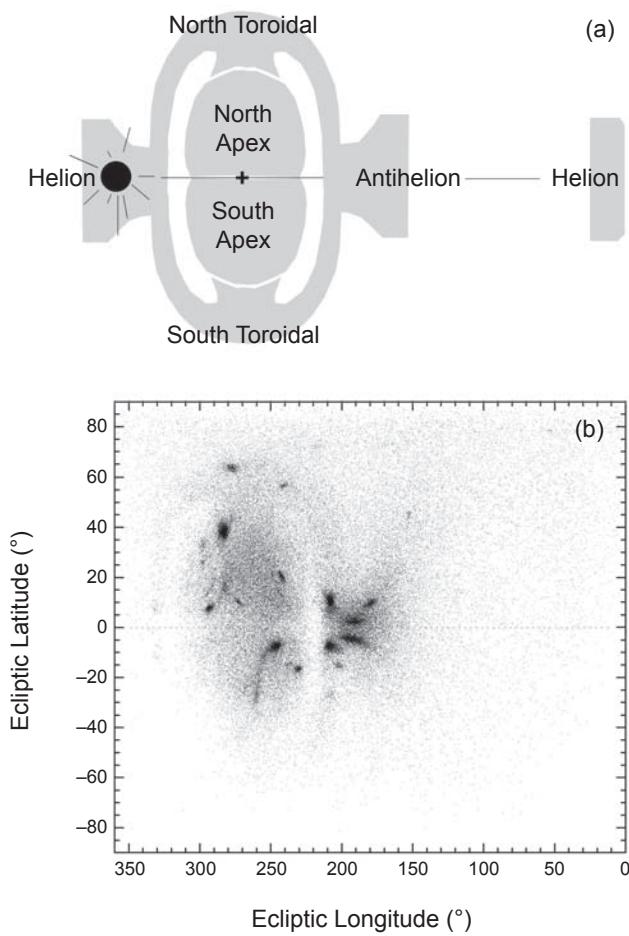

The new models are calibrated to the optical (peak emission, polarization, and Fraunhofer lines) and infrared observations of the zodiacal cloud (e.g., *Levasseur-Regourd and Lasue*, 2010), but only the meteor observations provide orbital-element distributions of the actual meteoroids.

Before discussing the new models, I will first discuss the latest meteor observations. Meteor observations are capable of probing both the small <1-mm grains that dominate the mass influx from the zodiacal cloud, also probed by dust impact detectors, and the large >1-mm grains that carry most mass loss of their source, but are relatively rare and not easily detected by dust detectors or by remote sensing in astronomical observations.

The small meteoroids are detected by specular meteor radars, which sample underdense echoes from meteors of magnitude +6 and fainter, and by high-power large-aperture (HPLA) radars that can also detect the head-echoes of small meteoroids. The larger meteoroids are observed as visual and video-detectable meteor showers and fireballs (e.g., *Borovička et al.*, 2005; *Jenniskens et al.*, 2011), as head echoes by radar (e.g., *Kero et al.*, 2012; *Piško et al.*, 2013), and as impact flashes on airless bodies such as the Moon (e.g., *Suggs et al.*, 2014). Bright meteors and impact flashes are relatively few, but advances in low-light-level video observations now provide insight into the population of ~1 g–1 kg meteoroids that carry much of a comet's mass loss.

Figure 4 shows the six principal source directions from which sporadic meteors (both small and large) approach Earth (*Hawkins*, 1956; *Taylor*, 1997; *Jones and Brown*, 1993; *Younger et al.*, 2009). Observational and technical biases affect how these sources are sampled.

Most easily detected are the fast 40–72 km s<sup>-1</sup> meteors approaching from the northern and southern apex sources, which originate from Oort cloud comets (long-period comets with orbital period  $P > 250$  yr and retrograde Halley-type comets with  $250 > P > 20$  yr). Of intermediate 30–50 km s<sup>-1</sup>

**Fig. 4.** (a) Cartoon showing the sporadic meteoroid source regions identified by Hawkins (1956), Taylor (1997), and Jones and Brown (1993). (b) An example of measured approach directions of meteoroids to Earth; all +1 to +4 magnitude meteors throughout the year observed in CAMS video observations (Jenniskens et al., 2015).

apparent entry speed are the toroidal sources, which mostly are rich in faint meteors and are prominent in radar observations (Campbell-Brown, 2008; Pokorny et al., 2013).

More important for the total mass input in the zodiacal cloud, however, are the slow and therefore hard to see 11–40 km s<sup>-1</sup> meteors in the antihelion and helion sources (Fig. 4), which are meteoroids from JFCs and main-belt asteroids.

Much effort has gone into debiasing the radar-observed populations (e.g., Taylor, 1997; Jones and Brown, 1993; Galligan and Baggaley, 2002; Nesvorný et al., 2011a; Kero et al., 2012, 2013; Píško et al., 2013). Both specular and head-echo radar observations have strong velocity-dependent biases, because ionization has a complex and steep dependence on speed and altitude. After debiasing for these observational effects, most mass from the larger observed particles, and therefore most mass input into the interplanetary dust cloud, arrives from the antihelion and helion sources. The derived orbital data shows that the meteoroid density falls off with heliocentric distance ( $r$ ) according to  $r^{-1}$  inside 1 AU and

according to  $r^{-2}$  outside 1 AU, with a weak excess at 2–4 AU (Galligan and Baggaley, 2002; Dikarev et al., 2004, 2005; Jenniskens, 2006).

Surprisingly, the sensitive AMOR (+14 limiting magnitude) and not-so-sensitive CMOR (+8 limiting magnitude) radar results show a sporadic population with similar orbital-element distributions, with antihelion source orbits on relatively small  $a \sim 1.0$  orbits (Fig. 5).

For CMOR particles to evolve to  $a = 1$  AU orbits by P-R drag requires more time than allowed by the collisional lifetime according to Grün et al. (1985). Nesvorný et al. (2011a) assumed that CMOR-detected particles, about 0.6 mm in size, survived as long as the smaller 0.09-mm-diameter AMOR-detected particles, some  $3 \times 10^5$  yr, about 4–10× as long as calculated by Grün et al. (1985).

The same is measured for the CAMS-detected sporadic meteors (Jenniskens et al., 2015a). The debiased distribution of semimajor axis peaks at 2.1–2.8 AU, but has a P-R-evolved component (Fig. 5). These particles survived collisions for  $1\text{--}3 \times 10^6$  yr, 10× longer than calculated by Grün et al. (1985).

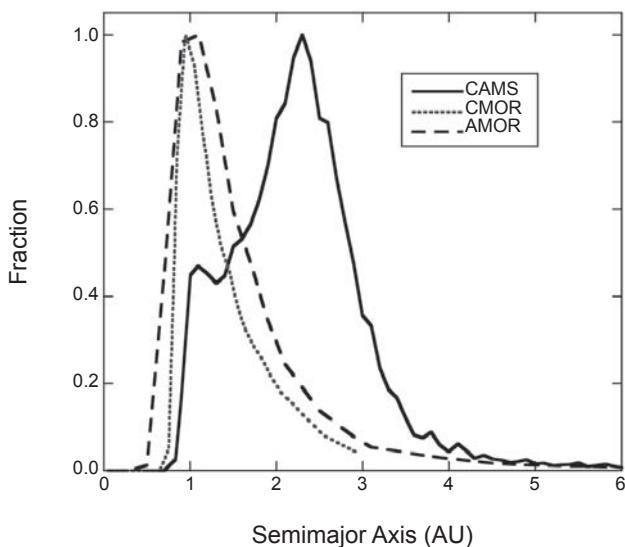

Above 100 µm, the size frequency distribution of meteoroids falling to Earth falls off steeply to larger sizes. The short lifetime required to explain the relative lack of the CAMS-detected 7-mm-sized meteoroids at Earth (Grün et al., 1985) suggests that these meteoroids disappear on a short timescale of 300–10<sup>4</sup> yr, not from collisions, but from other processes that disrupt the meteoroids into smaller grains. A small fraction of large grains remains and goes on to evolve by P-R drag (Jenniskens et al., 2015a).

Large meteoroids deposited by comets disappear over time, before their streams evolve and dynamically merge with the sporadic background. Freshly deposited comet dust fades over timescales as short as 300 yr for the Leonids of Comet 55P/Tempel-Tuttle and 50 yr for the Camelopardalids of 209P/Linear, needing the scaling down of the model activity in Fig. 1 to match the observations, for example (Jenniskens, 2014). Other meteoroids survive longer, but streams linked to weakly active comets or asteroidal parent bodies are rarely older than about 10<sup>4</sup> yr, not old enough to differentially rotate the nodal line and create twin showers at their other node (Jenniskens et al., 2015b).

CMOR samples large enough particles to recognize the meteoroid streams, being most sensitive to showers rich in faint meteors and with intermediate entry speeds of 20–50 km s<sup>-1</sup> (Brown et al., 2008a,b, 2010; Weryk and Brown, 2012).

The meteoroid streams of faster, slower, and larger particles are best detected by optical techniques, but bright meteors are much less frequent. Only in recent years have significant numbers of meteoroid trajectories been measured by scaling up multi-station video observations. These surveys are ongoing, but already show the presence of many additional meteoroid streams.

CAMS is just one of these surveys [for an overview of other projects, see Jenniskens et al. (2011)]. CAMS detects the +1 to +4 meteors (~1-g- and ~1-cm-sized meteoroids)

**Fig. 5.** The measured orbital element distribution at Earth for 7-mm-sized (CAMS), 0.6-mm-sized (CMOR), and 0.09-mm-sized (AMOR) meteoroids. The distributions are debiased by correcting for observational effects and mass weighted, but are not corrected for the collisional probability with Earth (Jenniskens et al., 2015a).

approaching from the nightside antihelion source, but not those arriving on the dayside after circling the Sun, called the helion source (Fig. 4). The cameras measure luminosity, with luminous efficiency (= the fraction of kinetic energy converted into the light detected by the cameras) depending in an uncertain manner on entry speed.

Slightly more than a quarter (25.6%) of all CAMS-detected meteors between October 2010 and March 2013 were assigned to 230 meteor showers, of which 86 are newly discovered [listed among the International Astronomical Union (IAU) Meteor Shower Working List numbers 427, 448–502, 506–507, and 623–750]. The IAU keeps a tally of meteor showers and assigns names, numbers, and codes (Jenniskens et al., 2009). So far, only 95 showers are considered “established,” meaning that we can be certain that they exist. Based on the new data, this number is expected to increase.

Only a small fraction of these showers has known parent bodies. It was long thought that the lack of parent bodies for most showers meant they had disappeared. This view has now changed dramatically. With a surge in NEO discoveries, it was realized that many meteor shower parent bodies are hiding as asteroid-looking objects. Most are weakly active or dormant comets and a few are primitive asteroids (Jenniskens, 2008).

Whipple (1983) was the first to point out that asteroid (3200) Phaethon moves in the Geminid stream (#4, GEM), but that association was long dismissed as a possibly coincidental alignment of orbits. However, Phaethon moves in an eccentric asteroid-like orbit with small perihelion distance ( $q$ ), which makes a random association unlikely. As said, the stream has a Tisserand parameter with respect to Jupiter  $T_J = 4.4$ , well into the asteroid regime with  $T_J \geq 3$ . Phaethon now is known to be occasionally weakly active at

perihelion (Jewitt et al., 2013), and there is no longer doubt that Phaethon is the source of the Geminids.

This uncertainty was lifted following the discovery that asteroid 2003 EH<sub>1</sub> moves among the highly inclined 72° Quadrantids (#10, QUA) (Jenniskens, 2004). It was then found that asteroid 2005 UD moved in the Sextantid stream (#221, DSX) (Ohtsuka et al., 2006), which is related to the Geminids (Jewitt and Hsieh, 2006; Jenniskens, 2006), and asteroid 2008 ED<sub>69</sub> moved among the κ Cygnids (#12, KCY) (Jenniskens and Vaubaillon, 2008; Trigo-Rodriguez et al., 2009). Asteroid 2002 EX<sub>12</sub>, now better known as weakly active Comet 169P/NEAT, was proven to be the parent body of the α Capricornids (#1, CAP) (Wiegert and Brown, 2004; Jenniskens and Vaubaillon, 2010), while 2003 WY<sub>25</sub> was identified as a recovered fragment of Comet D/1819 W<sub>1</sub> (Blanpain), the source of the Phoenicids (#254, PHO) (Foglia et al., 2005; Jenniskens, 2006). Work on other proposed associations is ongoing (e.g., Babadzhanov et al., 2008, 2012; Rudawska et al., 2012). The situation should be similar on Mars and Venus (Christou, 2010).

Typically, the mass of meteoroids in each stream is similar to that of the remaining parent body (Jenniskens, 1994, 2006, 2008a,b). The implication is that the main mass-loss mechanism of JFCs is an episodic disruption, during which they lose about half their mass and create meteoroid streams.

Active comets were long known to contribute to the zodiacal cloud (e.g., Whipple, 1967; Zook, 2001), but are insufficient to account for the required steady-state mass input. Active JFCs contribute only about 300 kg s<sup>-1</sup> of large meteoroids that contribute to mid-IR emissions (Reach et al., 2007). The required steady-state averaged mass input in the zodiacal cloud is 10<sup>4</sup>–10<sup>5</sup> kg s<sup>-1</sup> (Nesvorný et al., 2011a).

Based on the new parent body identifications, we now know that the episodic breakup of mostly dormant comets solves this discrepancy (Jenniskens, 2008a,b). With the more prominent JFC streams today measuring about 2 × 10<sup>13</sup> kg (Table 8 in Jenniskens, 2006), there needs to be about 1 such breakup every 30 yr in the inner solar system to maintain the cloud, from a population that is about 2000 dormant comets and 600 active comets (Belton, 2015a).

Jupiter-family comets appear to break apart as often as Oort cloud comets (Levison et al., 2002; Belton, 2015) at a rate of about 5 × 10<sup>-5</sup> disruptions/yr for an active comet and a factor of 3 less for a dormant comet. Recent disruptions include that of meteoroid stream parents D/1819 V1 (Blanpain) in 1819, 3D/Biela in 1843, and 73P/Schwassmann-Wachmann 3 in 1995 (Reach et al., 2009). The latter released meteoroids during the 1995 breakup with a cumulative mass index of 0.85–1.00, dominated by particles >1 mm (Vaubaillon and Reach, 2010), and numerous fragments of which one large object survived. Eleven known short-period comets were observed to split in the last 200 yr, amounting to a rate of 1 in 18 years, but not all may have disrupted to the level required.

Activity from these events can linger, as in the case of weakly active 2P/Encke, the remnant of the Taurid complex (see below). The activity associated with 2P/Encke and the

Taurid complex meteoroid streams is recognized to be a significant contributor to the current helion and antihelion meteor shower sources (Whipple *et al.*, 1967; Wiegert *et al.*, 2009).

Discovering the dominant presence of dormant and weakly active comets among our antihelion source meteoroid streams inspired a revisiting of zodiacal cloud models to investigate whether or not mostly dormant comets can be the main source of our zodiacal meteoroids. Only recently have zodiacal dust cloud models been developed that are based on rigorous dynamical modeling of the meteoroid orbital evolution from their source to their demise in collisions with other meteoroids. All prior zodiacal cloud models were based on artificial constructs of components with presumed orbital dynamics (e.g., Divine, 1993; Dikarev, 2005; Ipatov *et al.*, 2008; Rowan-Robinson and May, 2013).

It was often assumed that main-belt asteroidal dust would evolve by P-R drag into near-circular orbits ( $e \sim 0.3\text{--}0.0$ ), from which they hit Earth at very low entry velocities. However, Doppler radial velocity profiles of Fraunhofer lines in scattered light from the zodiacal cloud show a typical  $e \sim 0.5$  eccentricity of small meteoroids (Ipatov *et al.*, 2008; May, 2008).

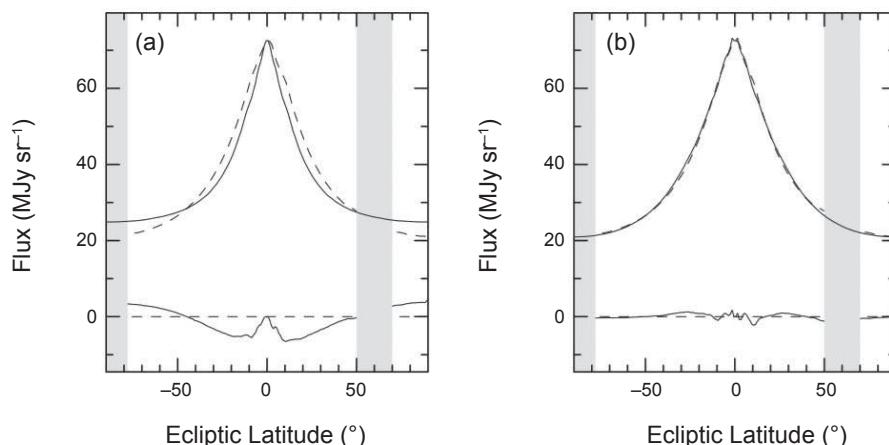

The new modeling showed that meteoroids evolving from asteroids would increase their eccentricity as required due to the action of resonances, but would not be pumped up to high enough inclinations to account for the observed latitudinal dispersion of the zodiacal cloud (Nesvorný *et al.*, 2010). In contrast, meteoroids ejected by the population of JFCs naturally created the observed width of the zodiacal cloud (Fig. 6) from an initial higher distribution of inclinations, coupled to an increase of inclinations from interactions with Jupiter when still having an aphelion near this planet. It was calculated that Kuiper belt comets in the form of JFCs

contribute more than 90% of all meteoroids in the inner solar system (Nesvorný *et al.*, 2010). Other derived properties for the zodiacal cloud are summarized in Table 2.

While deposited initially in JFC-like orbits ( $e \sim 0.7$ ), the dust does evolve by P-R and solar-wind drag to lower eccentricities ( $e \sim 0.5$ ) over time, finally hitting Earth with a median speed of  $\sim 14 \text{ km s}^{-1}$ , slow enough to explain these comets as the dominant source of our micrometeorites (Nesvorný *et al.*, 2010). However, if collisional lifetimes are reversed and small 10–100- $\mu\text{m}$  grains collide more frequently than in the Grün *et al.* (1985) model, it is possible that the P-R evolution is interrupted and meteoroids move in  $e \sim 0.3\text{--}0.5$ , as observed.

It was earlier assumed that the relative lack of large grains at Earth was because meteoroids with masses  $>10^{-6} \text{ g}$  ( $>1 \text{ mm}$ ) collided with smaller so-called  $\beta$ -meteoroids (radiation-pressure-driven, on hyperbolic orbits, generated deep inside 1 AU) before they had time to evolve from the asteroid belt to Earth. The observed size distribution slope at Earth was explained through a balance between the collisional loss of particles and the dust supply (Gustafson, 1994; Ishimoto, 1998). Collisional lifetimes at 1 AU were estimated at about 60,000 yr for a 1-mm meteoroid and 200,000 years for centimeter-sized grains (Nikolova and Jones, 2001). Collisional lifetimes may in fact be longer if collisions with larger meteoroids dominate their destruction (e.g., Davis *et al.*, 2012).

In summary, we now understand that the zodiacal cloud results mainly from episodic disruptions of weakly active and mostly dormant JFCs, followed by the formation of meteoroid streams of millimeter- to centimeter-sized particles, which then fade by meteoroid fragmentation to  $\sim 0.15\text{-mm}$  particles, with these smaller particles dynamically evolving to become the zodiacal cloud, until collisions finally shatter

**Fig. 6.** Two models of zodiacal cloud infrared emission (upper solid lines) with 25- $\mu\text{m}$  IRAS flux measurements (upper dashed lines, with gray areas prone to residual galactic plane emissions) and the differential of calculated–observed (bottom). **(a)** The best-fit model with asteroid and Oort cloud comet particles. This model does not fit IRAS observations well. The model profile is too narrow near the ecliptic and too wide overall. **(b)** A model with a dominant contribution of (mostly dormant and weakly active) JFC particles. From Nesvorný *et al.* (2010).

TABLE 2. Zodiacal cloud properties.

Property	Value	Ref.
<i>First stage — sources</i>		
Mass in young comp.	$\sim 5 \times 10^{15}$ kg	[4]
Mean age young comp.	$300\text{--}10^4$ yr	[4]
Steady state mass input	$10^4\text{--}10^5$ kg s $^{-1}$	[1]
Main-belt asteroids	<5% by mass	[1]
Jupiter-family (=Kuiper belt) comets	>90% by mass	[1]
Oort cloud comets	<10% by mass	[1]
Interstellar (at 1 AU)	$\ll 1\%$ by mass	[2]
Dominant size range	1 mm–10 cm	[4]
<i>Second stage — evolved</i>		
Total dust cross section	$1.7\text{--}3.5 \times 10^{17}$ m $^2$	[1]
Total mass	$\sim 4 \times 10^{16}$ kg	[1]
Mean age	$\sim 300,000$ yr	[1]
Dominant size range	150 $\mu$ m	[3]
Mass impacting Earth	$10\text{--}40 \times 10^3$ ton yr $^{-1}$	[1,3]
( $\phi = 1$ $\mu$ m to 5 cm)

the grains fine enough to be blown out of the solar system by radiation pressure.

## 5.2. The Contribution from Main-Belt Asteroids

Main-belt asteroids contribute less than 5% to the IR emission of the zodiacal cloud and the population of meteoroids (Wiegert *et al.*, 2009; Nesvorný *et al.*, 2010). The relative contribution of both JFC dust and asteroidal dust to Earth accretion is larger, because gravitational focusing increases the accretion rate of meteoroids that move with a low relative speed to Earth (e.g., Jones and Poole, 2007). If the smallest meteoroids approach Earth as slow as in the model by Nesvorný *et al.* (2010), then the fraction of main-belt asteroidal meteoroids can exceed 10% of the total accreted mass (Nesvorný *et al.*, 2010).

The contribution from main-belt asteroids is not zero. Some objects in the main belt are known to produce dust now (see the chapter by Jewitt *et al.* in this volume). The meteorites that fall from <1-m-sized meteoroids originate from collisions among smaller asteroids, presumably mainly in the asteroid families (e.g., Spurný *et al.*, 2012; Jenniskens *et al.*, 2014; see also the chapter by Borovicka *et al.* in this volume). And a period of increased extraterrestrial influx seen in the  $^3$ He concentration of seafloor sediments, starting  $8.2 \pm 0.1$  m.y. ago, is thought to have been caused by the formation of the Veritas asteroid family  $8.3 \pm 0.5$  m.y. ago (Farley *et al.*, 2006).

Among smaller ~1-g meteoroids, Borovicka *et al.* (2005) found that about 10% of sporadic meteors (out of a sample of 97) in short-period orbits have iron spectra only, lacking magnesium and sodium. Such nonchondritic abundances are possibly related to iron-nickel meteorites. This needs further study.

Another line of evidence for main-belt-asteroid meteoroids points to a group of slow meteoroids that have lower beginning heights compared to those of other JFCs (Fig. 3). All meteoroids impacting Earth with very low speeds (<13 km s $^{-1}$ ) appear to belong to this group. The low beginning heights are thought to be due to different thermal properties of the meteoroids that delay the onset of ablation (Whipple, 1954). It is possible that this group represents main-belt-asteroidal meteoroids (Weryk *et al.*, 2013), but there are some doubts. This group has median orbital-element semimajor axis  $\langle a \rangle = 2.13$  AU, eccentricity  $\langle e \rangle = 0.60$ , and inclination  $\langle i \rangle = 7.2^\circ$  ( $T_J = 3.45$ ), not unlike the meteoroids from Comet 2P/Encke. Their beginning height is also comparatively lower than that of the Geminids, which are thought to derive from a primitive main-belt asteroid. Moreover, CAMS also detected a population of low-beginning heights among the fast Oort cloud comet dust, causing a bimodal distribution of beginning heights (higher speeds in Fig. 3). The retrograde >50 km s $^{-1}$  meteors have  $\langle a \rangle = 4.9$  AU,  $\langle e \rangle = 0.84$ , and  $\langle i \rangle = 149.9^\circ$  ( $T_J = 0.15$ ). The cause of the bimodal behavior is not known. The P-R evolved population dominates the lower group at speeds less than 25 km s $^{-1}$ , which may represent comet dust that has become more sintered over time.

## 5.3. Oort Cloud Comets as a Source of Meteoroids

Oort cloud comets in the form of long-period and Halley-type comets contribute up to 10% of the observed mass of the zodiacal cloud (Nesvorný *et al.*, 2010). To discuss these active comets as a source of zodiacal dust seems outside the scope of this volume, but is relevant to understanding the role of zodiacal dust in meteoroid impacts on asteroid regolith, for example.

Like JFCs, Oort cloud comets produce meteoroids predominantly by disruption, with few surviving to return to the inner solar system on more than a few returns (Levison *et al.*, 2002). These meteoroids strike from retrograde orbits with the highest impact velocities, as a result of which there is little gravitational focusing by Earth.

Again, zodiacal cloud models were revisited using dynamical tools, inspired by the strong detection of the apex source in radar observations (e.g., Campbell-Brown, 2005, 2008), resulting in the work by Wiegert *et al.* (2009) and the discovery that HPLA radar observations of small meteoroids appear to be dominated by apex source meteoroids (e.g., Close *et al.*, 2002; Janches *et al.*, 2005, 2006; Dyrud *et al.*, 2005; Chau *et al.*, 2007; Fenzke *et al.*, 2009; Kero *et al.*, 2013), resulting in the study by Nesvorný *et al.* (2011b). The population is described by Francis (2005) and references therein.

These observations pertain mostly to small meteoroids <0.3 mm, which impact Earth from predominantly 55–65 km s $^{-1}$  orbits [MU radar head echoes (Kero *et al.*, 2013)], only slightly smaller than the 57–70 km s $^{-1}$  orbits detected for larger particles in the CAMS survey. The smaller particles detected by Advanced Research Projects Agency (ARPA) Long-Range Tracking and Instrumentation Radar (ALTAIR) and Arecibo radar observations seem to have lower entry

speeds of 40–65 km s<sup>-1</sup>, as do AMOR and Harvard radar-detected meteoroids (Campbell-Brown, 2005). Some of that is a selection effect, with the radars being most sensitive in this velocity range (Close *et al.*, 2007). Janches *et al.* (2008) have argued, however, that this is not the case for Arecibo. If so, very-small-apex source meteoroids in the inner solar system have also very short semimajor axis  $a \sim 1$  AU and a wide range of eccentricity.

Nesvorný *et al.* (2011b) found that <100-μm-sized particles deposited on long-period orbits are easily blown out of the solar system, while particles larger than 300 μm evolve so slowly that they are scattered by Jupiter before P-R drag lowers the semimajor axis significantly. Only about 1% of ejected particles, mostly particles with sizes in between, reach orbits with semimajor axis  $a \sim 1$  AU by P-R drag, contributing to the radar-observed apex source meteors. If so, the apex source dominates that of the helion/antihelion sources for small (<100 μm) sizes, even if the meteoroids are ejected from JFCs and Oort cloud comets in similar proportions for all sizes. The resulting particle density follows an  $r^{-1.5}$  dependence with heliocentric distance for  $r < 5$  AU and an  $r^{-2}$  dependence for  $r > 10$  AU.

However, the resulting eccentricities tend to still have high  $e \sim 1$ , and the meteoroid radiants peaked at higher ecliptic latitude than observed (Nesvorný *et al.*, 2011b). This needs further study.

#### 5.4. Kuiper Belt and Interstellar Dust

Note that the situation in the outer solar system can be very different, where dust from the Kuiper belt objects and interstellar dust can be important contributors (Landgraf *et al.*, 2002; Moro-Martin and Malhotra, 2002; Sterken *et al.*, 2012; Poppe and Horányi, 2012; Rowan-Robinson and May, 2013). Because this has perhaps less relevance to main-belt asteroids, I refer to these papers for more information.

### 6. FUTURE WORK

The perception that the zodiacal dust bands are caused by ongoing asteroid collisions in the main belt may still change. Precession of the longitude of perihelion can be fast and the rotation of the nodal line can still cause most dust at aphelion to be in the higher inclined orbits. The Taurid complex meteoroid streams, for example, maintain a near constant proper inclination with precessing longitude of perihelion, and spread along 360° in longitude of perihelion over time (Wiegert *et al.*, 2009), even though the meteoroids have relatively high eccentricities ( $e \gg 0.2$ ). The reported fading of meteoroids in the dust bands (Grogan *et al.*, 1997) may not be due to collisions. The relative role of the Taurid complex in the formation of small antihelion source meteoroids needs to be better understood.

We now know that episodic fragmentation of dormant and weakly active comets and active asteroids plays a key role in the evolution from parent body to meteoroids. However, it is unclear what mechanisms will cause a significant fraction of

the comet to fall to dust. The large relative mass in meteoroid streams suggests that whole comet lobes are affected.

Also, what mechanism is responsible for the meteoroids fading over time? This could be the heating and cooling cycles from rotation (day/night) or orbital evolution (perihelion/aphelion). It could also be radial velocity stresses from spinup, or perhaps other effects such as disrupting grain-grain bonds by solar wind or cosmic-ray bombardment. If so, main-belt asteroidal meteoroids in the form of millimeter-sized chondrules, CAIs, and metals and metal sulfide grains may be more resilient against fragmentation and survive longer before falling apart into the smaller zodiacal cloud dust. Are these materials a significant fraction of the millimeter-sized anti-helion source influx at Earth, as hinted at in the study by Borovicka *et al.* (2005)?

The dynamical models for the apex source also need more work, first to better understand the contribution from Halley-type comets. Wiegert *et al.* (2009) pointed to the importance of the three Halley-type comets that currently have strong showers at Earth: 55P/Tempel-Tuttle, 1P/Halley, and 109P/Swift-Tuttle. Tempel-Tuttle and Halley are perhaps responsible for the peak of the north and south apex source being at relatively low ecliptic latitude (Nesvorný *et al.*, 2011b). On the other hand, these comets have been in the inner solar system for only a short period of time: ~1000 yr, <18,000 yr, and <200,000 yr, respectively. It is hard to see how the observed inclination distribution of sporadic meteoroids can be as widely dispersed as observed if only these three sources dominate the input.

The dynamical models for the long-period comet contribution to the apex source need work also. CAMS sees much structure in the apex source of large 2-mm (~0.001 g) meteoroids, which have a high eccentricity  $e \sim 0.95$  (most  $e > 0.8$ ) and semimajor axis  $a \sim 12$  AU, suggesting many intermediate long-period comets have streams of large meteoroids that are not yet dispersed beyond recognition. The question remains how to get from this situation to one of having a broad range of eccentricity  $e = 0.2\text{--}1.0$ , with short semimajor axis ~1 AU for the smaller meteoroids observed by radar.

Meteor shower surveys are ongoing, as are surveys to find NEOs. Together, they are expected to create a more detailed picture of the formation and evolution of the zodiacal cloud in the years to come.

**Acknowledgments.** This review was greatly improved by comments from D. Nesvorný and two anonymous referees, who generously provided their time. J. Vaubaillon contributed three panels of Fig. 1 and D. Nesvorný contributed Fig. 6. I hope that this work will inspire and serve to further the goals of the IAU Commission “Meteors, Meteorites and Interplanetary Dust,” and acknowledge support from NASA’s Near Earth Object Observation program (grant NNX12AM14G).

Valerio Carruba

*Universidade Estadual Paulista*

Asteroids formed in a dynamically quiescent disk but their orbits became gravitationally stirred enough by Jupiter to lead to high-speed collisions. As a result, many dozen large asteroids have been disrupted by impacts over the age of the solar system, producing groups of fragments known as asteroid families. Here we explain how the asteroid families are identified, review their current inventory, and discuss how they can be used to get insights into long-term dynamics of main-belt asteroids. Electronic tables of the membership for 122 notable families are reported on the Planetary Data System node. See related chapters in this volume for the significance of asteroid families for studies of physics of large-scale collisions, collisional history of the main belt, source regions of the near-Earth asteroids, meteorites and dust particles, and space weathering.

## 1. INTRODUCTION

As witnessed by the heavily cratered surfaces imaged by spacecrafts, the chief geophysical process affecting asteroids is impacts. On rare occasions, the impact of a large projectile can be so energetic that the target asteroid is violently torn apart, and the pieces are thrown into space. The sites of such cosmic accidents are filled with debris that gravitationally accumulate into larger conglomerates, and drift away at speeds that are roughly commensurate with the escape speed from the original target body ( $V_{\text{esc}}$ ). Initially, all orbits are similar, because  $V_{\text{esc}} \ll V_{\text{orb}}$ , where  $V_{\text{orb}} \approx 15\text{--}20 \text{ km s}^{-1}$  is the orbital speed of main-belt asteroids. On longer timescales, however, the orbits are altered by gravitational perturbations from planets, and the orbital elements of individual bodies start to diverge.

It may therefore seem challenging to identify fragments of a catastrophic collision that happened eons ago. Fortunately, starting with the pioneering work of K. Hirayama (Hirayama, 1918; see also Cimrman, 1917), astronomers have developed various methods to deal with this issue (section 2). Roughly speaking, these methods consist in a transformation that brings the orbital elements at the observed epoch to a standard, called the *proper elements* (Knežević et al., 2002), that is unchanging in time (or, at least, would be unchanging if chaotic dynamics, nongravitational forces, and other perturbations could be ignored). Thus, ideally, daughter fragments produced by breakup of a parent asteroid will appear as a group in space of the proper elements even giga-

years after the original collision. These groups are called asteroid families, or dynamical families, to emphasize that they have been identified from dynamical considerations.

Telescopic surveys such as the Sloan Digital Sky Survey (SDSS), Wide-field Infrared Survey Explorer (WISE), and AKARI All-Sky Survey provide a wealth of data on physical properties of the main-belt asteroids (Ivezic et al., 2001; Mainzer et al., 2011; Usui et al., 2013). They have been used to cross-link the color and albedo measurements with the lists of dynamical families, in much the same way that spectroscopic and taxonomic data have previously been applied to this purpose (for a review, see Cellino et al., 2002). This work is useful to physically characterize the asteroid families (see the chapter by Masiero et al. in this volume), including cases where two or more dynamical families overlap, and identify distant “halo” family members that would otherwise be confused with the local background (e.g., Brož and Morbidelli, 2013). Given that the SDSS and WISE catalogs now contain data for more than 100,000 unique asteroids, it has also become practical to conduct search for families in extended space, where the color and/or albedo data are taken into account simultaneously with the orbital elements (e.g., Parker et al., 2008; Masiero et al., 2013; Carruba et al., 2013a).

The physical data can be used to identify *interlopers*. The problem of interlopers arises because the clustering criterion applied to identify the dynamical families is only a rough expression of the true membership. Unrelated asteroids that just happen to have nearby values of proper elements will

be grouped together with the true members, and will thus appear in the lists of dynamical families obtained from the proper elements (e.g., *Migliorini et al.*, 1995). These interlopers, especially the large ones, introduce ambiguity in the interpretation of impact conditions that produced individual families, and in the implications of these studies for asteroid interiors (cf. *Michel et al.*, 2003; *Nesvorný et al.*, 2006a). Here we discuss how large interlopers and true largest members in families can be found by applying the “V-shape” criterion, which is based on the notion that large fragments are ejected at low speeds, and have less mobility due to the Yarkovsky effect (section 4).

Based on the synthesis of asteroid families extracted from recent publications (*Mothé-Diniz et al.*, 2005; *Nesvorný et al.*, 2005; *Gil-Hutton*, 2006; *Parker et al.*, 2008; *Nesvorný*, 2010, 2012; *Novaković et al.*, 2011; *Brož et al.*, 2013; *Masiero et al.*, 2011, 2013; *Carruba et al.*, 2013a; *Milani et al.*, 2014), we attempt to build a consensus that could serve as a starting point for future studies. We classify the asteroid families into notable cases (those that have a high statistical significance, and are thus real, and/or are notable for other reasons) and candidate families (less interesting cases where the statistical significance is low or cannot currently be established). The distinction between notable and candidate families is somewhat arbitrary, and will intentionally be left strictly undefined, because that is the nature of things. We expect that many candidate families will be confirmed with more data, and that a few notable families may fall into oblivion. The lists of notable families are being made available at the Planetary Data System (PDS) node, and are discussed in section 7.

A new and exciting development in the past decade was the detection of several asteroid families with very young formation ages. For example, the Karin family was shown to have formed only  $5.8 \pm 0.2$  m.y. ago (*Nesvorný et al.*, 2002a). These cases are important, because various collisional and dynamical processes had little time to act on these families to alter their properties. The young families have thus attracted much attention from scientists studying impact physics, space weathering, debris disks, etc. As we explain in section 3, the age of a young family can be determined by numerically integrating the orbits of its members backward in time and demonstrating that they converge to each other at some specific time in the past. This is the time of a breakup, and the family age,  $t_{\text{age}}$ , is the time elapsed from the breakup event.

The method of backward integration of orbits only works for the families with  $t_{\text{age}} \leq 10$  m.y. This is because dynamics of main-belt asteroids on longer timescales is governed by chaos, encounters with (1) Ceres and other large asteroids, and nongravitational forces. A complementary statistical method for the estimation of family age has been developed in *Vokrouhlický et al.* (2006a,b). The method tracks, in detail, how the family structure in semimajor axis changes over time as the family members drift away by the Yarkovsky effect (section 5). The semimajor axis spread of an older family will generally be greater than

that of a younger family. A compilation of formation ages of the asteroid families can be used to constrain how the population of the asteroid belt collisionally evolved over time (e.g., *Bottke et al.*, 2005a,b; *Cibulková et al.*, 2014), and how asteroid surfaces age by space weathering (see the chapter by Brunetto et al. in this volume).

## 2. IDENTIFICATION METHOD

Here we discuss the standard method to identify asteroid families. This method consists of the (1) computation of proper elements, or other elements unchanging with time, for asteroids with well-known orbits; (2) identification of concentrations or groups of asteroids in proper element space; and (3) establishing the statistical significance of identified groups. These steps are discussed in sections 2.1, 2.2, and 2.3. In section 2.4, we examine the “overlap problem,” where two or more families overlap in proper element space and need to be separated. For this it is useful to consider families in *extended* space, with physical data being included in addition to the proper elements. The search in extended space can also lead to the identification of new families (section 2.5). Very young families ( $t_{\text{age}} \leq 1$  m.y.), for which the member orbits have not had time to differentially precess away from each other, can also be identified as groups in space of the *osculating* orbital elements (section 2.6).

### 2.1. Proper Elements

The ejection speeds of sizable fragments produced by collisional breakups of main-belt asteroids are generally much smaller than their orbital speeds. The fragments will therefore initially cluster near the original orbit of their parent body, and will appear as such if the subsequent effects of planetary perturbations are removed by projecting orbits into space of proper elements. The three most useful proper elements are the proper semimajor axis ( $a_p$ ), the proper eccentricity ( $e_p$ ), and the proper inclination ( $i_p$ ). They are close equivalents of their osculating element counterparts in that they define the size, elongation, and tilt of orbits (see Note 1 in section 9).

The definition of proper elements as quasi-integrals of asteroid motion, and the methods used to compute them, were explained in the *Asteroids III* volume (*Knežević et al.*, 2002). As these definitions and methods have not changed much, we do not discuss them here in detail. In brief, the proper elements are obtained from the instantaneous osculating orbital elements by removing periodic oscillations produced by gravitational perturbations of planets. This can be done analytically, using perturbation theory (*Milani and Knežević*, 1990, 1994), or numerically, by integrating the orbits and applying the Fourier analysis (*Knežević and Milani*, 2000; *Knežević et al.*, 2002) (Note 2).

The computation of analytic proper elements is relatively inexpensive in terms of CPU. They are made publicly available by A. Milani for both numbered and unnumbered

multiopposition asteroids at the AstDyS node (Note 3). The analytic proper elements lose precision for highly inclined orbits, because the expansion of the gravitational potential used to calculate them has poor convergence for high inclinations. The more-precise synthetic proper elements (precision generally at least 3× better than that of analytic elements), on the other hand, require a much larger CPU investment, and are only made available at the AstDyS node for the numbered asteroids.

## 2.2. Clustering Algorithm

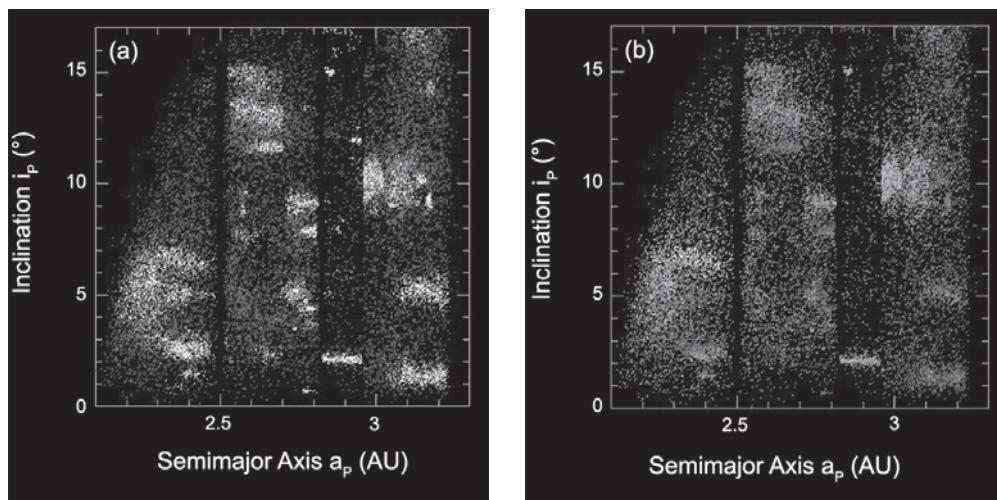

When these methods are applied to the asteroid belt, things are brought into focus with dozens of obvious clumps — asteroid families — emerging from the background (Fig. 1a). To identify an asteroid family, researchers apply a clustering algorithm to the distribution of asteroids in  $(a_p, e_p, i_p)$  space. The most commonly used algorithm is the Hierarchical Clustering Method (HCM) (Zappalà et al., 1990) (Note 4), which defines a cutoff distance,  $d_{cut}$ , and requires that the length of the link between two neighboring orbits clustered by the algorithm is  $d = d(a_p, e_p, i_p) < d_{cut}$ . A common definition of distance is  $d^2 \equiv (n a_p)^2 (k_a (\delta a_p / a_p)^2 + k_e (\delta e_p)^2 + k_i (\delta i_p)^2)$ , where  $n$  is the orbital frequency,  $(\delta a_p, \delta e_p, \delta \sin i_p)$  is the separation vector between orbits in three-dimensional space of proper elements, and  $(k_a, k_e, k_i)$  are coefficients on the order of unity.

The main advantage of the HCM over other methods is that there is no strong assumption built into the HCM about the shape of an asteroid family in proper element space. This is because the chain created by linking nearby orbits can track down family members even if their orbits dynamically evolved to produce an unusual overall shape. A prime example of this is the case of the Koronis family,

which is split into two parts by the secular resonance  $g + 2g_5 - 3g_6 = 0$  at  $\approx 2.92$  AU, where  $g$  is the apsidal frequency of an asteroid, and  $g_5$  and  $g_6$  are the 5th and 6th apsidal frequencies of the planetary system. The part of the Koronis family with  $a_p > 2.92$  AU has larger eccentricity than the part with  $a_p < 2.92$  AU, because family members drifting by the Yarkovsky effect from  $a_p < 2.92$  AU have their eccentricities increased by interacting with the  $g + 2g_5 - 3g_6 = 0$  resonance (Bottke et al., 2001).

The main disadvantage of the standard HCM, which becomes increasingly difficult to overcome with inclusion of numerous small asteroids in the new catalogs, is the problem of *chaining*. This problem arises because small fragments are typically ejected at higher speeds and have larger mobility due to the Yarkovsky effect. They therefore spread more, tend to be distributed more homogeneously throughout the main belt, and create bridges between different families if a single (large) value of  $d_{cut}$  is used. Clearly,  $d_{cut}$  should be set proportional to the asteroid size, or inversely proportional to the absolute magnitude  $H$ . Expressing this dependence, however, adds additional parameters to the HCM and makes the whole identification procedure more complex. Therefore, in reality, it is preferred to bypass the problem of chaining by artificial means (e.g., cuts in proper element space applied to deal with individual cases), or the proportionality is approximated by a two-step method with different cutoffs for small and large bodies (Milani et al., 2014).

A tricky part of the HCM algorithm is the choice of the cutoff distance. If the value of  $d_{cut}$  is too small, many dispersed but real families will remain unnoticed and large families will artificially be split into parts. If the value is too large, the algorithm will clump different families together, and will identify irrelevant clumps produced by random fluctuations. While many asteroid families can be identified for

**Fig. 1.** See Plate 5 for color version. **(a)** Clustering algorithm applied to the asteroid belt separates dynamical families from the background. **(b)** Variation in reflectance properties of main-belt asteroids. Here we plot  $\approx 25,000$  asteroids that were observed by both SDSS and WISE. The color code in **(b)** was chosen to highlight the albedo/color contrast of different families.

a wide range of  $d_{\text{cut}}$  values, and are real beyond doubt, some cases require a specific choice of  $d_{\text{cut}}$  and can potentially be confused with random fluctuations. Clearly, the statistical significance of the identified groups, or their insignificance, needs to be established before proceeding further.

### 2.3. Statistical Significance

To make reasonably sure that families identified from the HCM are real, one can opt for a conservative choice of  $d_{\text{cut}}$ . This can be done, for example, by collecting asteroids in a given region of proper element space and redistributing them randomly in that region. The HCM applied to this artificial distribution will reveal that the largest identified group with given  $d_{\text{cut}}$  contains  $N^*(d_{\text{cut}})$  members. Now, this procedure can be repeated, say, 1000 times, recording the largest  $N^*(d_{\text{cut}})$  obtained from these trials. We can then be 99% confident that random fluctuations cannot produce groups with more than  $N^*(d_{\text{cut}})$  members (this conservative estimate includes a 99% confidence interval computed by the Wilson score interval approximation). Any group identified in the real distribution with  $N > N^*(d_{\text{cut}})$  members is therefore reasonably likely to be real. Higher confidence levels can be achieved by increasing the sample size.

This basic concept, and various modifications of it, is known as the Quasi Random Level (QRL) (Zappalà *et al.*, 1994). In the ideal world, the QRL would be the ultimate solution to the family identification problem: Just choose  $d_{\text{cut}}$  and pick up all clumps with more than  $N > N^*(d_{\text{cut}})$ ; those clumps are real. Then there is the real world. First, the number density in proper element space is variable due to the primordial sculpting of the main belt and resonances (e.g., Minton and Malhotra, 2009). Applying a global QRL value in (parts of) the main belt may therefore lead to unsatisfactory results. Second, families do not live in isolation but are frequently close to each other, overlap, and/or are surrounded by empty regions. This introduces an ambiguity in the QRL definition, because it is not clear *a priori* what region in  $(a_p, e_p, i_p)$  space should be considered to define the local QRL in the first place. Results may depend on this choice.

In practice, the first choice made is often the minimum number of group members,  $N_{\min}$ , that is considered to be interesting. Then, the cutoff distance  $d_{\text{cut}}$  in some local region in  $(a_p, e_p, i_p)$  is defined such that groups of  $N > N_{\min}$  members cannot be produced with  $d_{\text{cut}}$  by random fluctuations. All groups with  $N > N_{\min}$  are then treated as meaningful asteroid families. Different researchers made different choices:  $N_{\min} = 5$  in Zappalà *et al.* (1990),  $N_{\min} = 100$  in Parker *et al.* (2008), and  $N_{\min} = 10–20$  in most other publications. The two disadvantages of this method are that (1) meaningful asteroid families with  $N < N_{\min}$  members are explicitly avoided, and (2)  $d_{\text{cut}}(N_{\min})$  depends on the population density in proper element space and must be recomputed when a new classification is attempted from ever-growing catalogs.

Another approach to this problem is to identify all groups, even if they have only a few members, and establish their statistical significance *a posteriori*. Those that are

judged to be insignificant are subsequently discarded and do not appear in the final lists. To determine the statistical significance of a group, one can generate mock distributions and apply the HCM to them. For example, the high statistical significance of the Karin family, which is embedded in the much larger Koronis family, can be demonstrated by generating 1000 orbital distributions corresponding to the Koronis family, and applying the HCM to each one (Nesvorný *et al.*, 2002a). With  $d_{\text{cut}} = 10 \text{ m s}^{-1}$ , no concentrations in this input can be found containing more than a few dozen members, while the Karin family currently has 541 known members. Therefore, the Karin family is significant at a  $<99\%$  level (again including a 99% confidence interval of the estimate). A systematic application of this or similar statistical arguments can be quite laborious if many borderline cases need to be resolved.

### 2.4. Overlap Problem and Interlopers

The overlap between different families has become more of a problem with a progressively larger share being taken in the proper element catalogs by small, kilometer- and subkilometer-sized asteroids. This is because small fragments are generally launched at higher speeds, and are therefore initially spread in a larger volume in  $(a_p, e_p, i_p)$  space. Mainly, however, the problem is caused by the larger mobility of small fragments due to the Yarkovsky effect. For example, the mean drift rate of a diameter  $D = 1 \text{ km}$  main-belt asteroid is estimated to be  $\approx 10^{-4} \text{ AU m.y.}^{-1}$  (Bottke *et al.*, 2006). The kilometer-sized members of a 1-G.y.-old family are therefore expected to be dispersed over  $\approx 0.2 \text{ AU}$  (the additional factor of 2 accounts here for fragments having different spin orientations, and thus  $da/dt < 0$  or  $da/dt > 0$ ), which is roughly one-fifth of the extension of the whole main belt. In addition, drifting asteroids encounter orbital resonances and can be dispersed by them in  $e_p$  and  $i_p$  as well.

A good illustration of this is the case of the Flora and Vesta families in the inner main belt. To separate these families from each other down to their smallest members, the scope of the HCM can be restricted by an artificial cut in proper element space. Alternatively, one can first apply the HCM to the distribution of large members, thus identifying the core of each family, and then proceeding by trying to “attach” the small members to the core. This second step must use a lower  $d_{\text{cut}}$  value than the first step to account for the denser population of smaller asteroids. In practice, this has been done by applying an absolute magnitude cutoff,  $H^*$ , with  $H < H^*$  for the core and  $H > H^*$  for the rest. In the low- $i$  portion of the inner main belt, where the Flora and Vesta families reside, Milani *et al.* (2014) opted to use  $H^* = 15$ , and identified cores of families with  $N_{\min} = 17$  and  $d_{\text{cut}} = 60 \text{ m s}^{-1}$ , and small members with  $N_{\min} = 42$  and  $d_{\text{cut}} = 40 \text{ m s}^{-1}$ .

Another solution to the overlap problem is to consider the *physical* properties of asteroids. Previously, the spectroscopic observations of members of dynamical families have been used to (1) establish the physical homogeneity of asteroid families (the difference between physical prop-

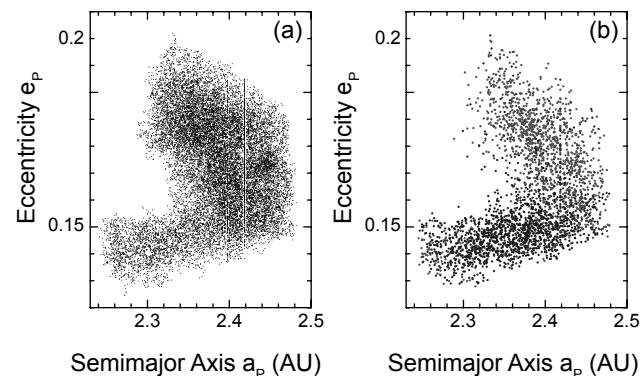

erties of members of the same family tends to be smaller than the differences between physical properties of different families), and (2) identify large interlopers (asteroids classified as family members based on proper elements but having spectroscopic properties distinct from the bulk of the family). With the color and albedo data from SDSS and WISE (Note 5), the physical homogeneity of asteroid families has been demonstrated to hold down to the smallest observable members (Ivezic et al., 2001; Parker et al., 2008) (see Fig. 1b). A straightforward implication of this result is that the interior of each disrupted body was (relatively) homogeneous, at least on a scale comparable to the size of the observed fragments ( $\sim 1\text{--}100$  km) (Note 6).

The physical homogeneity of asteroid families can be used to identify interlopers as those members of a dynamical family that have color and/or albedo significantly distinct from the rest of the family. The number density of apparent color/albedo interlopers in a family can then be compared with the number density of the same color/albedo asteroids in the immediate neighborhood of the family. Similar densities are expected if the identified bodies are actual interlopers in the family. If, on the other hand, the density of color/albedo outliers in the family is found to be substantially higher than in the background, this may help to rule out the interloper premise, and instead indicate that (1) the disrupted parent body may have been heterogeneous, or (2) we are looking at two or more overlapping dynamical families with distinct color/albedo properties. Finally, as for (2), it is useful to verify whether the family members with different color/albedo properties also have different proper element distributions, as expected if breakups happened in two (slightly) different locations in proper element space (e.g., the Nysa-Polana complex; see Fig. 2).

## 2.5. Families in Extended Space

Another useful strategy is to include the color and/or albedo information *directly* in the clustering algorithm. This can be done by first separating the main belt into two (or more) populations according to their color and albedo properties. For example, asteroids in the S-complex can be separated from those in the C/X-complex based on the SDSS colors (Nesvorný et al., 2005), and the high-albedo asteroids can be separated from the low-albedo asteroids based on the albedo measurements of WISE (Masiero et al., 2013). The HCM is then applied to these populations separately. This method is capable of identifying small/dispersed S-complex families in the C/X-type background, and vice versa, or low-albedo families in the high-albedo background, and vice versa. It can also be useful to characterize the so-called family “halos” (section 6.4).

A more general method for including the color/albedo information in the clustering algorithm consists in the application of the HCM in space of increased dimension (e.g., Parker et al., 2008; Carruba et al., 2013a). When considering the proper elements and SDSS colors, the distance in five dimensions can be defined as  $d_2^2 \equiv d^2 + n^2 a_p^2 (k_1(\delta C_1)^2 +$

**Fig. 2.** The Nysa-Polana complex. **(a)** The HCM applied to this region of the inner main belt reveals a major concentration of asteroids with  $2.25 < a_p < 2.48$  AU and  $0.13 < e_p < 0.22$ . The shape of the concentration in the  $(a_p, e_p)$  projection is unusual and difficult to interpret. **(b)** The WISE albedos of members of the Nysa-Polana complex: black for  $p_V < 0.15$  and gray for  $p_V > 0.15$ . It becomes clear with the albedo information that the Nysa-Polana complex is two overlapping groups with distinct albedos. Furthermore, based on the V-shape criterion (section 4), the low-albedo group is found to consist of two asteroid families [the Polana and Eulalia families (Walsh et al., 2013)]. The vertical feature at  $a_p \approx 2.42$  AU is the 1:2 mean-motion resonance with Mars.

$k_2(\delta C_2)^2$ ), where  $d$  is the distance in three-dimensional space of proper elements defined in section 2.2,  $C_1$  and  $C_2$  are two diagnostic colors defined from the SDSS (Ivezic et al., 2001; Nesvorný et al., 2005), and  $k_1$  and  $k_2$  are coefficients whose magnitude is set to provide a good balance between the orbital and color dimensions (e.g., Nesvorný et al., 2006b). Similarly, we can define  $d_3^2 \equiv d^2 + n^2 a_p^2 k_p(\delta p_V)^2$  (in four dimensions) and  $d_4^2 \equiv d_2^2 + n^2 a_p^2 k_p(\delta p_V)^2$  (in six dimensions) to include the measurements of albedo  $p_V$  from WISE. The  $d_4$  metric applies the strictest criteria on the family membership, because it requires that the family members have similar proper elements, similar colors, and similar albedos. Note, however, that this metric can only be applied to a reduced set of main-belt asteroids for which the proper elements, colors, and albedos are simultaneously available (presently  $\approx 25,000$ ; Fig. 1b).

## 2.6. Very Young Families in Orbital Element Space

Short after a family’s creation, when the mutual gravity effects among individual fragments cease to be important, the fragments will separate from each other and find themselves moving on heliocentric orbits. Initially, they will have very tightly clustered orbits with nearly the same values of the osculating orbital angles  $\Omega$ ,  $\varpi$ , and  $\lambda$ , where  $\Omega$  is the nodal longitude,  $\varpi$  is the apsidal longitude, and  $\lambda$  is the mean longitude. The debris cloud will be subsequently dispersed by the (1) Keplerian shear (different fragments are ejected with different velocity vectors, have slightly different values of the semimajor axis, and therefore different orbital

periods) and (2) *differential precession* of orbits produced by planetary perturbations.

As for (1), the fragments will become fully dispersed along an orbit on a timescale  $T_n = \pi/(a\partial n/\partial a)(V_{\text{orb}}/\delta V) = (P/3)(V_{\text{orb}}/\delta V)$ , where  $P = 2\text{--}4$  yr is the orbital period and  $\delta V$  is the ejection speed. With  $\delta V = 1\text{--}100$  m s $^{-1}$ , this gives  $T_n = 300\text{--}30,000$  yr. Therefore, the dispersal of fragments along the orbit is relatively fast, and the clustering in  $\lambda$  is *not* expected if a family is older than a few tens of thousand years.

The dispersal of  $\Omega$  and  $\varpi$  occurs on a timescale  $T_f = \pi/(\alpha\partial f/\partial \alpha)(V_{\text{orb}}/\delta V)$ , where the frequency  $f = s$  or  $g$ . For example,  $\partial s/\partial a = -70$  arcsec yr $^{-1}$  AU $^{-1}$  and  $\partial g/\partial a = 94$  arcsec yr $^{-1}$  AU $^{-1}$  for the Karin family ( $a = 2.865$  AU). With  $\delta V = 15$  m s $^{-1}$  (Nesvorný *et al.*, 2006a) and  $V_{\text{orb}} = 17.7$  km s $^{-1}$ , this gives  $T_s = 3.8$  m.y. and  $T_g = 2.8$  m.y. Since  $t_{\text{age}} > T_s$  and  $t_{\text{age}} > T_g$  in this case, the distribution of  $\Omega$  and  $\varpi$  for the Karin family is not expected to be clustered at the present time (Fig. 3). Conversely, the clustering of  $\Omega$  and  $\varpi$  would be expected for families with  $t_{\text{age}} \leq 1$  m.y.

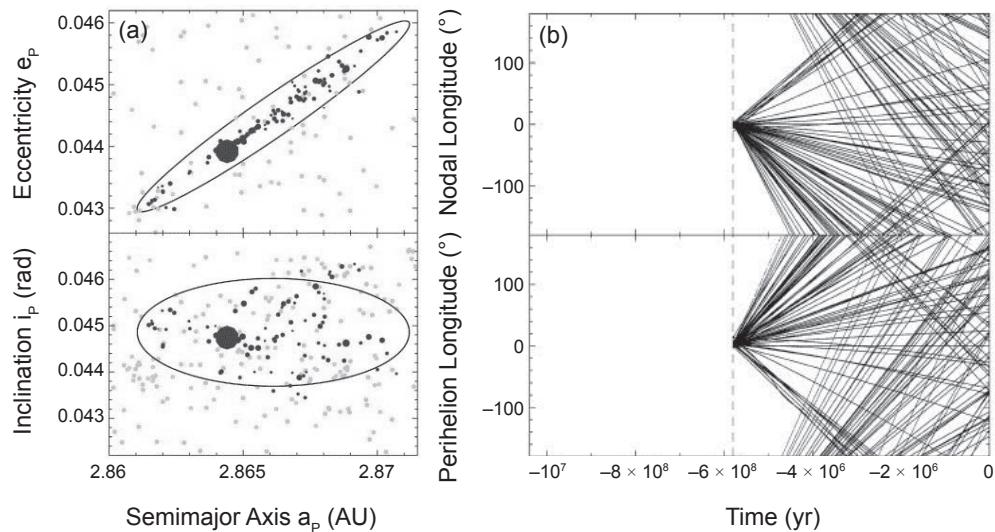

This expectation leads to the possibility that the families with  $t_{\text{age}} \leq 1$  m.y. could be detected in the catalogs of osculating orbital elements (Marsden, 1980; Bowell *et al.*, 1994), where they should show up as clusters in five-dimensional space of  $a$ ,  $e$ ,  $i$ ,  $\varpi$ , and  $\Omega$ . The search in five-dimensional space of the osculating orbital elements can be performed

with the HCM method and metric  $d_5^2 = d^2 + (na)^2(k_\Omega(\delta\Omega)^2 + k_\varpi(\delta\varpi)^2)$ , where  $d = d(a,e,i)$  was defined in section 2.2, and  $k_\Omega$  and  $k_\varpi$  are new coefficients. [Different metric functions were studied by Rožek *et al.* (2011), who also pointed out that using the mean elements, instead of the osculating ones, can lead to more reliable results.]

This method was first successfully used in practice for the identification of the Datura family (Nesvorný *et al.*, 2006c), and soon after for the discovery of the asteroid pairs (Vokrouhlický and Nesvorný, 2008). The Datura family now consists of 15 known members ranging in size from  $\approx 10$ -km-diameter object (1270) Datura to subkilometer fragments. They have  $\Omega$  and  $\varpi$  clustered to within a few degrees near  $98^\circ$  and  $357^\circ$ , respectively. The age of the Datura family is only  $530 \pm 20$  k.y., as estimated from the backward integration of orbits (Vokrouhlický *et al.*, 2009). Table 1 reports other notable cases of families with  $t_{\text{age}} < 1$  m.y.

### 3. DETECTION OF RECENT BREAKUPS

The detection of families with very young formation ages was one of the highlights of asteroid research in the past decade. A poster child of this exciting development is the Karin family, part of the larger Koronis family, that was shown to have formed only  $5.8 \pm 0.2$  m.y. ago (Nesvorný *et al.*, 2002a). The Karin family was identified by the tra-

**Fig. 3.** (a) Proper elements of members of the Karin family. The size of each dark symbol is proportional to the diameter of a family member. Light gray dots indicate background bodies near the Koronis family. The black ellipses show the proper orbital elements of test bodies launched at 15 m s $^{-1}$  from  $a_p = 2.8661$  AU,  $e_p = 0.04449$ , and  $i_p = 0.03692$ , assuming that  $f = 30^\circ$  and  $\omega + f = 45^\circ$ , where  $f$  and  $\omega$  are the true anomaly and perihelion argument of the disrupted body at the time of the family-forming collision. (b) The convergence of angles at 5.8 m.y. ago demonstrates that the Karin family was created by a parent asteroid breakup at that time. The plot shows past orbital histories of 90 members of the Karin family: (top) the proper nodal longitude, and (bottom) the proper perihelion longitude. Values of these angles relative to (832) Karin are shown. At  $t = 5.8$  m.y. (broken vertical line), the nodal longitudes and perihelion arguments of all 90 asteroids become nearly the same, as expected if these bodies had initially nearly the same orbits. Adapted from Nesvorný and Bottke (2004).

TABLE 1. Recently formed asteroid families.

Family/Pair	$t_{age}$	References	Notes
(832) Karin	$5.75 \pm 0.05$ m.y.	Ne02,NB04	2.1° dust band
(158) Koronis(2)	10–15 m.y.	MH09	near (832) Karin
(490) Veritas	$8.3 \pm 0.5$ m.y.	Ne03,F06,T07	9.3° band, late Miocene dust shower
(656) Beagle	~10 m.y.	Ne08	1.4° band, member Elst-Pizzaro?
(778) Theobalda	$6.9 \pm 2.3$ m.y.	No10	$t_{age}$ needs to be confirmed
(1270) Datura	$530 \pm 20$ k.y.	Ne06,V09	identified in 5D, E/F dust band?
(2384) Schulhof	$780 \pm 100$ k.y.	VN11	secondary breakup event?
(4652) Iannini	≤5 m.y.	Ne03,W08	chaotic dynamics
(5438) Lorre	$1.9 \pm 0.3$ m.y.	No12a	$i_p \approx 28^\circ$
(14627) Emilkowalski	$220 \pm 30$ k.y.	NV06	only 3 members known
(16598) 1992 YC2	50–250 k.y.	NV06	only 3 members known
(21509) Lucascavin	300–800 k.y.	NV06	only 3 members known
(300163) P/2006 VW139	$7.5 \pm 0.3$ m.y.	No12b	main-belt comet
P/2012 F5 (Gibbs)	$1.5 \pm 0.1$ m.y.	No14	main-belt comet

ditional means, using the HCM on proper elements. The diagonal shape of this family in the  $(a_p, e_p)$  projection is a telltale signature of a recent breakup, because this initial shape is expected if a breakup occurs near the perihelion of the parent body orbit (Fig. 3). In this case, the tilt  $\alpha$  of the family shape in the  $(a_p, e_p)$  projection is expected to be, and indeed is in the case of the Karin family,  $\tan \alpha = \Delta e_p / (\Delta a_p / a_p) = (1 - e_p) = 0.956$ . Thus,  $\alpha \approx 45^\circ$ . All other known families, with an exception of the similarly young Veritas family, have  $\alpha \sim 0$  (i.e., are nearly horizontal features in  $a_p, e_p$ ). This is because these families are old and their original shape was stretched in  $a_p$  by the Yarkovsky effect (e.g., Dell'Oro et al., 2004).

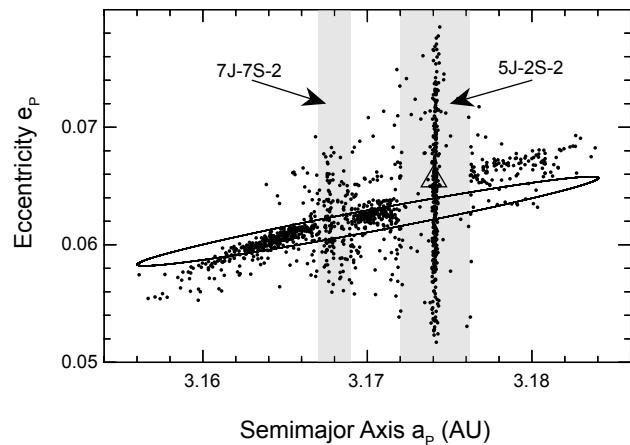

The age of the Karin family has been established by numerically integrating the orbits of identified members back in time in an attempt to identify their past convergence (Fig. 3). The past convergence is expected because the spread of the Karin family in  $a_p, e_p, i_p$  indicates that the ejection speeds of observed fragments were only  $\leq 15$  m s $^{-1}$ . These low speeds imply a very tight *initial* distribution (to within  $\approx 1^\circ$ ) of  $\lambda$ ,  $\varpi$ , and  $\Omega$ . The backward integration showed that the convergence occurred at  $5.8 \pm 0.2$  m.y. ago. In addition, the past convergence improved, with  $\varpi$  and  $\Omega$  of all member orbits converging to within a degree, if the backward integration included the Yarkovsky drift (Nesvorný and Bottke, 2004). This was used to measure the rate of the Yarkovsky drift for individual members of the family, determine their obliquities, and pin down the age of the Karin family to  $t_{age} = 5.75 \pm 0.05$  m.y.

The method of backward integration of orbits was applied to several families (Nesvorný et al., 2002a, 2003, 2008b; Novaković et al., 2010a,b, 2012a,b, 2014) (some of these results will need to be verified; see also Table 1). One of the interesting results that emerged from these studies is a possible relationship between the young families and main-belt comets (MBCs) (see chapter by Jewitt et al. in

this volume). For example, (7968) P/133 Elst-Pizzaro can be linked to the Beagle family [ $t_{age} \sim 10$  m.y. (Nesvorný et al., 2008b)], and (300163) P/2006 VW139 and P/2012 F5 (Gibbs) can be linked to small families that probably formed within the past 10 m.y. (Novaković et al., 2012a, 2014). If this relationship is confirmed by future studies, this can help us to understand how the MBCs are “activated.”

Another notable case of a recent breakup is the Veritas family (Fig. 4). It has previously been hypothesized that the Veritas family is <50 m.y. old (Milani and Farinella, 1994). This claim was based on the argument that the largest member of the dynamical family, (490) Veritas, has chaotic dynamics and would be expected to diffuse away in  $e_p$  from the rest of the family, if the family were older than ~50 m.y. [Note, however, that recent impact modeling may indicate that (490) Veritas is not a true member of the Veritas family (e.g., Michel et al., 2011).] A backward integration of orbits confirmed the young age, and showed that the Veritas family formed only  $8.3 \pm 0.5$  m.y. ago (Nesvorný et al., 2003).

A similarly young age was later obtained by an independent method, known as the “chaotic chronology,” based on tracking the evolution of orbits in one of the diffusive resonances that intersect the Veritas family (Tsiganis et al., 2007; see also Knežević and Pavlović, 2002). Tsiganis et al. (2007) considered the chaotic diffusion of the Veritas family members in the 5J-2S-2 three-body resonance at 3.174 AU (Nesvorný and Morbidelli, 1999). Based on numerical integrations of chaotic orbits, they estimated that the observed spread in the 5J-2S-2 resonance can be obtained for  $t_{age} = 8.7 \pm 1.7$  m.y. Interestingly, the Veritas family is also intersected by the 7J-7S-2 resonance at 3.168 AU. The observed distribution of eccentricities in this resonance is rather wide and cannot be explained by normal diffusion over the estimated age (the 7J-7S-2 resonance is ~100× less diffusive than the 5J-2S-2 resonance). Perhaps the problem is with the HCM chaining, discussed in section 2.2, which

**Fig. 4.** The Veritas family. Here we plot the proper elements of 1294 members of the Veritas family identified from a new catalog (August 2014). (490) Veritas itself is marked by a triangle. The gray vertical strips indicate two three-body resonances that act to diffuse the orbits of family members in  $e_p$ . The black ellipse shows the orbital elements of test bodies launched at  $\delta V = 35 \text{ m s}^{-1}$  from  $a_p = 3.17 \text{ AU}$  and  $e_p = 0.0062$ , assuming that  $f = 30^\circ$ , where  $f$  is the true anomaly of the disrupted body at the time of the family-forming collision.

links unrelated asteroids in the 7J-7S-2 resonance, or the dynamical modeling is missing some important ingredient. Novaković (2010) applied the method of chaotic chronology to the Theobalda family and found that the estimated age is consistent with that obtained from a backward integration of the regular orbits ( $t_{\text{age}} = 6.9 \pm 2.3 \text{ m.y.}$ ).

There is a close relationship between the young asteroid families and the *asteroid dust bands* (see chapter by Jenniskens in this volume), which are strips of infrared emission running roughly parallel to the plane of the solar system (Low *et al.*, 1984). The three most prominent dust bands, known as  $\alpha$ ,  $\beta$ , and  $\gamma$ , have previously been thought to originate in the Themis, Koronis, and Eos families (Dermott *et al.*, 1984). Detailed modeling, however, has shown that the sources of these dust bands are the recently formed Karin, Beagle, and Veritas families (Dermott *et al.*, 2002; Nesvorný *et al.*, 2003, 2006, 2008b), mainly because (1) the Veritas family with  $i_p = 9.3^\circ$  provides a better fit to the latitudinal position of the  $\gamma$  band than the Eos family with  $i_p = 10^\circ$ , and (2) the young families should now be more prolific sources of dust than the old families, because the dust production in a collisional cascade is expected to drop with time. A tracer of the Veritas family breakup has been found in measurements of extraterrestrial  ${}^3\text{He}$  in  $\approx 8.2\text{-m.y.-old}$  deep ocean sediments (Farley *et al.*, 2006).

#### 4. V-SHAPE CRITERION

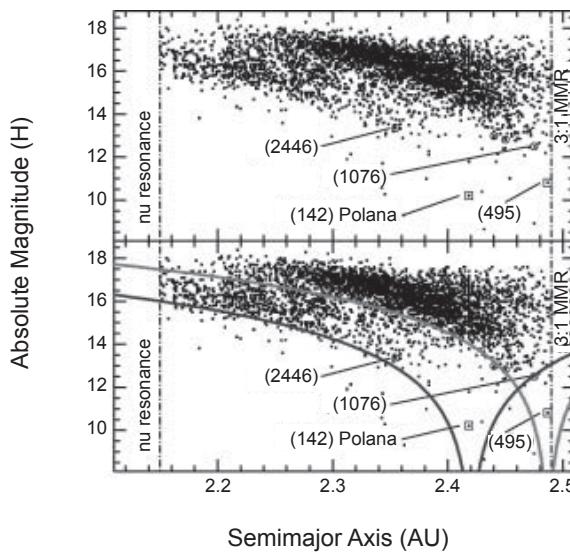

A correct identification of the brightest/largest members in a family is important for several reasons. For example, the spectroscopic observations are magnitude limited and

can typically only be conducted for bright targets. The interpretation of spectroscopic observations of asteroid families, and implications for the homogeneity/heterogeneity of their parent bodies, therefore depend on whether the bright asteroids are the actual members of a family or not (e.g., Reddy *et al.*, 2011). The large objects in families are also critically important for asteroid impact studies, in which the size frequency distribution (SFD) of family members is used to calibrate the results of impact experiments. Finally, the uncertainty in the membership of the largest family members critically affects our estimates of size of the disrupted parent bodies (e.g., Durda *et al.*, 2007).

While the interloper problem may not have an ideal solution, there exists a straightforward method that can be used to remove obvious bright/large interlopers based on dynamical considerations. This method is inspired by the “V shape” of asteroid families, which becomes apparent when the absolute magnitude  $H$  of family members is plotted against  $a_p$  (Fig. 5). The V shape results from two processes. First, larger (smaller) fragments tend to be ejected at lower (higher) speeds, and thus tend to be located, on average, closer to (further away from) the family center (see the chapter by Michel *et al.* in this volume). The second and typically more dominant “V” is contributed by the Yarkovsky effect.

The Yarkovsky effect (YE) is a recoil force produced by anisotropic emission of thermal photons from an asteroid surface (see the chapter by Vokrouhlický *et al.* in this volume). The diurnal component of the YE, which is more important for asteroid-sized bodies than its seasonal counterpart, can increase the semimajor axis of an asteroid with a prograde rotation and decrease the semimajor axis for a retrograde rotation. The semimajor axis drift is generally given by  $da_p/dt = \text{const.} \cos \theta (a_p^2 D)$ , where  $\theta$  is the asteroid obliquity,  $D$  is the effective diameter, and the constant depends on material properties. The maximum drift occurs for  $\theta = 0^\circ$  or  $\theta = 180^\circ$ . Thus, the envelope of the distribution of family members in  $(a_p, H)$  is expected to follow  $|a_p - a_c| = C_{\text{YE}} 10^{H/5}$ , where  $a_c$  is the family center (often assumed to coincide with the largest fragment), and  $C_{\text{YE}}$  is a constant related to  $t_{\text{age}}$  (section 5). Interestingly, if the ejection speed  $\delta V \propto 1/D$ , as found for the youngest families (e.g., Nesvorný *et al.*, 2006a) and some laboratory experiments (e.g., Fujiwara *et al.*, 1989), then the ejection velocity field will produce the same dependence,  $|a_p - a_c| = C_{\text{EV}} 10^{H/5}$ , where  $C_{\text{EV}}$  is related to the magnitude of the ejection velocities.

These considerations allow us to define the V-shape criterion (e.g., Nesvorný *et al.*, 2003). Consider a family extracted by the HCM as described in section 2.2. Fit an envelope to the distribution of small family members in  $(a_p, H)$  using the functional dependence between  $a_p$  and  $H$  defined above. The envelope is then continued to low  $H$  values, and the bright members of the HCM family that fall outside the envelope boundaries can be rejected. On the other hand, the brightest HCM family members that fall within the envelope boundaries are good candidates for the largest family members. This method is illustrated in Fig. 5.

**Fig. 5.** A recent application of the V-shape criterion to define the Polana and Eulalia families, and identify the largest members in these families (Walsh et al., 2013). The plot shows the absolute magnitude  $H$  of dark ( $p_V < 0.1$ ) asteroids with  $0.1 < e_p < 0.2$  and  $i_p < 10^\circ$  as a function of  $a_p$ . The bottom panel illustrates the best-fit V-shape curves to the (left) Polana and (right) Eulalia families. (142) Polana and (495) Eulalia, the largest dark asteroids inside the left and right zones, respectively, are the likely largest members of the two families.

In practice, a number of additional effects can complicate the application of the V-shape criterion described above. For example, strong nearby resonances can remove family members that drifted into them, thus producing cutoffs of the  $a_p - a_c$  distribution beyond which no family members can be identified (e.g., the 3:1 resonance in Fig. 5). Also, family members can be displaced in  $a_p$  by encounters with (1) Ceres and other massive main-belt asteroids (Nesvorný et al., 2002b; Carruba et al., 2003, 2007a, 2012, 2013b; Delisle and Laskar, 2012). In addition, the physics of large-scale collisions is still poorly understood, and the possibility that some large fragments can be accelerated to very high speeds cannot be ruled out. Therefore, while the V-shape criterion defined above is a useful guide, it cannot be rigidly applied.

Possibly the best way to deal with this issue is to define the value of  $C_0 = 10^{-H/5}|a_p - a_c|$  that best fits the V-shaped family envelope and report  $C_j/C_0$ , where  $C_j = 10^{-H_j/5}|a_{p,j} - a_c|$ , for each family member  $j$  identified by the HCM. Asteroids with  $|C_j/C_0| > 1$  can be flagged (but not removed), because they are potential interlopers in a dynamical family according to the V-shape criterion. The results can then be cross-linked with the spectroscopic data (or colors, or albedo measurements) to determine whether there is a good correspondence between the flagged bodies and (suspected) spectroscopic interlopers. An illustration of this procedure can be found in Vokrouhlický et al. (2006a) who examined the Eos family. They found that many large bodies in the

HCM family with  $|C_j/C_0| > 1$  have physical properties that are indeed incompatible (mainly dark C types) with the bulk of the Eos family (mainly brighter K types).

## 5. FAMILY AGE ESTIMATION

The method of backward integrations of orbits described in section 3 cannot be used to determine ages of the families much older than  $\sim 10$  m.y., mainly because the orbital evolution of main-belt asteroids is generally unpredictable on long timescales and sensitively depends on nongravitational effects, which are difficult to model with the needed precision. Instead, the age of an old family can be estimated by a statistical method, which is based on the general notion that the spread of an asteroid family in  $a_p$  increases over time as its members drift away due to the Yarkovsky effect. Expressed in terms of the equations discussed in the previous section, the age can be estimated as

$$t_{\text{age}} \approx 1 \text{ G.y.} \times \left( \frac{C_0}{10^{-4} \text{ AU}} \right) \left( \frac{a}{2.5 \text{ AU}} \right)^2 \times \left( \frac{\rho}{2.5 \text{ g cm}^{-3}} \right) \left( \frac{0.2}{p_V} \right)^{\frac{1}{2}} \quad (1)$$

where  $\rho$  is the asteroid bulk density and  $p_V$  is the visual albedo. While the equation above is scaled to typical values expected for an S-type asteroid, a change to  $\rho = 1.5 \text{ g cm}^{-3}$  and  $p_V = 0.05$ , which would be more appropriate for a dark C-type asteroid, produces two multiplication factors that nearly compensate each other. The biggest uncertainty in the inversion from  $C_0$  to  $t_{\text{age}}$  lies in the unknown density factor. Additional uncertainty, not explicitly apparent from equation (2), stems from the dependence of the drift rate on surface conductivity  $K$ . Together, the conversion from  $C_0$  to  $t_{\text{age}}$  has an uncertainty of about a factor of 2.

More fundamentally, equation (1) neglects complicating factors such as the contribution of the original ejection field and nearby resonances that can remove drifting bodies. If  $C = C_{YE} + C_{EV}$ , under the assumptions on the ejection speeds discussed in section 4, the two effects cannot be decoupled from each other, and  $t_{\text{age}}$  estimated from  $C_0$  will always overshoot the real age of the family. This happens, in essence, because this simple method only fits the family envelope.

Vokrouhlický et al. (2006a,b) have developed a more general statistical method that uses the actual distribution of family members within the V-shape envelope. It works as follows. First, the code generates a newborn family. The distribution of the ejection speeds of fragments is approximated by the Gaussian distribution in each velocity component with the size-dependent standard deviation  $\delta V = V_5(5 \text{ km/D})$ , where  $V_5$  is a free parameter. This functional dependence generally provides a good match to the ejection speeds inferred from the young families and impact simulations (Michel et al., 2001, 2003, 2004; Nesvorný et al., 2002a, 2006a; Durda et al., 2004, 2007). The Yarkovsky-YORP (hereafter YY) code (where YORP is an acronym for

Yarkovsky-O'Keefe-Radzievskii-Paddack) then evolves the orbits of fragments accounting for the semimajor axis drift due to the YE, and the spin evolution from the YORP effect (Rubincam, 2000). To speed up the calculation, planetary perturbations were not taken into account in the original YY code [but see Masiero *et al.* (2012); results based on full N-body integrations are discussed in the following section].

When applied to an asteroid family, the goal is to find a combination of parameters  $V_5$  and  $t_{\text{age}}$  that best fits the observed  $(a_p, H)$  distribution in the family. Since the model does not contain an SFD-related evolution component, this can be conveniently done by simply fitting the observed distribution of  $C_j$ . The results are found to be credible in cases such as the Ergone family (Fig. 6), where the YY model is capable of adequately representing the observed  $C$  distribution, which shows void space near  $C = 0$ , a maximum at intermediate values of  $C$ , and a relatively sharp drop toward the largest  $C$  values seen in the family. This dependence is produced by the YORP effect, which tilts the spin axis away from the orbital plane and therefore, through the  $\cos \theta$  dependence of the YE, tends to maximize the drift rates. This gives some asteroid families the characteristic appearance in  $(a_p, H)$ , which different authors, with noticeably different gifts for subtleties of poetic expression, called “ears,” “wings,” or “petals.”

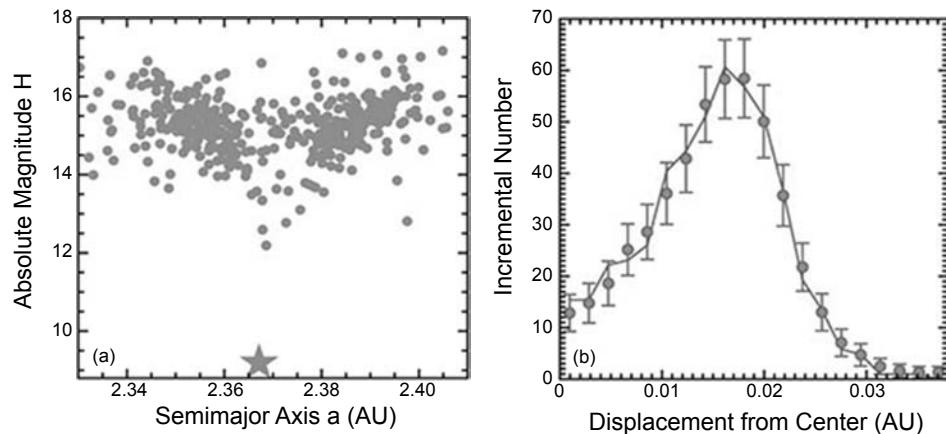

But not all families have ears, wings, or petals. In fact, most families have more uniform distribution of  $C$  that goes all the way from 0 to  $C_{\text{max}}$ . This is thought to have something to do with how the YE and YORP operate on gigayear-long timescales. It is perhaps related to the variability of the spin-related YORP torque, which sensitively depends on small perturbations of the asteroid surface. As

a result of this dependence, the spin rate of each individual asteroid can undergo a random walk [stochastic YORP (Bottke *et al.*, 2015)] and, when spun down completely, the asteroid spin axis would chaotically tumble for some time, and subsequently reorient. This process could mix up the total drifts suffered by family members and, rather unpoetically, remove the ears, wings, or petals from the old families.

The application of the standard YY code (and also, for that matter, the simple method based on the “V”-shape envelope) is problematic in cases when a family is cut by nearby mean-motion resonances and looks like a box in  $(a_p, H)$ , or when  $C_{\text{EV}}$  is expected to be larger than  $C_{\text{YE}}$ , perhaps because the family's parent was an object with large escape speed [e.g., the Vesta family; (4) Vesta has  $V_{\text{esc}} \approx 360 \text{ m s}^{-1}$ ], or because the family formed recently (e.g., the Datura, Karin, and Veritas families have  $C_{\text{YE}} \approx 0$ ). A complete list of families to which the YY code was successfully applied so far is:

- Agnia ( $t_{\text{age}} = 100 \pm 100 \text{ m.y.}$ ,  $V_5 \approx 15 \text{ m s}^{-1}$ )
- Massalia ( $t_{\text{age}} = 150 \pm 50 \text{ m.y.}$ ,  $V_5 \approx 20 \text{ m s}^{-1}$ )
- Baptista ( $t_{\text{age}} = 160 \pm 50 \text{ m.y.}$ ,  $V_5 \approx 40 \text{ m s}^{-1}$ )
- Merxia ( $t_{\text{age}} = 250 \pm 100 \text{ m.y.}$ ,  $V_5 \approx 25 \text{ m s}^{-1}$ )
- Astrid ( $t_{\text{age}} = 250 \pm 100 \text{ m.y.}$ ,  $V_5 \approx 15 \text{ m s}^{-1}$ )
- Ergone ( $t_{\text{age}} = 300 \pm 100 \text{ m.y.}$ ,  $V_5 \approx 30 \text{ m s}^{-1}$ )
- Eos ( $t_{\text{age}} = 1.3 \pm 0.5 \text{ G.y.}$ ,  $V_5 \approx 70 \text{ m s}^{-1}$ )
- Tina ( $t_{\text{age}} = 170 \pm 50 \text{ m.y.}$ ,  $V_5 \approx 20 \text{ m s}^{-1}$ )

Here we have taken the liberty of updating and rounding off the estimates, and giving more generous errors than in the original publications (Vokrouhlický *et al.*, 2006a,b,c; Bottke *et al.*, 2007; Carruba and Morbidelli, 2011) [for the Padua family, see also Carruba (2009a)]. Note that these errors do not include the uncertainty of about a factor of 2 from the

**Fig. 6.** (a) The Ergone family projected onto a plane of proper semimajor axis vs. absolute magnitude  $H$ ; (163) Ergone is the filled star. The family has been separated into two clouds ( $a_p \leq 2.37 \text{ AU}$ ;  $a_p \geq 2.37 \text{ AU}$ ) by the Yarkovsky/YORP evolution. (b) A comparison between model results (solid line) and binned Ergone family [gray dots (see Vokrouhlický *et al.*, 2006b)]. The error bars are the square root of the number of bodies in each bin. The x-axis is the distance of family members from the the family center. Based on this result, Vokrouhlický *et al.* (2006b) estimated that  $t_{\text{age}} = 280^{+30}_{-50} \text{ m.y.}$  and  $V_5 = 26^{+14}_{-11} \text{ m s}^{-1}$ , where the error bars do not include the uncertainty originating from uncertain material properties (e.g., density, surface conductivity).

poorly known bulk density and surface conductivity of the asteroids in question. Including this uncertainty, *Masiero et al.* (2012) found that the best-fitting age of the Baptistina family can be anywhere between 140 and 320 m.y.

The estimated ejection speeds are  $V_5 = 15\text{--}50 \text{ m s}^{-1}$ , except for the Eos family, which formed in a breakup of a very large parent asteroid ( $D_{\text{PB}} \sim 300 \text{ km}$ ). These results are consistent with the ejection speeds inferred from the young Karin family, which has  $V_5 \approx 15 \text{ m s}^{-1}$  for a relatively small parent body [ $D_{\text{PB}} \approx 35 \text{ km}$  (*Nesvorný et al.*, 2006a)]. The ejection speeds contribute by  $\approx 20\%$  (for oldest Eos) to 50% (for youngest Agnia) to the total family spread in the semi-major axis. Ignoring this contribution, as in equation (2), would thus lead to an overestimate of  $t_{\text{age}}$  by  $\approx 20\text{--}50\%$ . While one must therefore be careful in applying equation (2) to the small/young families that did not have enough time to significantly spread by the YE, the effect of the ejection speeds should be less of an issue for old families.

## 6. DYNAMICAL EVOLUTION

### 6.1. Initial State

The dynamical evolution of asteroids in families is similar to the dynamical evolution of main-belt asteroids in general. Studying the dynamical evolution of individual families is useful in this context, because we more or less know how the families should look like initially. Things may thus be learned by comparing these ideal initial states with how different families look now, after having dynamically evolved since their formation. The dynamical studies can also often provide an independent estimate of  $t_{\text{age}}$ .

Assuming that  $\delta V \ll V_{\text{orb}}$ , the initial shape of families in  $(a, e, i)$  can be obtained from the Gauss equations (e.g., *Zappalà et al.*, 2002), which map the initial velocity perturbation  $\delta V = (V_R, V_T, V_Z)$ , where  $V_R$ ,  $V_T$ , and  $V_Z$  are the radial, tangential, and vertical components of the velocity vector, to the change of orbital elements  $\delta E = (\delta a, \delta e, \delta i)$ . If the ejection velocity field is (roughly) isotropic, the Gauss equations imply that initial families should (roughly) be ellipsoids in  $(a, e, i)$  centered at the reference orbit  $(a^*, e^*, i^*)$ . The transformation from  $(a, e, i)$  to  $(a_p, e_p, i_p)$  preserves the shape, but maps  $(a^*, e^*, i^*)$  onto  $(a_p^*, e_p^*, i_p^*)$  such that, in general,  $a_p^* \neq a^*$ ,  $e_p^* \neq e^*$ , and  $i_p^* \neq i^*$ .

The shape of the ellipsoids in  $(a_p, e_p, i_p)$  is controlled by the true anomaly  $f$  and the argument of perihelion  $\omega$  of the parent body at the time of the family-forming breakup. The projected distribution onto the  $(a_p, e_p)$  plane is a tilted ellipse with tightly correlated  $a_p$  and  $e_p$  if the breakup happened near perihelion (see Fig. 3a), or tightly anticorrelated  $a_p$  and  $e_p$  if the breakup happened near aphelion. The two recently formed families for which this shape is clearly discernible, the Karin and Veritas families, have correlated  $a_p$  and  $e_p$ , implying that  $|f| = 30^\circ$  (Figs. 3 and 4).

The projected initial distribution onto the  $(a_p, i_p)$  plane is an ellipse with horizontal long axis and vertical short axis. The short-to-long axis ratio is roughly given by  $\cos(\omega + f)$

$V_Z/V_T$ . Thus, breakups near the ascending ( $\omega + f = 0$ ) and descending ( $\omega + f = \pi$ ) nodes should produce “fat” ellipses while those with  $\omega + f = \pm\pi/2$  should make “squashed” ellipses with  $\delta i_p \approx 0$ . While the Karin family neatly fits in this framework with  $\omega + f \approx \pi/4$  (Fig. 3), the Veritas family shows large  $\delta i_p$  values, indicating that the ejection velocity field should have been anisotropic with  $V_Z$  some  $\approx 2\text{--}4\times$  larger than  $V_T$ .

The reference orbit  $(a_p^*, e_p^*, i_p^*)$  is often taken to coincide with the proper orbit of a largest family member. This should be fine for families produced in cratering or mildly catastrophic events, where the orbital elements of the impacted body presumably did not change much by the impact. For the catastrophic and highly catastrophic breakups, however, the largest surviving remnant is relatively small and can be significantly displaced from the family’s center. For example, (832) Karin, the largest  $\approx 17\text{-km}$ -diameter member of the Karin family produced by a catastrophic breakup of a  $\approx 40\text{-km}$ -diameter parent body [mass ratio  $\approx 0.08$  (*Nesvorný et al.*, 2006a)], is displaced by  $\approx -0.002 \text{ AU}$  from the family center ( $\approx 20\%$  of the whole extension of the Karin family in  $a_p$ ). This shows that, in general, the position of the largest fragment does not need to perfectly coincide with the family center, and has implications for the V-shape criterion discussed in section 4 (where an allowance needs to be given for a possible displacement).

### 6.2. Dynamics on Gigayear Timescales

An overwhelming majority of the observed asteroid families are not simple Gaussian ellipsoids. While this was not fully appreciated at the time of the *Asteroids III* book, today’s perspective on this issue is clear: *The families were stretched in  $a_p$  as their members drifted away from their original orbits by the Yarkovsky effect.* The asteroid families found in the present main belt are therefore nearly horizontal and elongated structures in  $(a_p, e_p)$  and  $(a_p, i_p)$ . This shows that the original ejection velocity field cannot be easily reconstructed by simply mapping back today’s  $(a_p, e_p, i_p)$  to  $(V_R, V_T, V_Z)$  from the Gauss equations (Note 7).

Moreover, many asteroid families have weird shapes that, when taken at face value, would imply funny and clearly implausible ejection velocity fields. A prime example of this, briefly mentioned in section 2.2, is the Koronis family (*Bottke et al.*, 2001). Since the case of the Koronis family was covered in the *Asteroids III* book (*Bottke et al.*, 2002), we do not discuss it here. Instead, we concentrate on the results of new dynamical studies, many of which have been inspired by the Koronis family case. The dynamical effects found in these studies fall into three broad categories:

1. Members drifting in  $a_p$  encounter a mean-motion resonance with one of the planets [mainly Jupiter, Mars, or Earth (see *Nesvorný et al.*, 2002c)]. If the resonance is strong enough (e.g., 3:1, 2:1, or 5:2 with Jupiter), the orbit will chaotically wander near the resonance border, its eccentricity will subsequently increase, and the body will be removed from the main belt and transferred onto a planet-crossing

orbit (*Wisdom*, 1982). If the resonance is weak, or if the asteroid is small and drifts fast in  $a_p$ , the orbit can cross the resonance, perhaps suffering a discontinuity in  $e_p$  during the crossing, and will continue drifting on the other side. If the resonance is weak and the drift rate is not too large, the orbit can be captured in the resonance and will slowly diffuse to larger or smaller eccentricities. It may later be released from the resonance with  $e_p$  that can be substantially different from the original value. The effects of mean-motion resonances on  $i_p$  are generally smaller, because the eccentricity terms tend to be more important in the resonant potential. The inclination terms are important for orbits with  $i_p \geq 10^\circ$ . A good example of this is the Pallas family, with  $i_p = 33^\circ$  (*Carruba et al.*, 2011).

2. Drifting members meet a secular resonance. The secular resonances are located along curved manifolds in  $(a_p, e_p, i_p)$  space (*Knežević et al.*, 1991). Depending on the type and local curvature of the secular resonance, and asteroid's  $da/dt$ , the orbit can be trapped inside the resonance and start sliding along it, or it can cross the resonance with a noticeably large change of  $e_p$  and/or  $i_p$ . A good example of the former case are orbits in the Eos family sliding along the  $z_1 = g - g_6 + s - s_6 = 0$  resonance (*Vokrouhlický et al.*, 2006a). An example of the latter case is the Koronis family, where eccentricities change as a result of crossing of the  $g + 2g_5 - 3g_6 = 0$  resonance (*Bottke et al.*, 2001). If the secular resonance in question only includes the  $g$  (or  $s$ ) frequency, effects on  $e_p$  (or  $i_p$ ) are expected. If the resonance includes both the  $g$  and  $s$  frequencies, both  $e_p$  and  $i_p$  can be affected. If the orbit is captured in a resonance with the  $g$  and  $s$  frequencies, it will slide along the local gradient of the resonant manifold with changes of  $e_p$  and  $i_p$ , depending on the local geometry.

3. Encounters with (1) Ceres and other massive asteroids produce additional changes of  $a_p$ ,  $e_p$ , and  $i_p$  (*Nesvorný et al.*, 2002b; *Carruba et al.*, 2003, 2007a, 2012, 2013b; *Delisle and Laskar*, 2012). These changes are typically smaller than those from the Yarkovsky effect on  $a_p$  and resonances on  $e_p$  and  $i_p$ . They are, however, not negligible. The effect of encounters can be approximated by a random walk (for a discussion, see *Carruba et al.*, 2007a). The mean changes of  $a_p$ ,  $e_p$ , and  $i_p$  increase with time roughly as  $\sqrt{t}$ . The asteroid families become puffed out as a result of encounters, and faster so initially than at later times, because of the nature of the random walk. Also, a small fraction of family members, in some cases perhaps including the largest remnant, can have their orbits substantially affected by a rare, very close encounter. Additional perturbations of asteroid orbits arise from the linear momentum transfer during nondisruptive collisions (*Dell'Oro and Cellino*, 2007).

### 6.3. Discussion of Dynamical Studies

The case of the Koronis family (*Bottke et al.*, 2001) sparked a great deal of interest in studies of the dynamical evolution of asteroid families on very long timescales. Here we review several of these studies roughly in chronologic

order. The goal of this text is to illustrate the dynamical processes discussed in the previous section on specific cases.

*Nesvorný et al.* (2002b) considered the dynamical evolution of the Flora family. The Flora family is located near the inner border of the main belt, where numerous mean-motion resonances with Mars and Earth produce slow diffusion of  $e_p$  and  $i_p$ . The numerical integration of orbits showed how the overall extent of the Flora family in  $e_p$  and  $i_p$  increases with time. The present width of the Flora family in  $e_p$  and  $i_p$  was obtained in this study after  $t = 0.5$  G.y. even if the initial distribution of fragments in  $e_p$  and  $i_p$  was very tight. The Flora family expansion saturates for  $t > 0.5$  G.y., because the Flora family members that diffused to large eccentricities are removed from the main belt by encounters with Mars [the Flora family is an important source of chondritic near-Earth asteroids (NEAs) (*Vernazza et al.*, 2008)]. The present spread of the Flora family in  $a_p$ , mainly contributed by the Yarkovsky effect, indicates  $t_{age} \sim 1$  G.y.

*Carruba et al.* (2005) studied the dynamical evolution of the Vesta family. The main motivation for this study was the fact that several inner main-belt asteroids, such as (956) Elisa and (809) Lundia, have been classified as V-types from previous spectroscopic observations (*Florczak et al.*, 2002), indicating that they may be pieces of the basaltic crust of (4) Vesta. These asteroids, however, have orbits rather distant from that of (4) Vesta and are not members of Vesta's dynamical family even if a very large cutoff distance is used. It was therefore presumed that (1) they have dynamically evolved to their current orbits from the Vesta family, or (2) they are pieces of differentiated asteroids unrelated to (4) Vesta. *Carruba et al.* (2005) found that the interplay of the Yarkovsky drift and the  $z_2 \equiv 2(g - g_6) + s - s_6 = 0$  resonance produces complex dynamical behavior that can indeed explain the orbits of (956) Elisa and (809) Lundia, assuming that the Vesta family is at least  $\approx 1$  G.y. old. This gives support to assumption (1) above.

In a follow-up study, *Nesvorný et al.* (2008a) performed a numerical integration of 6600 Vesta fragments over 2 G.y. They found that most V-type asteroids in the inner main belt can be explained by being ejected from (4) Vesta and dynamically evolving to their current orbits outside the Vesta family. These V-type "fugitives" have been used to constrain the age of the Vesta family, consistent with findings of *Carruba et al.* (2005), to  $t_{age} \geq 1$  G.y. Since previous collisional modeling of the Vesta family suggested  $t_{age} \leq 1$  G.y. (*Marzari et al.*, 1999), the most likely age of the Vesta family that can be inferred from these studies is  $t_{age} \sim 1$  G.y. This agrees well with the age of the  $\approx 500$ -km-diameter Rheasilvia basin on (4) Vesta inferred from crater counts [ $\approx 1$  G.y. (*Marchi et al.*, 2012)] (Note 8).

*Vokrouhlický et al.* (2006a) studied the dynamical evolution of the Eos family. The Eos family has a complicated structure in proper element space, leading some authors to divide it into several distinct families (e.g., *Milani et al.*, 2014). Diagnostically, however, the Eos family, although somewhat physically heterogeneous, has the color, albedo, and spectral properties that contrast with the local, predomi-

nantly C-type background in the outer asteroid belt, which suggests that it is a single family. As we discuss below, the complicated structure of the Eos family arises from the presence of several mean-motion and secular resonances.

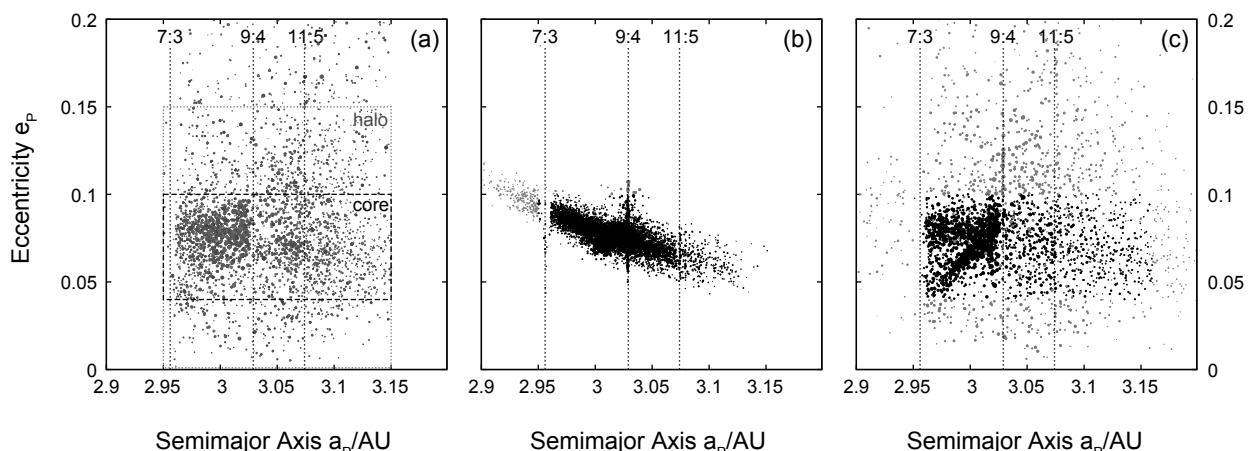

To start with, Vokrouhlický et al. (2006a) showed that the Eos family members drifting by the Yarkovsky effect into the 7:3 resonance with Jupiter are removed (see Fig. 7). This cuts the family at 2.957 AU. Members drifting with  $da/dt > 0$ , on the other hand, will encounter the 9:4 resonance at 3.03 AU. This resonance, being of higher order and thus weaker, is not an unpenetrable barrier, especially for smaller members with higher drift rates. The estimated fraction of bodies that can cross the 9:4 resonance is  $<10\%$  for  $H < 12$  but reaches  $\approx 35\%$  for  $H = 16$ . This is consistent with the magnitude distributions of the Eos family members on both sides of the 9:4 resonance. The larger dispersion of the part of the Eos family with  $a_p > 3.03$  AU is attributed to perturbations of  $e_p$  and  $i_p$  during the 9:4 resonance crossing (Fig. 7). Finally, many orbits in the central part of the Eos family are trapped in the secular resonance  $z_1 \equiv g + s - g_6 - s_6 = 0$ , and slide along it while drifting in  $a_p$  (Note 9).

Finally, we discuss additional processes whose significance is shadowed by the Yarkovsky effect and resonances, but which can be important in some cases. Nesvorný et al. (2002b) considered encounters with (1) Ceres and found that the characteristic change of the semimajor axis due to these encounters is  $\Delta a \approx 0.001$  AU over 100 m.y. Assuming that the scattering effect of encounters can be described by a random walk with  $\Delta a \propto \sqrt{t}$ , the expected changes over 1 G.y. and 4 G.y. are  $\approx 0.003$  AU and  $\approx 0.007$  AU, respectively. The orbital changes were found to be larger for orbits

similar to that of (1) Ceres, because the orbital proximity leads to lower encounter speeds and larger gravitational perturbations during the low-speed encounters. Carruba et al. (2003) studied the effect of encounters on the Adeona and Gefion families, both located near (1) Ceres in proper element space. They found that the semimajor axis of members of the Adeona and Gefion families can change by up to  $\sim 0.01$  AU over the estimated age of these families.

With similar motivation, Carruba et al. (2007a) considered the effect of encounters of the Vesta family members with (4) Vesta. They found the characteristic changes  $\Delta a = 0.002$  AU,  $\Delta e = 0.002$ , and  $\Delta i = 0.06^\circ$  over 100 m.y. In a follow-up work, Delisle and Laskar (2012) included the effects of 11 largest asteroids. They showed that encounters of the Vesta family members with (4) Vesta and (1) Ceres are dominant, contributing roughly by 64% and 36% to the total changes, respectively. The functional dependence  $\Delta a = 1.6 \times 10^{-4} \sqrt{t/1 \text{ m.y}} \text{ AU}$  was used in this work to extrapolate the results to longer time intervals. Moreover, Carruba et al. (2013b) studied the influence of these effects on the Pallas, Hygiea, and Euphrosyne families. They showed that the effects of (2) Pallas — the third most massive main-belt asteroid — on the Pallas family are very small, because these asteroids have high orbital inclinations ( $i_p = 33^\circ$ ), lower frequency of encounters, and higher-than-average encounter speeds.

Dell'Oro and Cellino (2007) pointed out that orbits of main-belt asteroids can change as a result of the linear momentum transfer during nondestructive collisions. They found that the expected semimajor axis change from these collisions for a  $D = 50$ -km main-belt asteroid is  $\Delta a \sim$

**Fig. 7.** Dynamical evolution of the Eos family. From left to right, the panels show (a) the observed family and its halo in the  $(a_p, e_p)$  projection, (b) the assumed initial shape of the family, and (c) the family's structure after 1.7 G.y. In (a), we plot all asteroids with Eos-family colors [ $0.0 < a^* < 0.1$  mag and  $-0.03 < i-z < 0.08$  mag; see Ivezic et al. (2001) for the definition of color indexes from the SDSS]. The size of a symbol is inversely proportional to absolute magnitude  $H$ . The boxes approximately delimit the extent of the core and halo of the Eos family. In (b), 6545 test particles were distributed with assumed isotropic ejection velocities,  $V_5 = 93 \text{ m s}^{-1}$ ,  $f = 150^\circ$ , and  $\omega = 30^\circ$ . Nearly all initial particles fall within the family core. In (c), an N-body integrator was used to dynamically evolve the orbits of the test particles over 1.7 G.y. The integration included gravitational perturbations from planets, and the Yarkovsky and YORP effects. The vertical lines show the locations of several resonances that contributed to spreading of orbits in  $e_p$  (7:3, 9:4, and 11:5 with Jupiter, also 3J-2S-1) and  $z_1 \equiv g + s - g_6 - s_6 = 0$ . Adapted from Brož and Morbidelli (2013).

$10^{-4}$  AU over 100 m.y. [with the scaling laws from *Benz and Asphaug* (1999)]. This is an order of magnitude lower than the change expected from close encounters with large asteroids and comparable to the sluggish drift rate expected from the Yarkovsky effect for  $D = 50$  km. For  $D < 50$  km, the orbital changes from nondestructive collisions sensitively depend on several unknown parameters, such as the SFD of subkilometer main-belt asteroids, but the general trend is such that  $\Delta a$  drops with decreasing  $D$  [assuming that the cumulative SFD index is  $<4$  (*Dell'Oro and Cellino*, 2007)]. Since  $\Delta a$  is independent of  $D$  for encounters with (1) Ceres, and  $\Delta a \propto 1/D$  for the Yarkovsky force, these two effects outrun the nondestructive collisions for  $D < 50$  km. This limits the significance of nondestructive collisions for the dynamical evolution of asteroid families. Their effect on  $e_p$  and  $i_p$  is also minor.

#### 6.4. Family Halos

When dynamical families are identified and removed from the main belt, they leave behind holes in the distribution of proper elements that are surrounded by regions with increased asteroid density (Fig. 8). These peripheral regions are known as the family halos. The families and family halos surrounding them are clearly related, which can most conveniently be demonstrated by considering their physical properties. For example, the Koronis family and its halo consist of bright asteroids (mean albedo  $p_V = 0.15$ ) that are classified as S in the asteroid taxonomy (moderate spectral slope and shallow absorption band near  $1\text{ }\mu\text{m}$ ). These properties contrast with the local background in the outer main belt, which is mostly dark ( $p_V \approx 0.05$ ) and C-type (featureless neutral spectrum). The Eos family and its halo (K-type,  $p_V = 0.13$ ) also stand out from the dark outer belt background.

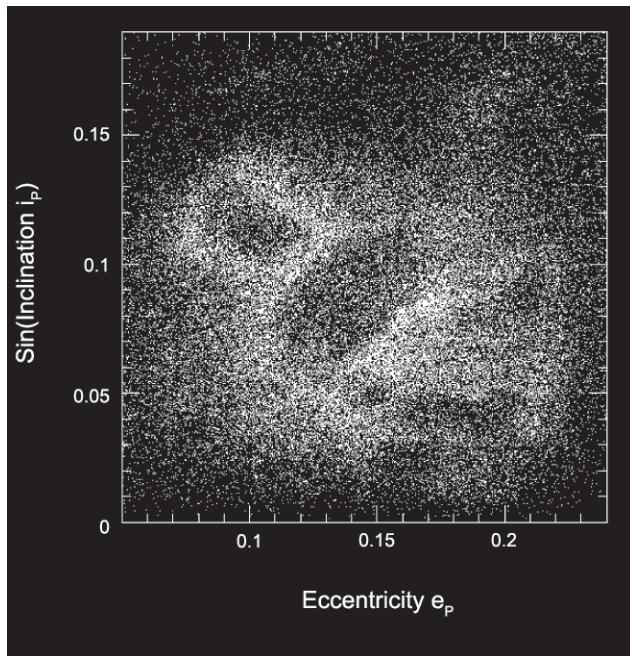

The distinction between families and family halos is, in a sense, formal, because it appears as a consequence of the identification method. Indeed, to extract the family halo by applying the HCM in three-dimensional space of proper elements, one would need to increase the value of the  $d_{cut}$  parameter. If it is increased, however, the identification would fail due to the problem of chaining (section 2.2). This is a consequence of the fact that the number density of halo asteroids is comparable to, or only slightly larger than, the number density of background asteroids. A better method for extracting the families jointly with their halos consists in applying the HCM in space of extended dimensions, where physical properties are used in addition to the proper elements (section 2.5) (*Parker et al.*, 2008; *Carruba et al.*, 2013a; *Masiero et al.*, 2013).

The origin of family halos is attributed to at least two processes. In the case of the Eos family, the observed dispersion of halo in  $e_p$  and  $i_p$  is too large ( $0\text{--}0.15$  and  $7^\circ\text{--}14^\circ$ , respectively) to be related to the the ejection speeds. Instead, *Brož and Morbidelli* (2013) showed how the Eos family halo gradually appears as a result of complex orbital dynamics in the Eos family region (Fig. 7). The age of the Eos family inferred from this work,  $1.5\text{ G.y.} < t_{age} < 2.2\text{ G.y.}$ ,

is larger than that obtained from the YY code [ $t_{age} = 1.3 \pm 0.2$  G.y.; *Vokrouhlický et al.* (2006a) and section 5], but the two estimates are consistent at the  $1\sigma$  level.

The Koronis family and its halo, on the other hand, are located in a dynamically quiet region of the main belt ( $2.82 < a_p < 2.95$  AU,  $e_p \approx 0.045$ ,  $i_p = 2^\circ$ ) where no major resonances exist [except for  $g + 2g_5 - 3g_6 = 0$  (*Bottke et al.*, 2001)]. The long-term dynamics of the Koronis family therefore has a relatively small influence on the overall width of the family in  $e_p$  and  $i_p$ . In contrast, the present shift of the Koronis family/halo members from the family's center is relatively large (up to  $\approx 0.015$  in  $e_p$  and  $\approx 0.5^\circ$  in  $i_p$ ). This can plausibly be explained by the ejection speeds.

Assuming an isotropic ejection velocity field and  $\delta V = V_5(5\text{ km/D})$  with  $V_5 = 50\text{ m s}^{-1}$ , we find that  $\delta a_p/a_p \approx 2\delta V/V_{orb} \approx 0.018$  for  $D = 5$  km fragments. This represents a small share of the Koronis family width in  $a_p$  (the population of  $D = 5$  km members stretches from the 5:2 resonance at 2.82 AU to the 7:3 resonance at 2.95 AU), consistent with the idea that the observed spread in  $a_p$  is mainly due to the Yarkovsky effect. With  $D = 1.5$  km, which is roughly the size of the smallest asteroids observed in this part of the main belt, the expected changes are  $\delta e_p = (1\text{--}2) \times \delta V/V_{orb}$ .

**Fig. 8.** The halos of families in the inner main belt ( $2 < a_p < 2.5$  AU). The dynamical families were identified by the HCM in three dimensions of proper elements and were removed, leaving behind what resembles a fuzzy chalk contour of victim's body removed from a crime scene. The head, body, and bottom leg correspond to the locations of the Vesta, Flora, and Nysa-Polana families. The halos surrounding these families, mainly composed of small asteroids, are rather dramatic in this projection. This figure illustrates a major weakness of the traditional family-identification method based on the HCM in three-dimensional space of proper elements.

$V_{\text{orb}} = 0.015$  and  $\delta i_p \leq \delta V/V_{\text{orb}} \approx 0.6^\circ$ . This is comparable to the present width of the Koronis family/halo in  $e_p$  and  $i_p$ .

Another notable argument in this context is that the Koronis halo is populated by small asteroids with diameters near the minimum detectable size (while the big ones are inside the family core). This suggests a certain size dependency of the process that created the halo, presumably related to the size dependency of the ejection speeds (see the chapter by Michel et al. in this volume). This important trend was pointed out by Cellino et al. (2004), and further discussed in Cellino et al. (2009).

## 7. SYNTHESIS

### 7.1. Method, Family Names, and Family Identification Number

Here we present a synthesis of asteroid families extracted from many past publications (Mothé-Diniz et al., 2005; Nesvorný et al., 2005; Gil-Hutton, 2006; Parker et al., 2008; Nesvorný, 2010, 2012; Novaković et al., 2011; Brož et al., 2013; Masiero et al., 2011, 2013; Carruba et al., 2013a; Milani et al., 2014). The synthesis is based on the numerically computed proper elements [AstDyS catalog from August 2014 with the proper elements for 384,337 numbered asteroids; the proper elements of 4016 Jupiter Trojans were taken from Rozehnal and Brož (2013)] and the latest releases of data from SDSS and WISE.

First, we collected a long list of all (228) families reported in these publications. Second, we checked to see whether the clustering in proper elements of each reported group is meaningful, and whether the group has reasonably homogeneous colors and albedos (see methods in section 2). The families that passed the preliminary tests were scrutinized further to establish the best cutoff value  $d_{\text{cut}}$  (the values of  $d_{\text{cut}}$  were informed from past publications), apply the V-shape criterion to identify large interlopers (section 4), and estimate  $t_{\text{age}}$  from the envelope-based method (section 5).

We made sure that each identified group with  $d_{\text{cut}}$  was complete (i.e., not missing any extension that would make sense dynamically), and not part of a larger structure. In some cases, a cut in proper element space was applied to avoid the problem of chaining. In several cases, following Masiero et al. (2013), we used an albedo cutoff,  $p_V < 0.15$ , to identify dark families in the inner and central belts [the (84) Klio, (313) Chaldaea, and (2262) Mitidika families]. Finally, we removed all identified families and searched for significant groups in the leftover population. This led to the identification of several additional families [e.g., the (589) Croatia, (926) Imhilde, and (1332) Marconia families in the outer belt].

A difficulty we had to deal with is that different authors often listed the same family under different names. For example, Masiero et al. (2013) renamed the families after their largest fragments [e.g., the (158) Koronis family was referred to as the (208) Lacrimosa family]. While it is very useful to identify the largest fragment, this naming conven-

tion creates chaos because some well-established family names disappear (Koronis, Maria, Flora, Gefion, Dora, etc.) and new names are used to refer to the same groups (Lacrimosa, Roma, Augusta, Gudiachvili, Zhongolovich, etc.). It is also not clear in many cases what the true largest member is [(208) Lacrimosa is only slightly larger than (158) Koronis, some large objects have peripheral orbits and can be interlopers, etc.].

A simple solution to this problem is to think of the family names as *labels*, used for historical and other reasons, which do not necessarily reveal what the largest or lowest-numbered asteroid is. Thus, the Koronis family would remain the Koronis family, regardless of whether (158) Koronis, (208) Lacrimosa, or some other large asteroid is an actual family member, largest or not.

Anticipating that some authors will still prefer to rename some families, here we assign each family a unique Family Identifier Number (FIN). The FIN goes from 101 to 399 for families identified from the analytic proper elements: 1XX for the inner belt (2–2.5 AU), 2XX for the middle belt (2.5–2.82 AU), and 3XX for the outer belt (2.82–3.7 AU). The families identified from the synthetic proper elements were assigned FINs from 401 to 999: 4XX and 7XX for the low- and high-inclination families in the inner belt, 5XX and 8XX for the low- and high-inclination families in the middle belt, and 6XX and 9XX for the low- and high-inclination families in the outer belt. The division between low and high inclinations was taken at  $\sin i_p = 0.3$  ( $i_p = 17.5^\circ$ ), which coincides with the highest inclinations for which the analytic proper elements are available. The FINs of the low-inclination families are “aligned” such that 101 and 401, 102 and 402, 201 and 501, etc., are the same families identified from two different datasets. The families among Hungarias with  $a < 2$  AU, Hildas with  $a \approx 3.8$  AU, and Jupiter Trojans with  $a \approx 5.2$  AU are given a FIN between 001 and 099.

The main idea behind this notation is that even if a family is eventually renamed, its FIN will remain the same. Therefore, it should suffice to list the FIN of the renamed family in a new publication to make it clear how the new name relates to the designation(s) used in the past. For example, the Koronis family is given the FIN 605 (synthetic proper elements, outer belt, low  $i$ , 5th notable family), and the *number* will remain “605” even if the *name* “Lacrimosa family” is eventually adopted. Since it will be easy to check and see that the Koronis and Lacrimosa families have the same FIN (assuming that authors list the FIN in their publications), it will be obvious that we are talking about the same family.

A potential difficulty with this scheme would arise if families that were previously assigned a FIN are later found to be nonexistent (e.g., because they are later determined to be statistically insignificant or part of a larger structure that was not evident in the original data). We suggest that such families be deleted and the associated FINs left void (i.e., not assigned to any family), so there is no possibility of confusion. Finally, in order to avoid having numerous

void FINs, and to not run out of the possible FINs with the three-digit scheme described above, FINs should be given only to families that are reasonably secure. Other, less-secure families can be tentatively listed as family candidates and can wait to be assigned a FIN until their existence is verified with the new data. If the number of families in the inner, middle, and/or outer belts exceeds 99, the three-digit FIN scheme described here can be easily modified to a four-digit scheme by adding 0 at the second decimal digit, e.g., FIN 401 (the Vesta family) becomes FIN 4001. This change can be implemented if the need arises.

## 7.2. Family Lists

There are 122 notable asteroid families reported in Table 2 and 19 family candidates listed in Note 10. The vast majority of families listed in Table 2 have been reported in many past publications and are clear beyond doubt (Vesta, Massalia, Eunomia, Gefion, Koronis, Eos, Themis, etc.). Many additional families, reported in only one or two previous publications, are also clear beyond doubt with the new data. Eleven families are reported here for the first time: ((329) Svea and (108138) 2001 GB<sub>11</sub> in the inner belt; (89) Julia, (369) Aeria, (1484) Postrema, (2782) Leonidas, and (3152) Jones in the central belt; and (589) Croatia, (926) Imhilde, (1332) Marconia, and (106302) 2000 UJ<sub>87</sub> in the outer belt. There are 20 notable families in the inner belt (the Nysa-Polana complex is counted as three families here): 47 in the central belt, 46 in the outer belt, 2 among Hildas in the 3:2 resonance with Jupiter, 1 in Hungarias, and 6 among Jupiter Trojans. Of these, 17 have high orbital inclinations ( $i_p > 17.5^\circ$ ). Figure 9 shows the orbital location of the notable families in the main belt.

The lists of members of the notable families can be downloaded from the PDS node (Note 11). Each list contains (1) the asteroid number, (2)  $a_p$ , (3)  $e_p$ , (4)  $\sin i_p$ , and (5) the absolute magnitude  $H$  from the Minor Planet Center. Also, for families that have a well-defined V-shape envelope in ( $a_p, H$ ), we fit  $C_0$  to this shape (section 4, column 7 in Table 2) and report  $C_j/C_0$  for each family member in column 6 of the PDS files. The average albedo of each family was obtained from WISE, and is reported in column 9 of Table 2 ( $p_V$ ). The taxonomic type of families, reported in column 8 of Table 2, was taken from the previous taxonomic classification of families (Cellino et al., 2002) or was deduced from the SDSS colors.

Columns 5 and 6 of Table 2 report the estimated diameter of the largest member,  $D_{LM}$ , and diameter of a sphere with volume equivalent to that of all fragments,  $D_{frag}$ .  $D_{LM}$  was obtained from AKARI, if available, or from WISE, if available, or was estimated from  $H$  and average  $p_V$ . The largest member and suspected interlopers with  $|C_j/C_0| > 2$  were excluded in the estimate of  $D_{frag}$ . The comparison of  $D_{LM}$  and  $D_{frag}$  helps to establish whether a particular breakup event was catastrophic ( $D_{frag} > D_{LM}$ ) or cratering ( $D_{frag} < D_{LM}$ ), but note that this interpretation may depend on sometimes uncertain membership of the largest family objects. Also, the diameter of the parent body of each family can be estimated

as  $D_{PB} = (D_{LM}^3 + D_{frag}^3)^{1/3}$ , but note that this estimate ignores the contribution of small (unobserved) fragments.

## 7.3. Comparison with Previous Datasets

The family synthesis presented here is consistent with the results reported in Nesvorný (2012), Brož et al. (2013), and Carruba et al. (2013a). For example, all families reported in Nesvorný (2012) were found to be real here [except the (46) Hestia family, which was reclassified as a candidate family; see Note 10]. Nesvorný (2012), however, used very conservative criteria for the statistical significance of a family, and reported only 76 families (or 78 if the Nysa-Polana complex is counted, as it should be, as three families). Using the 2014 catalog of proper elements, albedo information from Masiero et al. (2013), and validating several new families from Milani et al. (2014), we now have 44 families that did not appear in Nesvorný (2012). Almost all families reported in Brož et al. (2013) also appear here [a notable exception is a large group surrounding (1044) Teutonia that we do not believe to be a real family; see Note 10], but many new cases were added. The correspondence with Carruba et al. (2013a) is also good.

Parker et al. (2008) used  $N_{min} = 100$  and therefore missed many small families that did not have more than 100 members in the 2008 catalog. Also, given that they used a subset of asteroids with SDSS colors, even relatively large families were unnoticed in this work [e.g., the (752) Sulamitis family in the inner belt now has 303 members]. The high-i families were not reported in Parker et al. (2008) because they only used the analytic proper elements, which are not available for the high-i orbits. The strength of Parker et al.'s identification scheme was its reliability. Indeed, of all the families reported in Parker et al. (2008), only (1044) Teutonia, (1296) Andree, and (2007) McCuskey (part of the Nysa-Polana complex) are not included among the notable families here [Parker et al.'s (110) Lydia family appears here as the (363) Padua family].

Masiero et al. (2013) (hereafter M13) reported 28 new cases and found that 24 old families were lost when compared to the family lists in Nesvorný (2012). Most families not listed in M13 are well-defined families such as Karin, Beagle, Datura, Emilkowalski, Lucascavin, etc. These families were not listed in M13, because they overlap with larger families (and were included in their membership lists in M13) or because they only have a few known members (i.e., fall below  $N_{min}$  used in M13). On the other hand, we verified that many new cases reported in Masiero et al. (2013) are genuine new families that can be conveniently found with the albedo cutoff [e.g., the (84) Klio, (144) Vibilia, (313) Chaldaea — which is the same as (1715) Salli in M13 — (322) Phaeo, (623) Chimarea, (816) Julian, and (1668) Hanna families]. These families were included here. In some cases, we found that M13's new family barely stands out from the background and thus seems uncertain. To stay on the safe side, we therefore report these cases as the candidate families in Note 10. These families may be

TABLE 2. Notable asteroid families.

Columns are (1) Family Identification Number (FIN), (2) family name, (3) cutoff distance ( $d_{\text{cut}}$ ) used on a subset of asteroids with  $p_V < 0.15$ , (4) number of family members identified with  $d_{\text{cut}}$ , (5) largest member(s) in the family [either the number designation of the largest member(s), in parenthesis, if different from the asteroid after which the family is named, or the estimated diameter of the largest member,  $D_{LM}$ ], (6) diameter of a sphere with volume equivalent to that of all fragments ( $D_{\text{frag}}$ ), (7)  $C_0$  parameter defined in section 4, (8) taxonomic type, (9) mean geometric albedo from WISE ( $p_V$ ), and (10) various references and notes. We do not report  $t_{\text{age}}$  here but note that  $t_{\text{age}}$  can be estimated from  $C_0$  given in column 7 and equation (2). For additional information on asteroid families, see <http://sirrah.mrao.iap.ac.ru/~mrao/mpfams/> (Brož *et al.*, 2013).

**Fig. 9.** The orbital location of notable families from Table 2. A triangle is placed at the orbit of an asteroid after which the family is named. The label near the triangle shows the designation number of that asteroid.

real, but their statistical significance needs to be carefully tested with the new data.

Finally, we compare the family synthesis with Milani *et al.* (2014) (hereafter M14), who used the newest catalog from all previous works discussed here. They identified many new families that are certain beyond doubt [e.g., (96) Aegle, (618) Elfriede, (2344) Xizang, (3438) Inarradas, (3811) Karma, (7468) Anfimov, and (53546) 2000 BY<sub>6</sub>; the (96) Aegle and (618) Elfriede families were also reported in M13]. These cases highlight the strength of the M14 identification scheme and are included in the family synthesis in Table 2. Some smaller families located inside bigger families [e.g., the (832) Karin family in the (158) Koronis family, (656) Beagle in (24) Themis] were not reported in M14. In addition, several families were not reported, presumably because the QRL was set too low to detect them. This happens, most notably, in the 2.82–2.96-AU region (i.e., between the 5:2 and 7:3 resonances), where the number density of asteroids is relatively low (see Figs. 1 and 9). The notable cases in this region include the (81) Terpsichore, (709) Fringilia,

(5567) Durisen, (5614) Yakovlev, (7481) San Marcello, and (10811) Lau families. A possible solution to this issue, in terms of the M14 identification scheme, would be to use a separate QRL level for the 2.82–2.96-AU region. Also, several families were split in M14 into several parts. This affects (8) Flora (split in four parts), (31) Euphrosyne (three parts), (221) Eos (five parts), (702) Alauda (four parts), (1400) Tirela (eight parts), (2085) Henan (four parts), (4203) Brucato (four parts) (here we only list families that were split to three or more parts in M14).

## 8. CONCLUSIONS

It is clear from several different arguments that the list of known families must be largely incomplete. For example, most families with an estimated parent body size below  $\approx 100$ –200 km are found to have ages  $t_{\text{age}} \leq 1$  G.y. (e.g., Brož *et al.*, 2013). In contrast, the rate of impacts in the main belt, and therefore the rate of family-forming events, should have been roughly unchanging with time over the

past  $\approx 3.5$  G.y. (and probably raised quite a bit toward the earliest epochs). So, there must be many missing families with the formation ages  $t_{\text{age}} > 1$  G.y. (Note 12). These families are difficult to spot today, probably because they have been dispersed by dynamical processes, lost members by collisional grinding, and therefore do not stand out sufficiently well above the dense main-belt background (they are now part of the background).

The significant incompleteness of known families is also indicated by the extrapolation of the number of families detected in the 2.82–2.96-AU zone to the whole main belt. As we hinted on at the end of the last section, the 2.82–2.96-AU zone is sparsely populated such that asteroid families can be more easily detected there. Nearly 20 families with  $i_p < 17.5^\circ$  were identified in this region. In comparison, the 2.96–3.3-AU zone, where  $\approx 20$  families with  $i_p < 17.5^\circ$  can also be found, is about twice as wide as the 2.82–2.96-AU zone and contains about twice as many large asteroids. A straightforward conclusion that can be inferred from this comparison, assuming everything else is equal, is that the families in the 2.96–3.3-AU zone are (at least) a factor of  $\sim 2$  incomplete. A similar argument applies to the inner and central belts.

This is actually good news for future generations of planetary scientists, because this field is open for new discoveries. Figuring out how to find the missing asteroid families with  $t_{\text{age}} > 1$  G.y. will not be easy. One way forward would be to improve our capability to model the dynamical evolution of main-belt asteroids over gigayear timescales, such that we can rewind the clock and track fragments back to their original orbits. The modeling of the Yarkovsky effect could be improved, for example, if we knew the spin states, densities, conductivity, etc., of small main-belt asteroids on an individual basis. Another approach would consist of identifying families based on the physical properties of their members. While this method is already in use, mainly thanks to data from SDSS and WISE, we anticipate that it can be pushed much further, say, with automated spectroscopic surveys, or, in the more distant future, with routine sampling missions.

## 9. NOTES

**Note 1** — Alternatively, one can use the frequencies  $n$ ,  $g$ , and  $s$  (*Carruba and Michtchenko*, 2007, 2009), where  $n$  is the mean orbital frequency and  $g$  and  $s$  are the (constant) precession frequencies of the proper perihelion longitude  $\bar{\omega}_p$  and the proper nodal longitude  $\Omega_p$ , respectively. The use of frequencies, instead of the proper elements, can be helpful for asteroid families near or inside the secular orbital resonances [e.g., the Tina family in the  $v_6$  resonance (*Carruba and Morbidelli*, 2011)].

**Note 2** — Additional methods were developed and/or adapted for specific populations of asteroids such as the ones on the high-inclination and high-eccentricity orbits (*Lemaître and Morbidelli*, 1994) or in orbital resonances (*Morbidelli*, 1993; *Milani*, 1993; *Beaugé and Roig*, 2001; *Brož and Vokrouhlický*, 2008; *Brož and Rozehnal*, 2011).

**Note 3** — <http://hamilton.dm.unipi.it/asstdys/>

**Note 4** — See *Bendjoya and Zappalà* (2002) for a discussion of other clustering algorithms such as the wavelet analysis method (WAM) and D-criterion. The WAM was shown to produce results that are in good agreement with those obtained from the HCM (*Zappalà et al.*, 1994). The D-criterion was originally developed to identify meteorite streams (*Southwork and Hawkins*, 1963). These methods have not been used for the classification of asteroid families in the past decade, and we therefore do not discuss them here.

**Note 5** — The SDSS measured flux densities in five bands with effective wavelengths 354, 476, 628, 769, and 925 nm. The WISE mission measured fluxes in four wavelengths (3.4, 4.6, 12, and 22  $\mu\text{m}$ ), and combined the measurements with a thermal model to calculate albedos ( $p_V$ ) and diameters (D). The latest public releases of these catalogs include color or albedo data for over 100,000 main-belt asteroids with known orbits, of which about 25,000 have both color and albedo measurements. The catalogs are available at [http://www.sdss.org/dr6/products/value\\_added/index.html](http://www.sdss.org/dr6/products/value_added/index.html) and <http://irsa.ipac.caltech.edu/Missions/wise.html>.

**Note 6** — Most but not all asteroid families are physically homogeneous. The Eos family has the highest diversity of taxonomic classes of any known family (e.g., *Mothé-Diniz et al.*, 2008). This diversity has led to the suggestion that the Eos parent body was partially differentiated. It can also be the source of carbonaceous chondrites (*Clark et al.*, 2009). The Eunomia family may be another case of a relatively heterogeneous family (e.g., *Nathues et al.*, 2005). See *Weiss and Elkins-Tanton* (2013) for a review.

**Note 7** — *Dell’Oro et al.* (2004) attempted to model observed family shapes by Gaussian ellipsoids. The distribution of  $|f|$  obtained in this work was strongly peaked near  $\pi/2$ , while a more uniform distribution between 0 and  $\pi$  would be expected if different breakups occurred at random orbital phases. This result was attributed to the Yarkovsky effect.

**Note 8** — *Nesvorný et al.* (2008a) found evidence for a large population of V-type asteroids with slightly lower orbital inclinations ( $i_p = 3^\circ$ – $4^\circ$ ) than the Vesta family ( $i_p \approx 5^\circ$ ). Because these asteroids could not have dynamically evolved from the Vesta family region to their present orbits in  $\approx 1$  G.y., they are presumably fragments excavated from (4) Vesta’s basaltic crust by an earlier impact.

**Note 9** — Other asteroid families whose long-term dynamics have been studied in detail, listed here in alphabetical order, are the Adeona family [affected in  $e_p$  and  $i_p$  by the 8:3 resonance at 2.705 AU (*Carruba et al.*, 2003)], Agnia family [inside the  $z_1$  resonance (*Vokrouhlický et al.*, 2006c)], Astrid family [near the border of the 5:2 resonance (*Vokrouhlický et al.*, 2006b)], Eunomia family (*Carruba et al.*, 2007b), Euphrosyne family [located in a region with many resonances, including  $g-g_6 = 0$ , near the inner border of the 2:1 resonance (*Carruba et al.*, 2014)], Erigone family [cut in the middle by the  $z_2$  resonance (*Vokrouhlický et al.*, 2006b)], Gefion family [affected by various resonances near 2.75 AU (*Carruba et al.*, 2003; *Nesvorný et al.*, 2009)], Hilda and Schubart families in the 3:2 resonance with Jupiter (*Brož and Vokrouhlický*, 2008), Hungaria family [perturbed by  $2g-g_5-g_6 = 0$  and other secular resonances below 1.93 AU (*Warner et al.*, 2009; *Milani et al.*, 2010); see also *Galiazzo et al.* (2013, 2014) for the contribution of Hungarias to the E-type NEAs and *Čuk et al.* (2014) for their suggested relation to the aubrite meteorites], Hygiea family (*Carruba*, 2013; *Carruba et al.*, 2014), Massalia family [the part with

$a_p > 2.42$  AU disturbed by the 1:2 resonance with Mars [Vokrouhlický et al., 2006b)], Merxia family [spread by the 3J-1S-1 three-body resonance at  $a_p = 2.75$  AU (Vokrouhlický et al., 2006b)], Padua family (Carruba, 2009a), Pallas family (Carruba et al., 2011), Phocaea family (Carruba, 2009b), Sylvia family [(87) Sylvia has two satellites, possibly related to the impact that produced the Sylvia family (Vokrouhlický et al., 2010)], and Tina family (Carruba and Morbidelli, 2011).

**Note 10** — The candidate families are (929) Algunde, (1296) Andree, (1646) Rosseland, (1942) Jablunka, (2007) McCuskey, (2409) Chapman, (4689) Donn, (6246) Komurotoru, and (13698) 1998 KF<sub>35</sub> in the inner belt; (46) Hestia, (539) Palmina, (300163) P/2006 VW<sub>139</sub>, (3567) Alvema, and (7744) 1986 QA<sub>1</sub> in the central belt; and (260) Huberta, (928) Hilrun, (2621) Goto, (1113) Katja, and (8737) Takehiro in the outer belt. We tentatively moved the (46) Hestia family, previously known as FIN 503, to the family candidate status, because the existence of this group has not been conclusively proven with present data. The previously reported groups around (5) Astraea, (1044) Teutonia, (3110) Wagman, (4945) Ikenozenni, (7744) 1986 QA<sub>1</sub>, (8905) Bankakuko, (25315) 1999 AZ<sub>8</sub>, and (28804) 2000 HC<sub>81</sub> seem to align with the  $z_1 = g + s - g_6 - s_6 = 0$  resonance and are probably an artifact of the HCM chaining.

**Note 11** — <http://sbn.psi.edu/pds/resource/nesvornymfam.html>

**Note 12** — The list of known families corresponding to parent bodies with  $D > 200$  km, on the other hand, is probably reasonably complete, because the estimated ages of these families appear to be randomly distributed over 4 G.y. (Brož et al., 2013). These largest families can therefore be used to constrain the collisional history of the asteroid belt (see the chapter by Bottke et al. in this volume).

---

An asteroid family is typically formed when a larger parent body undergoes a catastrophic collisional disruption, and as such, family members are expected to show physical properties that closely trace the composition and mineralogical evolution of the parent. Recently a number of new datasets have been released that probe the physical properties of a large number of asteroids, many of which are members of identified families. We review these datasets and the composite properties of asteroid families derived from this plethora of new data. We also discuss the limitations of the current data, as well as the open questions in the field.

## 1. INTRODUCTION

Asteroid families provide waypoints along the path of dynamical evolution of the solar system, as well as laboratories for studying the massive impacts that were common during terrestrial planet formation. Catastrophic disruptions shattered these asteroids, leaving swarms of bodies behind that evolved dynamically under gravitational perturbations and the Yarkovsky effect to their present-day locations, both in the main belt and beyond. The forces of the family-forming impact and the gravitational reaccumulation of the collisional products also left imprints on the shapes, sizes, spins, and densities of the resultant family members (see the chapter by Michel et al. in this volume). By studying the physical properties of the collisional remnants, we can probe the composition of the parent asteroids, important source regions of transient populations like the near-Earth objects (NEOs), and the physical processes that asteroids are subjected to on million- and billion-year timescales.

In the 13 years since the publication of *Asteroids III*, research programs and sky surveys have produced physical observations for nearly 2 orders of magnitude more asteroids than were previously available. The majority of these characterized asteroids are members of the main belt, and approximately one-third of all known main-belt asteroids (MBAs) with sizes larger than a few kilometers can be associated with asteroid families. As such, these datasets

represent a windfall of family physical property information, enabling new studies of asteroid family formation and evolution. These data also provide a feedback mechanism for dynamical analyses of families, particularly age-dating techniques that rely on simulating the nongravitational forces that depend on an asteroid's albedo, diameter, and density.

In *Asteroids III*, Zappalà et al. (2002) and Cellino et al. (2002) reviewed the physical and spectral properties (respectively) of asteroid families known at that time. Zappalà et al. (2002) primarily dealt with asteroid size distributions inferred from a combination of observed absolute H magnitudes and albedo assumptions based on the subset of the family members with well-measured values. Surveys in the subsequent years have expanded the number of measured diameters and albedos by nearly 2 orders of magnitude, allowing for more accurate analysis of these families. Cellino et al. (2002) discussed the spectroscopic properties of the major asteroid families known at that time. The principal leap forward since *Asteroids III* in the realm of spectroscopy has been the expansion of spectroscopic characterization to near-infrared (NIR) wavelengths. The development of more sensitive instrumentation covering the 1- and 2-m silicate absorption features and new observing campaigns to acquire NIR spectra for a large number of objects have revolutionized studies of asteroid composition and space weathering.

By greatly expanding the number of family members with measured physical properties, new investigations of asteroid

families can be undertaken. Measurements of colors and albedo allow us to identify outliers in our population lists and search for variations in surface properties of family members that might indicate heterogeneity of the parent-body or weathering processes. Diameter measurements let us build a size frequency distribution and estimate the original parent-body size, both of which are critical to probing the physics of giant impacts. Spectra provide detailed mineralogical constraints of family members, allowing for more sensitive tests of space weathering and parent heterogeneity, albeit for a smaller sample size, while also probing the formation environment and allowing for comparisons to meteorite samples.

In this chapter, we highlight the datasets that have been obtained since *Asteroids III*, which have greatly expanded our ability to understand asteroid families. We discuss their implications for specific families, and tabulate average photometric, albedo, and spectroscopic properties for 109 families identified in the chapter by Nesvorný et al. in this volume. We also discuss the key questions that have been answered since *Asteroids III*, those that remain open, and the new puzzles that have appeared over the last decade.

## 2. NEW DATASETS

The field of asteroid research has benefited in the last 13 years from a huge influx of data. Many of these large sets of asteroid characterization data (including photometric and thermophysical data) have been ancillary results of surveys primarily designed to investigate astrophysical sources beyond the solar system. Simultaneously, observing programs designed to acquire more time-intensive data products such as asteroid spectra, photometric light curves, or polarimetric phase curves have also blossomed. We review below the main datasets that have advanced family characterization in recent years.

### 2.1. Optical Colors from the Sloan Digital Sky Survey

The Sloan Digital Sky Survey (SDSS) (York et al., 2000) produced one of the first extremely large, homogeneous datasets that contained information about asteroid surface properties at optical wavelengths. These data are archived in the SDSS Moving Object Catalog (<http://www.astro.washington.edu/users/ivezic/sdssmoc/sdssmoc.html>), which currently contains 471,569 entries of moving objects from survey scans conducted up to March 2007. The catalog entries can be associated with 104,449 unique known moving objects; however, ~250,000 entries do not have corresponding associations in the orbital element catalogs, implying the potential for a significant benefit from future data mining efforts.

While the SDSS five-color photometric system (u, g, r, i, z, with central wavelengths of 0.3543 μm, 0.4770 μm, 0.6231 μm, 0.7625 μm, and 0.9134 μm, respectively) was not designed with asteroid taxonomy in mind [unlike previous surveys such as the Eight Color Asteroid Survey (Zellner et al., 1985a)], the sheer size of the dataset coupled with its

extremely well-characterized performance has made SDSS an immensely valuable asset for defining asteroid families and exploring their properties. The near-simultaneous optical color information obtained during the course of the SDSS survey can be used to infer the spectroscopic properties of tens of thousands of asteroids at optical wavelengths.

The SDSS, primarily designed to measure the redshifts of a very large sample of galaxies, serendipitously observed many asteroids over the course of its several survey iterations. Under standard survey operations with 53.9-s exposures, its five-color camera was sensitive to stationary sources as faint as  $r \sim 22.2$ , with similar performance in u and g and somewhat brighter limits in i and z (21.3 and 20.5, respectively). To enable the accurate determination of photometric redshifts, high-precision internal and absolute calibrations were essential. The care and effort expended on these calibrations carried over into the dataset of moving object photometry, resulting in the largest well-calibrated dataset of multi-band asteroid photometry to date.

As of the latest data release, the Moving Object Catalog 4 (MOC4) (Parker et al., 2008) contains asteroid observations from 519 survey observing runs. The automatic flagging and analysis of moving objects required that they be brighter than magnitude  $r = 21.5$ . The brightest object in the sample is  $r \sim 12.91$ , giving the survey a dynamic range of over 8.5 mag. The large sample size and dynamic range of this survey make it a powerful tool for studying luminosity functions of dynamically — or photometrically — selected subpopulations of the moving objects, of which asteroid families are a natural example.

Because of the much smaller sample size of asteroids with u-band observations having photometric errors  $<0.1$  mag (44,737, compared with 442,743 with a similar precision in r-band), most large-scale asteroid studies using SDSS photometry have considered only the four longer-wavelength bands. These are often further collapsed into two principle components, a\* color [ $a^* = 0.89(g-r) + 0.45(r-i) - 0.57$ ] and the (i-z) color (see Ivezić et al., 2001).

Using the SDSS dataset, Ivezić et al. (2002) showed that asteroid families are easily identified from their optical colors. They found four primary color classes of families, which describe one of four characteristic compositions: Vesta, Koronis, Eos, and Themis. Jedicke et al. (2004) and Nesvorný et al. (2005) expanded upon this to investigate space weathering and find that older asteroid families have steeper spectral slopes from 0.55 to 1 μm than younger asteroid families.

Szabó and Kiss (2008) used SDSS photometry to constrain the shape distributions of eight large asteroid families. By assuming the observed magnitude differences between different epochs of observation were uncorrelated, they showed that both older families and families closer to the Sun tend to have more spherical shape distributions. This effect is what would be expected for a system where small-scale cratering collisions redistributed material into gravitational lows, resulting in a more spherical shape.

Parker et al. (2008) used the family color relationships found by Ivezić et al. (2002) as a springboard to refine the

definition of asteroid families beyond solely dynamical relationships. The ability to spectrophotometrically refine the sample of objects linked to each family meant family membership could be extended further into the background, and allowed the identification of diffuse family “halos” of compositionally distinct objects (Parker et al., 2008; Brož and Morbidelli, 2013; Carruba et al., 2013). Overlapping but compositionally distinct families such as Flora and Baptistina are easily separated with the addition of color information.

Using the wealth of SDSS data, Carvano et al. (2010) modeled established taxonomic classes to define the SDSS color parameters of each class. They then used these constraints to perform photometric taxonomic classifications of SDSS-observed asteroids, including many large asteroid families. This technique was later extended by DeMeo and Carry (2013) to better distinguish the boundaries between taxonomic classes. This taxonomic strategy can be applied to future photometric surveys to rapidly classify asteroids as a tool for improving family associations. While the resulting taxonomic grouping is of lower certainty than spectroscopic classification, spectrophotometric taxonomy offers a fast way to quantify the spectral behavior of large numbers of asteroids and provide high-quality candidates for spectroscopic follow-up.

## 2.2. Visible and Infrared Spectroscopic Surveys

Spectroscopic measurements provide unparalleled sensitivity to the mineralogical features on the surfaces of asteroids. As members of families come from the same progenitor object, surveys of many family members allow us to probe the composition of that parent body and search for mineralogical changes indicative of geological processes during the parent’s formation and early evolution. For families shown to have homogeneous spectral properties, these surveys can also be used to identify outlier objects that are compositionally distinct from the family, especially large objects that can present serious complications to the analysis of family evolution.

A major focus in the study of families has been the characterization of the effects of space weathering on the surfaces of atmosphereless bodies. Recent work using dynamical simulations to determine the ages of asteroid families (see the chapter by Nesvorný et al. in this volume for a discussion of these works) has opened a new avenue into investigating the potential effects of space weathering on asteroid surfaces. Assuming that the family-forming impact completely refreshed the surfaces of family members, we can look for families with similar compositions but different ages to search for spectral changes that would be the hallmark of space weathering. A number of researchers have conducted spectroscopic surveys of families to this end, although the results of these studies have been somewhat conflicting (e.g., Nesvorný et al., 2005; Willman et al., 2008; Vernazza et al., 2009; Thomas et al., 2011, 2012).

Shortly after the publication of *Asteroids III*, large-scale visible-wavelength (0.45–0.9 μm) spectral surveys were

published that were major drivers of asteroid compositional studies. Bus and Binzel (2002) and Lazzaro et al. (2004) published 1341 and 820 asteroid spectra, respectively, providing a wealth of data for asteroid studies. Also around this time NIR spectrometers became widely available, such as SpeX on the NASA Infrared Telescope Facility (IRTF) (Rayner et al., 2003). The NIR provides wavelength coverage that allows better characterization of silicate features (Burbine and Binzel, 2002; Gaffey et al., 1993). While no single large observing campaign has been initiated for main-belt asteroids in the NIR, many small programs have been carried out that targeted specific asteroid families (Sunshine et al., 2004; Mothé-Diniz et al., 2005, 2008; Vernazza et al., 2006; Mothé-Diniz and Nesvorný, 2008a,b; Willman et al., 2008; Harris et al., 2009; Reddy et al., 2009, 2011; de Sanctis et al., 2011; Ziffer et al., 2011; de Leon et al., 2012). A compilation of spectral taxonomic classifications of asteroids is given in the Planetary Data System by Neese (2010) and is periodically updated. We highlight here some of the specific families that were the subject of spectral investigations.

Vernazza et al. (2006) obtained spectra of Karin family members, finding them to be very similar to ordinary chondrite (OC) meteorites. Willman et al. (2008, 2010) extended this survey in an attempt to constrain space-weathering rates for asteroid surfaces, finding that spectral slopes are altered on the billion-year timescale. Harris et al. (2009) surveyed the Karin family using thermal infrared spectroscopy, and found albedos lower than expected for fresh asteroid surfaces, implying space weathering alters albedos on the million-year timescale, in conflict with the Willman et al. (2008, 2010) results.

Nathues (2010) used visible and NIR spectroscopy of the (97) Eunomia family members to study the potential differentiation history of the family parent. They show that the majority of family members have S-type taxonomy and the parent body was likely not fully differentiated, but may have undergone partial differentiation. Fieber-Beyer et al. (2011) obtained NIR spectroscopy of (12) Maria family members. From these data they associate this family with mesosiderite-type meteorites, a type of iron-rich meteorite thought to originate from a differentiated parent body.

Ziffer et al. (2011) obtained NIR spectra of 13 asteroids in the Themis and Veritas families and find distinct differences in the spectral behavior of the two families. They associate both families with CM2 chondrites, but find no evidence for space weathering of C-type objects.

Reddy et al. (2009, 2011) performed a spectroscopic survey of the Baptistina family aimed at constraining the composition of the family members. They found a range of compositions represented, but smaller objects as well as (298) Baptistina itself show clear association with LL-type ordinary chondrites. Ordinary chondrite meteorites show two distinct compositional phases, one at albedos similar to S-complex asteroids and one that is darker with muted silicate absorption bands. This darker material has been associated with former surface regolith that had gases implanted by the solar wind and was later relithified and impact-shocked, resulting in a significantly different reflectivity with only a

nominal difference in composition (Britt and Pieters, 1991). Studies of the recent Chelyabinsk meteorite (Kohout *et al.*, 2014; Reddy *et al.*, 2014) further confirm that shock darkening may play a critical role in the evolution of asteroid family spectra (cf. Cellino *et al.*, 2002).

Licandro *et al.* (2012) used the Spitzer Space Telescope to measure mid-infrared spectra for eight members of the Themis family, and determined their albedos and diameters. They were also able to constrain the surface thermal inertia and set limits on the surface composition, showing that family members must have a very low surface density.

Jasmim *et al.* (2013) performed a spectroscopic survey of objects classified as Qp in the SDSS spectrophotometric system in the Vesta family, but were not able to find any significant differences between these objects and canonical V-type asteroid spectra. This highlights the potential ambiguities in spectrophotometric taxonomic classifications, and the need for further spectroscopic follow-up of interesting asteroids to confirm their spectral behavior.

Recently, Vernazza *et al.* (2014) mineralogically analyzed spectra of six S-complex asteroid families and 83 background S-type objects and compared these results to compositions of various ordinary chondrite meteorites. They found a bimodality in their olivine/pyroxene mineral diagnostic for S-type asteroids that traces the compositional gradients measured for metamorphosed meteorites with a range of iron contents. This bimodality also extended to families, with Koronis, Agnia, Merxia, and Gefion more closely matching high-iron ordinary chondrites and Eunomia and Flora matching either low-iron chondrites from the interiors of bodies or ordinary chondrites from the near-surface regions showing little metamorphism. Mineralogical assessment of NIR spectra thus offers a new method of probing the compositions and metamorphic histories of these S-complex families.

### 2.3. Infrared Space Surveys

Recent improvements in mid-infrared detector technology have spurred renewed interest in their use for astronomical observations. Groundbased thermal infrared detectors can obtain data for a small subset of the brightest targets; however, the thermal background prohibits large-scale surveys of smaller asteroids. The space environment, however, is ideal for thermal infrared surveys of the sky, and two recent satellites have obtained all-sky survey data at mid-infrared wavelengths of a large number of asteroids. A more complete discussion of these surveys is presented in the chapter by Mainzer *et al.* in this volume, and so here we only highlight a few relevant aspects.

The AKARI space telescope was launched on February 21, 2006, and surveyed the sky at two thermal infrared wavelengths from May 6, 2006, until the telescope-cooling liquid helium was exhausted on August 28, 2007, covering over 96% of the sky (Murakami *et al.*, 2007; Ishihara *et al.*, 2010). The Asteroid Catalog Using AKARI (AcuA) (Usui *et al.*, 2011, <http://darts.jaxa.jp/ir/akari/catalogue/>

*AcuA.html*) database summarizes the asteroid survey data. Using the standard thermal model (Lebofsky *et al.*, 1986; Lebofsky and Spencer, 1989), diameters and visible albedos were derived for 5120 asteroids.

During the warm mission phase after the cryogen was exhausted, AKARI also performed spectroscopic observations of 70 asteroids, many of which are the largest members of asteroid families. These observations provide unique spectroscopic data covering the wavelength range from 2 to 5  $\mu\text{m}$  (Usui *et al.*, 2011). Kasuga *et al.* (2012) present physical properties of Cybele family members determined from this dataset, and discuss the taxonomic composition of this family by combining spectrally derived taxonomy with infrared photometry.

The Near-Earth Object Wide-field Infrared Survey Explorer (NEOWISE) mission launched on December 14, 2009, and surveyed the entire sky at four infrared wavelengths over the course of its cryogenic mission. The survey continued during its post-cryogenic and reactivated missions at the two shortest wavelengths. The NEOWISE data catalogs and images are publicly archived at the NASA/IPAC Infrared Science Archive (<http://irsa.ipac.caltech.edu/Missions/wise.html>) and contain thermal infrared measurements of more than 150,000 asteroids (Mainzer *et al.*, 2011, 2014). Many of these were identified as members of asteroid families, allowing for the determination of diameter and albedo distributions for an unprecedented number of families.

Masiero *et al.* (2011) presented albedos and diameters for over 120,000 main-belt asteroids, including over 32,000 members of 46 families from Nesvorný (2012). They showed that the albedo distribution within a family is usually very narrow, but some families have significant contamination from background objects or show a mixing of multiple families that overlap in proper-element space. Masiero *et al.* (2013) split the main belt into distinct orbital and albedo components and showed that overlapping families such as Polana and Hertha (aka Nysa) can be easily distinguished.

Masiero *et al.* (2013) used the NEOWISE diameters to measure the size-frequency distribution (SFD) for 76 asteroid families that they identify in their data. The SFD can be computed as  $N \propto D^\alpha$  where  $N$  is the number of objects with diameter greater than  $D$  and  $\alpha$  is the SFD slope. They found that larger families tended to show cumulative SFD slopes that converge toward the value of  $\alpha = -2.5$ , as expected for a collisionally equilibrated population (Dohnanyi, 1969), while smaller families have a wider dispersion. The family associated with (31) Euphrosyne has an anomalously steep SFD slope, which Carruba *et al.* (2014) explain as the result of a dynamical draining of the largest family fragments by the  $v_6$  resonance, which runs through the center of this family in semimajor axis-inclination space.

Ali-Lagoa *et al.* (2013) used the NEOWISE albedo measurements to show that the Pallas family has visible and infrared albedos that are distinct from the majority of B-type asteroids. Masiero *et al.* (2014) presented the 3.4- $\mu\text{m}$  albedo distributions of 13 asteroid families. They found that

the asteroid families form three distinct groupings of albedos at this wavelength. Additionally, the Eos family has unique NIR reflectance properties, which likely traces a mineralogy not seen elsewhere in the main belt.

#### 2.4. Asteroid Light Curves and Phase Curves

Over the last decade, a number of groups have carried out surveys of asteroid light curves, many focusing on the properties of specific families. Light curve analysis from a single epoch can provide rotation periods and constraints on amplitude, while multi-epoch observations can allow for rotational pole determination, shape model fitting, searches for binarity, and detection of non-principal-axis rotation. The binary fraction is an important test of formation mechanisms, while pole determination for a significant number of family members allows for constraints on Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) evolution of family spin states.

One of the key results from these lightcurve studies has been the confirmation of the YORP effect on spin poles of objects with similar ages (*Vokrouhlický et al.*, 2003). The YORP mechanism results from asymmetries in the thermal reemission of absorbed light, creating a torque on the asteroid. This can alter the rotation rate of these objects, but is also predicted to rapidly reorient the spin poles of most small objects to be perpendicular to the body's orbital plane. This will result in spin poles clustered near 0° and 180° from the orbital pole, and a spin rate distribution differing from the Maxwellian distribution that is expected for a collisionally equilibrated system. *Slivan et al.* (2003, 2008, 2009) measured light curves for 30 members of the Koronis family, showing a strongly anisotropic distribution of spin poles and a non-Maxwellian rotation rate distribution, both consistent with YORP-induced rotation changes.

Surveys of other families have come to similar conclusions: *Warner et al.* (2009) surveyed the Hungaria family asteroids and determined rotation properties for over 100 of these objects. They find a significant excess of slow rotators, which they attribute to YORP-induced spindown, as well as a binarity fraction of 15%, similar to the near-Earth asteroid (NEA) population. *Kryszczyńska et al.* (2012) surveyed 55 objects in the Flora family to determine their rotation periods and poles. They found that the Flora family rotation rates are non-Maxwellian, as is expected from long-term YORP evolution. *Kim et al.* (2014) determined rotation properties for 57 Maria family members, finding an excess of prograde rotation states consistent with the predictions of YORP and Yarkovsky evolution resulting in retrograde rotators moving into the 3:1 Jupiter resonance and being removed from the family.

*Hanuš et al.* (2011, 2013) used shape models derived from light curve inversion to study the spin pole positions of 10 asteroid families. They found a clear distinction in spin pole direction, where objects at semimajor axes smaller than the largest remnant have retrograde rotations while objects at larger semimajor axes have prograde rotations, as is expected from a system evolving under the Yarkovsky effect.

Using the large amount of photometric data available from the Minor Planet Center and the AstOrb database maintained by Lowell Observatory, *Oszkiewicz et al.* (2011, 2012) rederived the photometric phase functions of all known asteroids, applying the improved H<sub>G1</sub>, G<sub>2</sub> and H<sub>G12</sub> phase equations. They find that asteroid families show statistically similar phase slope parameters and that the major taxonomic complexes can be statistically differentiated. However, these distributions overlap, significantly limiting the use of phase curve parameters for direct family or taxonomy identification. *Bowell et al.* (2014) searched the Lowell data for statistical anisotropies in the ecliptic longitude distribution of rotation poles for asteroid family members. They show that the four largest groups considered (the Flora, Vesta, and Koronis families, and the Nysa-Polana complex) have anisotropic spin longitude distributions showing an excess in the 30°–110° longitude range and a dearth in the 120°–160° longitude range, consistent with the distribution seen for the main belt as a whole. The authors suggest this may be due to pole reorientation by the YORP effect, but that extensive modeling is required as well as consideration of potential selection biases.

#### 2.5. Polarimetric Surveys of Families

Measurement of the polarization of light scattered off the surface of an atmosphereless body as a function of phase angle can be used as an independent constraint on the object's albedo (*Cellino et al.*, 1999). Although the magnitude range accessible to polarimetric observations is comparable to that of NIR spectroscopy, multiple nights are required for each object to constrain the phase behavior and there are fewer available imaging polarimeters that are well-calibrated than NIR spectrometers. As such, there are fewer asteroids with measured polarimetric properties; however, polarimetric studies provide unique data on asteroid surface properties that can be important for disentangling ambiguities in other characterization surveys.

*Cellino et al.* (2010) polarimetrically surveyed the Karin and Koronis families as an independent test of the effect of space weathering on asteroid albedo. They find no significant differences between the albedos of Karin and Koronis, implying that space weathering must act on timescales shorter than the ~6-m.y. age of the Karin family.

*Cellino et al.* (2014) conducted a survey of the linear polarization phase curves of Watsonia asteroid family members, searching for analogs to the unusual polarization of (234) Barbara. Barbara and the related "Barbarian" objects have unusual polarimetric properties indicative of unique surface mineralogy and are taxonomically identified as Ld-type objects from spectra. They found that seven of the nine objects surveyed show indications of a surface rich in spinel, one of the oldest minerals in the solar system (*Burbine et al.*, 1992). This implies that the Watsonia parent object has undergone little to no mineralogical processing since the formation of the first solids in the protosolar disk

(Sunshine *et al.*, 2008), and may have been one of the oldest unprocessed bodies in the solar system.

### 3. COLOR, SPECTRA, ALBEDO, AND SIZE DISTRIBUTIONS OF FAMILIES

With the wealth of asteroid physical observations now available, we can determine the average characteristic properties for families. As the literature contains many different collections of family lists, here we focus on the consolidated list presented in the chapter by Nesvorný *et al.* in this volume. This improves our sensitivity to subtle physical differences between families, especially the biggest families, where the large sample size can greatly reduce the scatter in measured properties among individual members. We can also use these data to reject outlier objects from family lists, particularly when the family of interest is of distinct composition from other nearby families or the majority of background objects. Here we discuss some of the recent applications of the new physical property data that has become available.

#### 3.1. Homogeneity of Families and Use of Physical Properties to Distinguish Outliers

Family-forming collisions are expected to liberate material from a large fraction of the parent body's volume. Many of the resulting family members are likely to be accumulations of smaller ejecta, potentially from a range of lithologies within the parent (see the chapter by Michel *et al.* in this volume). For a heterogeneous parent body, we would expect to see a range of colors, spectra, and albedos among the resultant family members, while a homogeneous parent would instead produce a family with very narrow distributions of these properties. While it is possible that the family formed from an impact on a homogeneous parent by an impactor of a different composition could show heterogeneity, statistically the mass of any probable impactor will only be a small fraction of the mass of either the parent or the ejecta, and so would be unlikely to be a significant contaminant to globally averaged properties obtained from remote sensing. Subfamilies resulting from second-generation impacts could also show subtle property differences compared to the original family due to the reset of any space-weathering processes, but this would be most obvious only for very young families (e.g., Karin).

Early surveys of asteroid family spectra and colors indicated that with the exception of a handful of outliers (e.g., the Nysa-Polana complex), families had narrow distributions of physical properties, indicative of homogeneous parent bodies (see Cellino *et al.*, 2002, and references therein). This enabled the extrapolation of measured physical properties for a handful of family members to the entire family. As many of the largest remnants of family formation had been studied for decades, this became a boon to family research.

However, with the availability of physical property data for large numbers of family members, we can now use this

data to remove interloper objects from family lists when they have a different color, albedo, or spectrum from the bulk of the family. Refining family lists in this way is particularly important for improving the accuracy of age-dating techniques. In the past few years, a number of research groups have been actively using these data to this end, in an effort to better understand the formation and evolution of families and the parent bodies from which they came (e.g., Novaković *et al.*, 2011; Brož *et al.*, 2013; Masiero *et al.*, 2013; Carruba, 2013; Walsh *et al.*, 2013; Carruba *et al.*, 2013; Hanuš *et al.*, 2013; Milani *et al.*, 2014).

#### 3.2. Combined Properties of Individual Families

Using the various datasets presented above, we provide in Table 1 the average SDSS colors, average optical and NIR albedos, majority taxonomic type, and SFD slopes (as well as the diameter range that the SFD was fit to) for the families given in the chapter by Nesvorný *et al.* in this volume. We also present a visualization of the average albedo, SDSS colors, and spectra for families with sufficient data in Fig. 1. While mean values are often useful for extrapolating properties of family members that were not observed, or for comparing families to each other or other ground-truth data, there are important caveats that cannot be ignored. Sample size considerations and the uncertainty about individual measurements are the most critical of these caveats: Average values based on a small number of objects or even a single object should be considered potentially spurious, and treated as such. We include those values here for completeness.

Visible albedo mean values were derived by fitting a Gaussian to the distribution of all measured log  $p_V$  values, following the technique Masiero *et al.* (2011) applied to the NEOWISE data, and the quoted error gives the width of the observed distribution. The uncertainty on the mean value, when comparing mean albedos of various families, will be the measured Gaussian width over the square root of the sample size; thus for large families the mean albedos can be known quite accurately, even if individuals have large uncertainties. Family NIR albedo values are a median of the 3.4- $\mu\text{m}$  albedos given in Masiero *et al.* (2014).

Size-frequency distributions were computed for all families with more than 100 measured diameters from all infrared surveys and were found by fitting a power law to the cumulative size distribution, using only those bins with more than five objects (to reduce the influence of the large remnants) and less than half the total sample (to minimize the effects of incomplete diameter sampling at small sizes). Tabulated SDSS colors were calculated by performing an error-weighted mean of all observations having  $\text{SNR} > 10$  in the g, r, i, and z bands used to calculate  $a^*$  and  $i-z$ . Family taxonomy is given only for cases in which a majority of family members with taxonomic classes had the same class. If no subclass (e.g., Ch, Sq, Ld) had a majority, but a majority of members were in the same complex, that complex is listed (e.g., C, S, L). For each of these parameters we include the number of objects used to compute the listed value.

Although we implicitly assume that the variation in observed properties is a result of statistical uncertainties and that all family members should have the same physical properties, this is not necessarily true. Outlier objects may be statistical flukes, or background contamination, but they may just as easily be interesting pieces of the parent body warranting further study, a determination that cannot be made or captured here. Additionally, a single mean value ignores any size-dependent effects in the data, either real or imposed by detection or sample-selection biases.

Only a proper debiasing of each survey accounting for observing geometry, detector sensitivity, and detection efficiency can determine the true value for each parameter. This is particularly important for cases of mismatched sensitivities, such as the SDSS r vs. z magnitudes needed for colors or the NEOWISE W3 flux vs. groundbased H<sub>V</sub> magnitude needed for albedo determination; only objects seen in both datasets will have a measured value that strongly biases the outcome as a function of apparent brightness. Thus Table 1 is meant as a overarching guide, but caution is mandated for any interpretation of values or trends.

A number of low-albedo families can only be identified when the low-albedo population of the main belt is considered independently. This is due to the bias toward discovery of high-albedo objects by groundbased visible-light surveys. As the population of high-albedo asteroids is probed to smaller sizes (and thus larger numbers), these families will overwhelm traditional HCM techniques, particularly the calculation of the quasi-random level needed to assess the reality of a given family, making low-albedo families harder to identify. *Masiero et al.* (2013) circumvented this by considering each albedo component separately, and by restricting their sample to objects detected in the thermal infrared, which is albedo-independent (see the chapter by Mainzer et al. in this volume for further discussion). As the sample of known asteroids continues to increase, development of new techniques for the identification of asteroid families from the background population (e.g., *Milani et al.*, 2014) will increase in importance.

Below we discuss individual families that merit specific mention based on recent research. We include the Planetary Data System (PDS) ID number from *Nesvorný et al.* (2012)

**Fig. 1.** Average solar-corrected SDSS colors (points) and sample optical/NIR spectra (from SMASS) for all asteroid families listed in Table 1 with sufficient data. Plots are scaled such that the interpolated reflectance at 0.55 μm equals the average visible geometric albedo ( $p_V$ ) for the family from all infrared surveys. The “N” in the bottom right of each plot indicates the number of SDSS observations used, and taxonomic class is given when available. Note the reflectance scale in each plot is different.

both below and in Table 1 for easier association with other work and with the family dynamical properties given in the chapter by Nesvorný et al. in this volume.

**3.2.1. Hungaria.** The Hungaria asteroid family (PDS ID 003) occupies a region of space interior to the rest of the main belt and with an orbital inclination above the  $v_6$  secular resonance. This region is an island of stability between the major resonances that dominate this area of the solar system, and likely samples a unique region of the protoplanetary disk (Bottke et al., 2012). Warner et al. (2009) analyzed light curves of 129 Hungaria asteroids, finding a significant excess of very slow rotating bodies. They also showed that the binary fraction of this population is  $\sim 15\%$ , comparable to the fraction seen in the NEO population.

The albedos for Hungaria family members derived from the NEOWISE data by Masiero et al. (2011) have values significantly larger than  $p_V > 0.5$ ; however, this is an artifact of bad absolute magnitude fits for these objects in orbital element databases, which when corrected bring the best-fit albedo values to the range of  $0.4 < p_V < 0.5$  (B. Warner, personal communication). Spectroscopic and SDSS color studies of the Hungaria family show the classification to be X-type, which when combined with the very high albedos translates to an E-type classification (Carvano et al., 2001; Assandri and Gil-Hutton, 2008; Warner et al., 2009). Polarimetric observations by Gil-Hutton et al. (2007) of the overall Hungaria region indicate inconsistencies in the polarimetric behavior of asteroids in and around the Hungaria family.

**3.2.2. Flora.** The Flora family (PDS ID 401) is a large S-type family residing in the inner main belt. The largest remnant, (8) Flora, has an orbit just exterior to the  $v_6$  resonance, and only the half of the family at larger semimajor axes is seen today. The  $v_6$  resonance is particularly good at implanting asteroids into the NEO population (Bottke et al., 2000), meaning that Flora family members are likely well represented in the NEO population and meteorite collections. Recent spectroscopic observations of Flora family members have been combined with analyses of meteorite samples to link the LL chondrite meteorites to the Flora family (Vernazza et al., 2008; de Leon et al., 2010; Dunn et al., 2013). This provides an important ground-truth analog for interpreting physical properties of S-type objects in the main belt and near-Earth populations. We note that in contrast to previous analyses, Milani et al. (2014) did not identify a family associated with Flora, instead finding that candidate member asteroids merged with the Vesta and Massalia families, or are potentially part of their newly identified Levin family. However, the Vesta family has a distinct i-z color that is not shown by Flora family members (see Table 1), making these populations easily distinguished by their photometric properties. While the Flora and Massalia populations overall have properties that are consistent within uncertainties, the difference between the mean albedos of these two populations suggests they in fact are different populations.

**3.2.3. Baptistina.** Over the past decade, the Baptistina family (PDS ID 403) has been the focus of a number of investigations, leading to controversy over the physical char-

acteristics of these asteroids. Initial investigations assumed the family had characteristics similar to C-type asteroids (e.g., low albedo) based on spectra of the largest member, (298) Baptistina (Bottke et al., 2007). This was used in numerical simulations to show that Baptistina was a probable source of the K/T impactor. Further spectral investigations of a 16 large family members found compositions more analogous to LL chondrites, ruling out a C-type association (Reddy et al., 2011). However, a major difficulty in studying this family is the significant overlap in orbital element-space with the much larger Flora family [or with the Levin family, according to Milani et al. (2014)], making it difficult to ensure that the spectral studies were probing Baptistina and not Flora. Using albedos to separate these families finds a mean albedo of  $p_V = 0.16$ , which is not consistent with either C-type or LL-chondrite compositions (Masiero et al., 2013). Recent analysis of the Chelyabinsk meteorite samples showed that shock darkening of chondritic material could produce an albedo consistent with the Baptistina family without altering the composition (Reddy et al., 2014), offering a potential solution to the seemingly contradictory information about this family, but future work will be necessary to confirm this hypothesis.

**3.2.4. "Nysa-Polana."** In the years leading up to *Asteroids III* it had become increasingly clear that Nysa-Polana, interpreted as a single entity, was likely to be a short-lived phenomenon. Cellino et al. (2001) presented a spectroscopic study of 22 asteroids associated with the group, and found that the group was best understood as two compositionally distinct families partly overlapping in orbital-element space, one associated with the F class in the Tholen taxonomy and one with the S class, while (44) Nysa was compositionally distinct and potentially not associated with either family.

Masiero et al. (2011) showed that the albedo distribution of the  $\sim 3000$  asteroids identified as part of the Nysa-Polana complex were strongly bimodal, unlike the majority of families. Although overlapping in semimajor axis-inclination space, the high- and low-albedo components occupy distinct regions of semimajor axis-eccentricity space, supporting the theory that they are two distinct populations coincidentally overlapping as opposed to a single parent body that was composed of two distinct mineralogies.

Using albedo as a discriminant, Masiero et al. (2013) were able to uniquely identify two separate families, a low-albedo one associated with (142) Polana, and a high-albedo one associated with (135) Hertha (PDS ID 405), while (44) Nysa no longer linked to either family. In Table 1 we continue to refer to the high-albedo family as "Nysa" despite the evidence to the contrary, for consistency with other literature. Walsh et al. (2013) expanded on this, and used the family albedos to reject objects with S-type physical properties and focus on the low-albedo component of the Nysa-Polana group. Using dynamical constraints, they were able to further subdivide the low-albedo component of this group into two distinct families, which they identify as the Eulalia family and the "new Polana" family. They estimate ages for each of these families of 0.9–1.5 b.y. and  $> 2$  b.y.,

respectively. Conversely, *Milani et al.* (2014) identify the whole complex as associated with Hertha and split this region into two components by combining dynamics and physical properties, which they identify as the Polana and Burdett families (low and high albedo, respectively).

**3.2.5. Vesta.** The Vesta asteroid family (PDS ID 401) has historically been one of the most well-studied families, due to its clear association with one of the largest known asteroids, the high albedos and locations in the inner main belt making members favorable for groundbased observations, and association with the howardite-eucrite-diogenite (HED) meteorites leading to the interpretation of (4) Vesta as a differentiated parent body (*McCord et al.*, 1970; *Zappala et al.*, 1990; *Binzel and Xu*, 1993; *Consolmagno and Drake*, 1977; *Moskovitz et al.*, 2010; *Mayne et al.*, 2011). With the recent visit of the Dawn spacecraft to (4) Vesta (see the chapter by Russell et al. in this volume), ground-truth data can be compared to remote-sensing observations of family members. Additionally, constraints on the ages of the major impact basins of  $1.0 \pm 0.2$  b.y. for Rheasilvia and  $2.1 \pm 0.2$  b.y. years for Veneneia (*Schenk et al.*, 2012) set strong constraints on the possible age of Vesta family members. *Milani et al.* (2014) find that the Vesta family splits into two subgroups in their analysis, which they attribute to these two events.

The Vesta family has a unique mineralogical composition in the main belt, making it easily distinguishable in color-, albedo-, or spectral-space. In particular, members stand out from all other asteroids in terms of their high albedo, low i-z color, and deep 1- $\mu\text{m}$  and 2- $\mu\text{m}$  absorption bands. This has prompted searches for objects with similar properties at more distant locations in the main belt (e.g., *Moskovitz et al.*, 2008; *Duffard and Roig*, 2009; *Moskovitz et al.*, 2010; *Solontoi et al.*, 2012). These bodies could only have evolved from the Vesta family via a low-probability series of secular resonances (*Carruba et al.*, 2005; *Roig et al.*, 2008a), and may be indicative of other parent bodies that were differentiated. To date only a few candidate objects from these searches have been confirmed to be V-type, indicating that the collisional remnants of the other differentiated objects that must have formed in the early solar system has likely been dynamically erased.

**3.2.6. Eunomia.** The Eunomia family (PDS ID 502) is an old, S-type family located in the middle main belt. Spectral evidence presented by *Lazzaro et al.* (1999) indicates that the Eunomia family may have originated from a partially differentiated parent body. *Natheus et al.* (2005) and *Nathues* (2010) investigated the physical properties of the Eunomia largest remnant and 97 smaller family members as a probe of the composition and differentiation history of the original parent body. They found that the largest remnant shows two hemispheres with slightly different compositions that support an interpretation of the impact causing significant crust loss and some mantle loss on a partially differentiated core. *Milani et al.* (2014) found two subfamilies within Eunomia, which they attribute to separate cratering events.

**3.2.7. Eos.** The Eos family (PDS ID 606) represents the primary reservoir of K-type asteroids in the main belt,

and can easily be identified by their 3.4- $\mu\text{m}$  albedo (*Masiero et al.*, 2014). This spectral class has been proposed as the asteroidal analog of the CO and CV carbonaceous chondrite meteorites (*Bell et al.*, 1988; *Doressoundiram et al.*, 1998; *Clark et al.*, 2009). This would imply that the Eos family is one of the best-sampled collisional families in our meteorite collection, and would mean that many of these samples do not probe the C-complex asteroids as had frequently been assumed.

*Mothé-Diniz and Carvano* (2005) compared spectra of (221) Eos with meteorite samples and inferred that the Eos parent body likely underwent partial differentiation. *Mothé-Diniz et al.* (2008) extended this work to 30 Eos family members and found mineral compositions consistent with forsteritic olivine consistent with a history of differentiation or a composition similar to CK-type meteorites. However, *Masiero et al.* (2014) instead interpret the surface properties as consistent with shock darkening of silicates (cf. *Britt and Pieters*, 1994, *Reddy et al.*, 2014). Future work will enable us to resolve the ambiguity in the composition of these objects. The Eos family represents one of the key fronts of advancing our understanding of family formation that has been opened by our wealth of new data.

**3.2.8. Themis.** The Themis family (PDS ID 602) is one of the largest low-albedo families in the main belt. The majority of Themis family members are classified as C-complex bodies (*Mothé-Diniz et al.*, 2005; *Ziffer et al.*, 2011). Spectral surveys have found variations in the spectral slope among Themis members, ranging from neutral to moderately red (*Ziffer et al.*, 2011; *de Leon et al.*, 2012). As the first asteroid discovered to show cometary activity (133P Elst-Pizarro) is dynamically associated with Themis, *Hsieh and Jewitt* (2006) searched 150 other Themis family members for signs of cometary activity, discovering one additional object: (118401) 1999 RE<sub>70</sub>. The periodic nature of this activity points to volatile sublimation as the probable cause, as opposed to collisions or YORP spinup (see the chapter by Jewitt et al. in this volume), meaning that the Themis family members, and (24) Themis itself, likely harbor subsurface ice. Further, *Rivkin and Emery* (2010) and *Campins et al.* (2010) reported evidence of water ice features on the surface of (24) Themis. If this icy material was primordial to the Themis parent and not implanted by a later impact, this would set constraints on where the Themis parent formed relative to the “snow line” in the protosolar nebula. These objects are also likely to be a new reservoir of water, and may have contributed to the volatile content of the early Earth.

**3.2.9. Sylvia.** The Sylvia family (PDS ID 603) in the Cybele region resides at the outer edge of the main belt [ $3.27 < a \leq 3.70$  AU (*Zellner et al.*, 1985b)], beyond the 2:1 Jupiter mean-motion resonance. These asteroids, along with the objects in the Hilda and Jupiter Trojan populations, likely have limited contamination by materials from the inner solar system, and represent a pristine view of the materials present near Jupiter at the end of planetary migration. The Nice model proposed that these asteroids are transneptunian

objects (TNOs) that were scattered inward during the chaotic phase of planetary evolution (Levison *et al.*, 2009); however, the Cybeles show different spectral characteristics from the Hildas and Trojans, and thus may represent the material native to this region of the solar system.

Kasuga *et al.* (2012) studied the size- and albedo-distributions of the Sylvia asteroid family to better understand the history of these bodies. They found that the largest Cybeles ( $D > 80$  km) are predominantly C- or P-types, and the best-fit power law to the size distribution is consistent with a catastrophic collision. However, the estimated mass and size of the parent body lead to collisional timescales larger than the age of the solar system, assuming an equilibrium collisional cascade. These are comparable to the timescales for the Hildas, although they find that the Trojan population is consistent with collisional origin. Numerical simulations of the collisional formation and dynamical evolution of the Cybeles will allow for a more detailed study of the history of this population.

### 3.3. Relationship Between Albedo and Color

Almost every major taxonomic class of asteroid is represented in the list of asteroid families. Using the physical property data described above, we can investigate relationships between the averaged physical properties for each family. By nature of the large sample sizes, the SDSS colors and optical albedos are the best-determined parameters for the majority of families. Figure 2 shows the composite  $a^*$  and  $i-z$  colors derived for each family from SDSS compared to the composite optical albedo as determined via thermal radiometry. There is a clear linear correlation between the SDSS  $a^*$  color and the log of the albedo, although with significant scatter. The  $i-z$  color is approximately flat for low and moderate albedos, but decreases noticeably for high-albedo families. It is important to again note that these data are subject to

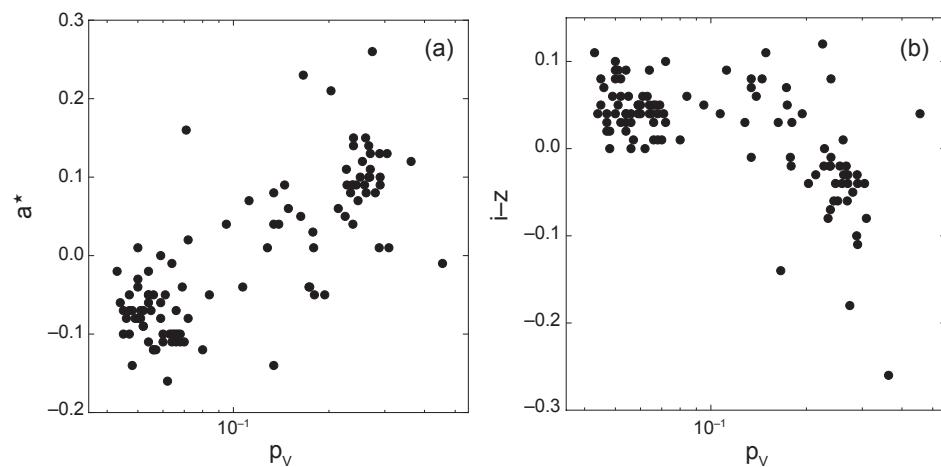

observational selection and completeness biases, and so these relations should be interpreted with caution.

## 4. DISCUSSION

### 4.1. Correlation of Observed Properties with the Primordial Composition of the Main Belt

When considering the distributions of colors and albedos, asteroid families fall into one of only a small number of groupings. The Hungaria, Vesta, and Eos families have unique properties that distinguish them from all other families. Similarly, the Watsonia family shows unique polarimetric properties. While the properties of these families can be used to efficiently identify family members and mineral analogs, it is more difficult to relate the mineralogy and history of these families to that of the currently observed main belt as a whole [although they may be good analogs for now-extinct populations (cf. Bottke *et al.*, 2012)].

Conversely, almost all other families fall into either the S-complex or the C-complex, both of which can be further subdivided by spectral taxonomic properties. Given the number of different parent bodies with these compositions, it has been inferred that these two complexes are probes of the pristine material from the protoplanetary disk in this region of the solar system. However, studies of the evolution of the giant planets in the early solar system call into question the specific locations from which these bodies originated (e.g., Gomes *et al.*, 2005). One possible scenario, known as the “Grand Tack” (Walsh *et al.*, 2012), postulates that the protoplanetary core of Jupiter migrated through the planetesimal disk, evacuating the main-belt region of its primordial material and repopulating it with material from both inward and outward in the disk (see the chapter by Morbidelli *et al.* in this volume). In this case, the two different compositional complexes would represent these implanted objects. Further

**Fig. 2.** Average SDSS  $a^*$  and  $i-z$  colors compared with optical albedos (logarithmically scaled) for asteroid families, as given in Table 1.

study of the physical properties of asteroid families and the other small-body populations of the solar system will allow us to test this theory.

#### 4.2. Properties of Observed Families Contrasted with the Background Population

Using computed  $a^*$  colors from the SDSS MOC 4, *Parker et al.* (2008) divided asteroid families into blue and red groups, tracing the C and S taxonomic complexes, respectively. For both groups, they found that family membership as a fraction of total population increased with decreasing brightness from  $\sim 20\%$  at  $H_V = 9$  to  $\sim 50\%$  at  $H_V = 11$ . For objects with absolute magnitudes of  $H > 11$  the fractions of blue and red asteroids in families diverge, with blue objects in families making up a smaller fraction of the total population while red objects stay at the levels seen at brighter magnitudes; however, it is unclear what contribution the survey biases have to these observed differences. If this difference in behavior is indeed a physical effect, it may indicate a difference in internal structure or collisional processing rates between the two populations.

When exploring the taxonomic distribution of asteroids as a function of distance from the Sun, families have been problematic because the large number of homogeneous objects concentrated in small regions of orbital-element space can skew the results. Studies of the overall distributions of physical properties therefore typically use only the largest member of the family, removing the smaller members (e.g., *Mothé-Diniz et al.*, 2003). Alternatively, the distribution could be explored by volume or mass, in which case all family members may be included because their individual volumes or masses contribute to the whole (e.g., *DeMeo and Carry*, 2013).

A comprehensive study of the taxonomic contribution of families to the population of small asteroids has not yet been undertaken; however, disentangling families from the background is critical to correctly interpreting an overall picture of the compositional makeup of the asteroid belt and how the asteroid belt and the bodies within it formed. Distinguishing between families and the background becomes increasingly difficult at smaller sizes where orbital parameters have evolved further due to gravitational and nongravitational forces. Even the background itself is likely composed of many small families forming from small parent bodies (*Morbidelli et al.*, 2003).

#### 4.3. Families as Feeders for the Near-Earth Object Population

The Yarkovsky and YORP nongravitational effects play a critical role in repopulating the NEOs with small bodies from the main belt (*Bottke et al.*, 2000). Primordial asteroids with diameters of  $\sim 100$  m should be efficiently mobilized from their formation locations into a gravitational resonance over the age of the solar system, limiting the contribution of these objects to the currently observed NEO population.

However, family-formation events act as an important source of objects in this size regime, injecting many thousands of small asteroids into the main belt with each impact (*Durda et al.*, 2007). The complete census of family physical properties, combined with better estimates for family ages that can now be made, enable us to trace the history of specific NEAs from their formation in the main belt to their present-day orbits. For the same reasons, recently fallen meteorites are also good candidates for comparisons to asteroid families, but the differences between the surface properties we can observe on asteroids and the atmosphere-selected materials surviving to the ground complicate this picture.

#### 4.4. Families Beyond the Main Belt

Although the vast majority of known asteroid families are in the main belt, massive collisions resulting in family-formation events are not unique to this region of the solar system. While the NEA population is dynamically young (*Gladman et al.*, 2000) and thus these objects have a low probability of undergoing collisional breakup, the more-distant reservoirs that date back to the beginning of the solar system are expected to undergo the same collisional processing as the main belt, albeit with lower impact velocities. Searches for young families in both the NEO and Mars Trojan populations have yielded only a single candidate family cluster associated with (5261) Eureka (*Schunová et al.*, 2012; *Christou*, 2013). Dynamical families have been identified in the Hilda, Jupiter Trojan, and TNO populations. The first two populations are trapped in long-term stable resonant orbits with Jupiter, providing a population that has suffered far less dispersion than the majority of main-belt families. Similarly, the TNO population is cross-cut by a range of Neptune resonances, some of which are similarly stable long term. The Yarkovsky and YORP effects are greatly diminished for all three populations compared to the main belt (especially the TNOs) due to the larger distances from the Sun, further reducing the dispersion of collisional fragments.

*Grav et al.* (2012) present visible and infrared albedos for the Hilda and Schubart asteroid families found in the 3:2 Jupiter mean-motion resonance. Using these albedos, they show the Hilda family is associated with D-type taxonomy, while the Schubart family is associated with C- or P-type taxonomy. The Hilda population in general is dominated by C- and P-type objects at the largest sizes, but transitions to primarily D-class at the smallest sizes measured, which may be indicative of the effect of the Hilda family on the overall population (*Grav et al.*, 2012; *DeMeo and Carry*, 2014). However, we note that recent family analysis by *Milani et al.* (2014) showed that the Hilda family was not statistically significant using their methodology, in contrast to previous work.

The Jupiter Trojans comprise the L4 and L5 Lagrange point swarms that lead and trail Jupiter (respectively) on its orbit. Multiple families have been identified in each of the swarms (*Milani*, 1993; *Beaugá and Roig*, 2001), but there is some debate as to the significance of these families

(cf. Brož and Rozehnal, 2011). Fornasier et al. (2007) combined measured spectra from multiple sources (Fornasier et al., 2004; Dotto et al., 2006) to characterize Trojan family members. In the L5 cloud, members of the Aneas, Anchises, Misenus, Phereclos, Sarpedon, and Panthoos families were found to have spectra with moderate-to-high spectral slopes, with most members being classified as D-type. The background population had a wider range of slopes and taxonomies from P- to D-type (Fornasier et al., 2004).

In the L4 cloud members of the Eurybates, 1986 WD and 1986 TS<sub>6</sub> families were studied. The 1986 WD and 1986 TS<sub>6</sub> family members had featureless spectra and high slopes resulting in a classification for most as D-types, while the few with lower slopes were placed in the C- and P-classes. Eurybates members, however, have markedly different spectra with low to moderate slopes splitting the classifications evenly between the C- or P-classes (Fornasier et al., 2007; De Luise et al., 2010). Roig et al. (2008b) used the SDSS data to investigate asteroid families in the Jupiter Trojan population, and found that the families in the Trojan populations account for the differences in the compositional distributions between the L4 and L5 clouds. In particular, the families in the L4 cloud show an abundance of C- and P-type objects not reflected in the L5 families or the background populations in either cloud.

The TNO population covers a much larger volume of space than any of the populations of objects closer to the Sun, but is also estimated to contain over  $1000\times$  the mass of the main belt. Collisions resulting in catastrophic disruptions are believed to have occurred at least twice in the TNO population. Pluto's five [or potentially more (Weaver et al., 2006)] satellites speak to a massive collision, which will be a key area of investigation of the New Horizons flyby of the Pluto system.

The dwarf planet Haumea is highly elongated with a very short rotational period ( $\sim 4$  h), is orbited by two small satellites, has a relatively high density, and has a spectrum that is consistent with nearly pure water ice. These properties are thought to be the result of a mantle-shattering collisional event, although the details of this event remain contentious. A group of TNOs with colors substantially bluer than the typical neutral-to-ultrared surfaces of the Kuiper belt, all sharing high inclinations similar to Haumea, has been identified as a collisional family produced by this event (Brown et al., 2007). Because of the orbital velocity regimes in transneptunian space, collisional families are in general unlikely to be identified there through dynamics alone (as they are in the asteroid belt). It was only through the unique composition of the family members (akin to the extremely distinct photometric properties of the Vesta family members) that the Haumea family could be readily identified. This implies that more collisional families may be hiding in the TNO population, but cannot be spotted by orbits alone.

Although massive collisions dominated the solar system environment during the epoch of planet building, they also played an important role in shaping all the major populations of small bodies during the subsequent  $\sim 4$  b.y. Collisional

evolution, although stochastic in nature, was a major determinant in the structure of the solar system we see today (see the chapter by Bottke et al. in this volume).

## 5. OPEN PROBLEMS AND FUTURE PROSPECTS

The effect of space weathering on asteroidal surfaces still remains an important topic for future exploration (see the chapter by Brunetto et al. in this volume for further discussion). The range of studies carried out so far have found a wide dispersion of results, both in terms of the timescale of weathering and the specific effects on various taxonomic classes. Studies to date have relied on the assumption that all asteroids with similar taxonomic types have identical mineralogical compositions, or have been based on a single pair of families known to be compositionally identical but with different ages (i.e., Karin and Koronis). As deeper surveys and dynamical analysis techniques begin to increase the number of identified cases of family-within-a-family, physical studies of these interesting populations will allow better measurements of the specific effects and timing of space-weathering processes.

Advances in physical measurements of asteroid families have not uniformly addressed the various parameters needed for a robust scientific investigation. In particular, there has been only a nominal advancement in the measurement of asteroid masses and densities, owing to the difficulty in determining these parameters. Carry (2012) compiled known measurements of asteroid densities into a comprehensive list; however, only a handful of families have more than one member represented, and for most the only measurement is of the largest remnant body. A larger survey of densities including many family members over a range of sizes would enable testing of family formation conditions via reaccretion (cf. the chapter by Michel et al. in this volume), as well as improve family ages derived from numerical simulations of gravitational and Yarkovsky orbital evolution (cf. the chapter by Nesvorný et al. in this volume). This could be accomplished by a more comprehensive search for binaries, or through modeling of gravitational perturbations to asteroid orbits detectable in next-generation astrometric catalogs.

One highly anticipated survey will be carried out by the European Space Agency's (ESA) Gaia mission (Hestroffer et al., 2010), which is expected to provide spectral characterization of all objects down to an apparent magnitude of  $V = 20$ , including many asteroid family members (Campins et al., 2012; Delbó et al., 2012; Cellino and Dell'Oro, 2012). This dramatic increase in the number of characterized family members will enable a host of new investigations of the composition and differentiation of family parent bodies. By spectrally probing bodies as small as  $\sim 2$  km, inhomogeneities in asteroid family composition may begin to be revealed. Another key scientific product will be refined astrometry for all asteroids, which can be searched for gravitational perturbations and used to determine the masses of the largest asteroids (Mignard et al., 2007). This wealth

of new data will feed into theoretical models and numerical simulations, allowing us to improve the ages determined from orbital evolution simulations (e.g., *Masiero et al.*, 2012; *Carruba et al.*, 2014).

The collision events that form families are very rare, and the probability of a massive collision in the next 10, 100, or 1000 years is vanishingly small (see the chapter by Bottke et al. in this volume). However, a new class of active main-belt objects has recently been identified that may nonetheless provide a window into the collisional environment of the solar system (see the chapter by Jewitt et al. in this volume for further discussion). While some of these objects show repeated activity indicative of a cometary nature complete with subsurface volatiles, others are best explained by impact events. In particular, the observed outburst events of P/2010 A2 (*Jewitt et al.*, 2010) and (596) Scheila (*Jewitt et al.*, 2011) are consistent with impacts by very small ( $D < 50$  m) asteroids. As current and future sky surveys probe to smaller diameters in the main belt, the frequency at which these events will be observed, or even predicted in advance, will increase. Study of these small-scale disruptions offers an important constraint on impact physics in the low-gravity environment of asteroids, and provides test cases for comparing to the small-scale impact experiments that can be performed in Earth-based laboratories.

Recently, *Reddy et al.* (2014) presented evidence that shock darkening may play a role in altering the spectroscopic properties of chondritic materials in the Baptistina and Flora families. If evidence for this effect is seen in other families across a range of compositions, this technique may provide a method for determining the conditions of family-forming impacts in the main belt, and thus provide better constraints on the ages of families. This may also help explain some of the differences observed in space-weathering studies that find albedo changes happen very quickly while spectral changes have long timescales.

As new datasets have rapidly increased our ability to characterize asteroid family members, and through this the parent body from which they originated, one glaring question remains at the forefront of the field: Where are the families of differentiated parent bodies that were completely disrupted? Vesta and its family members have given us a excellent example of the composition and resultant albedo, color, and spectral properties of the crust of a differentiated body (see the chapter by Russell et al. in this volume for further discussion). However, searches for objects with similar properties in different regions of the main belt have yielded no significant populations of these basaltic crust and mantle fragments that should be left over from these collisions. On the other hand, data from iron meteorites has indicated that differentiation of protoplanets, if not common, at a minimum happened multiple times (see the chapters by Scheinberg et al. and Scott et al. in this volume for further discussion). While it is possible that these collisions happened at the earliest stages of the solar system's formation and the evidence (in the form of families) was erased during the epoch of giant planet migration — the foundation

of the “Nice” model (see the chapter by Morbidelli et al. in this volume) — a dynamical explanation of this problem would need to preserve in the main belt the core material that still falls to Earth today. Conversely, if these impacts happened after the last great breakup of the solar system, a mineralogical explanation for how metallic cores could form without leaving a basaltic “residue” in the main belt is required. The limitations on what *could not* have happened that are being set by current surveys are just as important as our discoveries of what did happen.

The next decade of large surveys, both ground- and spacebased, promises to expand our knowledge of asteroid physical properties by potentially another order of magnitude beyond what is known today. In this data-rich environment, family research will focus not just on individual families and their place in the main belt, but on specific subgroupings within families: on the knots, clumps, and collisional cascade fragments that trace the disruption and evolutionary dynamics that families have undergone. As the sizes of objects probed reach smaller and smaller, we can expect to find more young families like Karin and Iannini that can be directly backward-integrated to a specific time of collision, improving our statistics of collisions in the last 10 m.y. As catalogs increase in size, we can also expect to more frequently have characterization data of objects both before and after they undergo catastrophic disruption. This will enable us to test our impact-physics models on scales not achievable on Earth. Additionally, we will begin to see a time when we routinely use remote sensing data of asteroids to not just associate families but also assess the mineralogy of family members as a probe of the parent body. Asteroid family physical properties, numerical simulations, and evolutionary theory will leapfrog off each other, pushing forward our understanding of the asteroids and of the solar system as a whole.

---

In the last decade, thanks to the development of sophisticated numerical codes, major breakthroughs have been achieved in our understanding of the formation of asteroid families by catastrophic disruption of large parent bodies. In this review, we describe numerical simulations of asteroid collisions that reproduced the main properties of families, accounting for both the fragmentation of an asteroid at the time of impact and the subsequent gravitational interactions of the generated fragments. The simulations demonstrate that the catastrophic disruption of bodies larger than a few hundred meters in diameter leads to the formation of large aggregates due to gravitational reaccumulation of smaller fragments, which helps explain the presence of large members within asteroid families. Thus, for the first time, numerical simulations successfully reproduced the sizes and ejection velocities of members of representative families. Moreover, the simulations provide constraints on the family dynamical histories and on the possible internal structure of family members and their parent bodies.

## 1. INTRODUCTION

Observed asteroid families in the main asteroid belt are each composed of bodies that are thought to originate from the catastrophic disruption of larger parent bodies (e.g., Farinella et al., 1996). Cratering collisions can also lead to families, such as the one associated with asteroid Vesta, but we do not address this origin scenario here as few families have been linked to cratering events and their modeling requires a different approach (for more details, see the chapter by Jutzi et al. in this volume). A few tens of asteroid families have been identified, corresponding to groups of small bodies well-concentrated in proper-orbital-element space (see, e.g., Hirayama, 1918; Arnold, 1969; and the chapter by Nesvorný et al. in this volume) and sharing similar spectral properties (see, e.g., Chapman et al., 1989 and the chapter by Masiero et al. in this volume). Large families contain up to several hundred identified members, while small and compact families have on the order of 10 identified members. Interestingly,

the theory of the collisional origin of asteroid families rested for decades entirely on these similarities in dynamical and spectral properties and not on the detailed understanding of the collisional physics itself. Indeed, laboratory experiments on centimeter-scale targets, analytical scaling rules, or even complete numerical simulations of asteroid collisions were unable to reproduce the physical and dynamical properties of asteroid families (e.g., Ryan and Melosh, 1998). The extrapolation of laboratory experiments to asteroidal scales yielded bodies much too weak to account for both the size distribution and the dynamical properties of family members. In other words, there was no solution to match both the sizes and ejection velocities of family members simultaneously. To produce the large (assumed coherent) fragments seen in real families required an impact energy leading to ejection speeds of individual fragments that were much too small for them to overcome their own gravitational attraction. The parent body would then be merely shattered but not dispersed and therefore no family would be created (Davis et al., 1979).

Conversely, matching individual ejection velocities and deriving the necessary fragment distribution resulted in a size distribution in which no big fragment was present, contrary to most real families (e.g., *Davis et al.*, 1985; *Chapman et al.*, 1989). Thus, big sizes implied no fragment dispersion (at the level of the dispersion of family members), and fragment dispersion implied no big fragments (at the level of the sizes of family members).

A big caveat in the extrapolation of laboratory results to large asteroid scales is that the role of gravity (of both the targets and their fragments) is not taken into account in a laboratory-scale disruption involving centimeter-sized targets. Thus, the role of gravity in the catastrophic disruption of a large asteroid at the origin of a family remained to be assessed. Indeed, a possible scenario reconciling the sizes and ejection velocities of family members could be that the parent body (up to several hundred kilometers in size) is disrupted into small pieces by the propagation of cracks resulting from a hypervelocity impact but then the small fragments generated this way would typically escape from the parent and, due to their mutual gravitational attraction, reaccumulate elsewhere in groups in order to build up the most massive family members. This idea had been suggested previously by *Chapman et al.* (1982), and numerical simulations by *Benz and Asphaug* (1999) had already shown that at least the largest remnant of an asteroid disruption had to be a bound aggregate. However, the formation of a full family by reaccumulation of smaller fragments remained to be demonstrated.

In the last decade, the formation of asteroid families was simulated explicitly for the first time accounting for the two phases of a large-scale disruption: the fragmentation phase and the gravitational reaccumulation phase. In these simulations, the two phases are usually computed separately using a hybrid approach. This chapter reviews the major advances achieved since *Asteroids III* thanks to this new modeling work, and the implications for our understanding of asteroid family formation and properties.

## 2. SIMULATING A FAMILY-FORMING EVENT

Families are thought to form from the disruption of a large asteroid, called the parent body, as a result of the impact of a smaller projectile. Simulating such a process requires accounting for both the propagation of cracks in the parent body, leading to its conversion into separate fragments, and the possible gravitational interactions of these fragments. As explained above, the latter gravitational phase turns out to be crucial for reproducing asteroid family properties. In asteroid disruptions resulting from an hypervelocity impact, the fragmentation and the gravitational reaccumulation phases have very different associated dynamical times. In the fragmentation phase, the timescale for the propagation of the shock wave is determined by the target's diameter divided by the sound speed of the material (a few to tens of seconds for an asteroid 100 km in diameter). In the second phase, the timescale for gravitational reaccumulation is proportional

to  $1/\sqrt{G\rho}$ , where G is the gravitational constant and  $\rho$  is the target bulk density, which corresponds to at least hours for  $\rho = 1$  to 3 g cm<sup>-3</sup>. Therefore it is possible to model the collisional event by separating the two phases. A hybrid approach is generally adopted that consists of simulating first the fragmentation phase using an appropriate fragmentation code (called a hydrocode; see the chapter by Jutzi et al. in this volume), and then the gravitational phase, during which the fragments produced by the fragmentation phase can interact under their mutual attraction, using a gravitational N-body code.

### 2.1. The Fragmentation Phase

Several hydrocodes exist and are used in the planetary science community (see the chapters by Asphaug et al. and Jutzi et al. in this volume). In the first studies devoted to direct simulations of asteroid family formation (*Michel et al.*, 2001, 2002, 2003, 2004), a three-dimensional “smoothed-particle hydrodynamics” (SPH) code was used. This code solves in a Lagrangian framework the usual conservation equations (mass, momentum, and energy) in which the stress tensor has a nondiagonal part. The first families modeled in this way (Eunomia, Koronis, and Flora) were of the S taxonomic type. S-type asteroids are expected to be mostly made of ordinary chondrite materials, for which basalt plausibly has similar properties, and therefore the parent bodies of these S-type families were assumed to be nonporous basalt. The Tillotson equation of state for basalt was used (*Tillotson*, 1962), which is computationally expedient while sophisticated enough to allow its application over a wide range of physical conditions. Plasticity was introduced by modifying the stresses beyond the elastic limit with a von Mises yielding relation (*Benz and Asphaug*, 1994, 1995). A yielding relation accounting for the dependence of shear stress on pressure, such as Mohr-Coulomb or Drucker Prager, is generally more appropriate for rock material (see the chapter by Jutzi et al. in this volume). It turns out to be important for cratering events for which part of the process is dominated by shearing or when the impacted body is composed of interacting boulders [a so-called “rubble pile” (*Davis et al.*, 1979) or gravitational aggregate (*Richardson et al.*, 2002); see also *Jutzi* (2015)]. However, it was found that in the case of the disruption of monolithic parent bodies, the details of the strength model (e.g., pressure-dependent vs. pressure-independent yield strength) do not play an important role (*Jutzi*, 2015). For the lower tensile stresses associated with brittle failure, a fracture model was used, based on the nucleation of incipient flaws whose number density is given by a Weibull distribution (*Weibull*, 1939; *Jaeger and Cook*, 1969). *Durda et al.* (2004) and *Nesvorný et al.* (2006) used a similar hydrocode to study the formation of satellites from asteroid disruptions and other family-forming events. *Leinhardt and Stewart* (2009) studied large-scale disruptions and modeled the shock deformation with an Eulerian shock-physics code, CTH (*McGlaun et al.*, 1990), instead of the Lagrangian SPH code used in previous works.

Recently, the SPH impact code used by Michel et al. (2001, 2002, 2003, 2004) was extended to include a model adapted for microporous materials (Jutzi et al., 2008, 2009) (see also the Jutzi et al. chapter in this volume). The formation of asteroid families formed from a microporous parent body, such as for dark- (carbonaceous) type families, could thus also be investigated (Jutzi et al., 2010; Michel et al., 2011). Another study looked at the case of rubble-pile parent bodies [containing macroporous voids (Benavidez et al., 2012)].

## 2.2. The Gravitational Phase

Once the fragmentation phase is over and fractures cease to propagate (within the first simulated tens of seconds), the hydrodynamic simulations are stopped and intact fragments are identified. For impact energies typical of asteroid disruptions and for targets with a diameter typically greater than 1 km, it was found that the bodies are totally shattered into fragments of mass equal to the mass resolution of the simulations. In the first simulations performed in this way, the numerical resolution was limited to a few  $10^5$  particles and corresponded to minimum boulder diameters of about 1 to 4 km, for a parent body of a few hundred kilometers in diameter. Thanks to increased computer performance, it is now possible to perform simulations with up to several million particles. However, the gain in particle size resolution is not dramatic and simulations are still limited to minimum fragment diameters of a few hundred meters for target diameter of a few hundred kilometers. Reaching fragment diameters down to meters or less is beyond the capabilities of current and probably near-future technologies. Only when the target's diameter is in the few hundred meters range can this minimum size be reached, but unfortunately, no asteroid family can be identified involving a parent body of such a small size.

Once identified in the simulation outcome, the fragments and their corresponding velocity distributions are then fed into a gravitational N-body code, which computes the gravitational evolution of the system from the handoff point to subsequent hours or days of simulated time. Because the number of fragments is up to a few  $10^6$ , and their gravitational interaction as well as their potential collisions need to be computed over long periods of time (up to several simulated days), a very efficient N-body code is required to compute the dynamics. The most appropriate code to tackle this problem, which is the only one used so far by various groups to simulate the outcome of the gravitational phase of a collision, is the code called *pkdgrav* [see Richardson et al. (2000) for the first application of this code to solar system problems]. This parallel hierarchical tree code was developed originally for cosmological studies. Essentially, the tree component of the code provides a convenient means of consolidating forces exerted by distant particles, reducing the computational cost, with the tradeoff of introducing a slight force error (on the order of 1%) that does not affect the results appreciably since the dynamics are dominated by dissipative collisions. The parallel component divides the

work evenly among available processors, adjusting the load at each timestep according to the amount of work done in the previous force calculation. The code uses a straightforward second-order leapfrog scheme for the integration and computes gravity moments from tree cells to hexadecapole order.

For the purpose of computing the gravitational phase of an asteroid disruption during which the generated fragments can interact and collide with each other, collisions are identified at each step with a fast neighbor-search algorithm in *pkdgrav*. Once a collision occurs, because the relative speeds are small enough (on the order of meters per second), it is assumed that no further fragmentation takes place between components generated during the fragmentation phase. In fact, the simulations presented by Michel et al. (2001) assumed perfect sticking of colliding fragments and all colliding fragments were forced to merge into a single particle regardless of their relative velocities. This assumption is justified because the initial impact results in an overall expanding cloud of fragments of relatively small individual masses, down to the minimum fragment size imposed by the numerical resolution, and colliding fragments have typical relative speeds that are smaller than their individual escape speeds. Since the fragments in *pkdgrav* are represented by spheres, when two spherical fragments reaccumulate, they are merged into a single spherical particle with the same momentum. The same assumption was used by Durda et al. (2004) and Nesvorný et al. (2006) in their studies of satellite formation and other family-forming events. In a second and subsequent papers, Michel et al. (2002, 2003, 2004) improved their treatment of fragment collisions by using a merging criterion based on relative speed and angular momentum. In this case, fragments are allowed to merge only if their relative speed is smaller than their mutual escape speed and the resulting spin of the merged fragment is smaller than the threshold value for rotational fission (based on a simple prescription of a test particle remaining on the equator of a sphere). Nonmerging collisions are modeled as bounces between hard spheres whose post-collision velocities are determined by the amount of dissipation taking place during the collisions. The latter is computed in these simulations using coefficients of restitution in the normal and tangential directions [see Richardson (1994) for details on this computation]. Note that Durda et al. (2011, 2013) performed bouncing experiments between 1-m granite spheres as well as between centimeter-scale rocky spheres. These experiments gave a value for the normal coefficient of restitution of  $\approx 0.8$ , although much lower values are found with increasing roughness of contact surfaces. These results are particularly interesting because they are performed in an appropriate size regime (meter-sized bodies). However, bouncing in simulations occur at somewhat higher speeds (up to tens of meters per second) than in those experiments, which may result in a decrease in the coefficient of restitution due to the start of cracking and other energy dissipation processes. Moreover, although in our numerical modeling, perfect spheres are used, it is reasonable to account for actual irregularities of fragments formed during the fragmentation phase to set the value of the coefficient of restitution. Since

the values of these coefficients are poorly constrained, we usually arbitrarily set them equal to 0.5, meaning, for example, the rebound speed is set to half the impact speed.

More recently, *Richardson et al.* (2009) enhanced the collision handling in *pkdgrav* to preserve shape and spin information of reaccumulated bodies in high-resolution simulations of asteroid family formation. Instead of merging, fragments are able to stick on contact and optionally bounce or subsequently detach, depending on user-selectable parameters that include for the first time several prescriptions for variable material strength/cohesion. As a result, the reaccumulated fragments can take a wide range of shapes and spin states, which can be compared with those observed. This comes with a cost in terms of computation time as several weeks to months are needed for one simulation using a few tens of current processors. This is the reason why this approach has so far only been used for particular cases, such as modeling the formation of the asteroid Itokawa (*Michel and Richardson*, 2013), and not systematically for family-formation investigations.

And finally, we must note that the Soft-Sphere Discrete Element Method (SSDEM) has been introduced in *pkdgrav* (*Schwartz et al.*, 2012; chapter by Murdoch et al. in this volume), which accounts more realistically for the contact forces between colliding/reaccumulating particles. This method should eventually replace the one developed by *Richardson et al.* (2009) to investigate the shape of reaccumulated fragments as it avoids arbitrary particle sticking and rather lets the reaccumulated particles evolve naturally toward the resulting equilibrium shape of the aggregate. However, solving for all contact forces between particles over the whole timescale of the gravitational phase, and covering a large enough parameter space (accounting for the uncertainty on the various friction coefficients), remains a computational challenge. Nevertheless, some collisional studies started using the SSDEM implementation in *pkdgrav* focusing on low-speed impact events. In effect, no fragmentation code was used for the impact phase, which is needed for impacts during which the sound speed of the material is reached. Thus, *Ballouz et al.* (2014, 2015) used *pkdgrav* and SSDEM to simulate low-speed impacts between rotating aggregates and investigate the influence of the initial rotation of colliding bodies on the impact outcome and the sensitivity of some friction parameters. The number of particles was small enough ( $10^4$  at most) that simulations could be performed within a reasonable computation time. In the case of a family formation, the outcome of hydrocode simulations consists in several hundred thousands to millions of particles. Feeding them into the SSDEM version of *pkdgrav* requires another level of computer performance, although tests are underway.

### 3. MODELING THE FAMILY PARENT BODIES

Different possible internal structures have been considered for the family parent bodies. Monolithic parent bodies composed of one material type with or without microporosity (meaning micropores in the solid rock; for a definition of

microporosity, see the chapter by Jutzi et al. in this volume) have been considered, as well as pre-shattered or rubble-pile parent bodies, with or without microporosity in the solid components. The assumed pre-shattered state could be seen as a natural consequence of the collisional evolution of main-belt asteroids. Indeed, several studies (see, e.g., *Asphaug et al.*, 2002; *Davis et al.*, 2002; *Richardson et al.*, 2002) have indicated that for any asteroid, collisions at high impact energies leading to a disruption occur with a smaller frequency than collisions at lower impact energies leading to shattering effects only. Thus, in general, a typical asteroid gets battered over time until a major collision eventually disrupts it into smaller dispersed pieces. Consequently, since the formation of an asteroid family corresponds to the ultimate disruptive event of a large object, the internal structure of this body before its disruption may be shattered by all the smaller collisional events that it has suffered over its lifetime in the belt, as suggested by *Housen* (2009) based on laboratory experiments and extrapolations using scaling laws. This would result in the presence of internal macroscopic damaged zones and/or voids.

To model a pre-shattered target, *Michel et al.* (2003, 2004) devised an algorithm that distributes a given number of internal fragments of arbitrary shape and size within the volume of the parent body. The reason the internal fragments are given arbitrary shapes is that a network of fractures inside a parent body resulting from many uncorrelated small impacts is unlikely to yield spherical internal fragments whose sizes follow a well-defined power law. Then, void spaces are created by randomly removing a given number of particles from the fractured set. Since there are various ways to define a pre-shattered internal structure, *Michel et al.* (2004) also built a model of a pre-shattered parent body in which large fragments are preferentially distributed near the center and smaller fragments are generated close to the surface.

Another model, closer to the definition of a rubble pile, was also built by *Michel et al.* (2003). In that case, spherical components whose sizes followed a specified power law distribution were distributed at random inside the parent body. Particles not belonging to one of these spherical components were removed to create void space and particles at the interface of two or more spherical components were assigned to fractures. Some simulations were performed using those two additional models and the collisional outcomes did not show any major qualitative difference compared to those obtained from the first pre-shattered model. *Benediz et al.* (2012) constructed arbitrary rubble-pile targets by filling the interior of a 100-km-diameter spherical shell with an uneven distribution of solid basalt spheres having diameters between 8 km and 20 km. However, simulations performed so far using such rubble-pile parent bodies used a version of a SPH hydrocode with a strength model that did not allow the proper modeling of friction between the individual components of the rubble pile. As found by *Jutzi* (2015), the bodies in this case show a fluid-like behavior and are very (somewhat unrealistically) weak. Therefore, in the following, we will only consider the results obtained for

monolithic and pre-shattered bodies (as defined by Michel et al., 2003, 2004) either with or without microporosity.

#### 4. REPRODUCING WELL-KNOWN FAMILIES

For the first time, Michel et al. (2001) simulated entirely and successfully the formation of asteroid families from monolithic basalt-like parent bodies in two extreme regimes of impact energy leading to either a small or a large mass ratio of the largest remnant to the parent body  $M_{lr}/M_{pb}$ . Two well-identified families were used for comparison with simulations: The Eunomia family, with a 284-km-diameter parent body and  $M_{lr}/M_{pb} \approx 0.67$ , was used to represent the barely disruptive regime, whereas the Koronis family, with a 119-km-diameter parent body and  $M_{lr}/M_{pb} \approx 0.04$ , represented the highly catastrophic one. Both families are of the S taxonomic type, for which ordinary chondrites are the best meteorite analog, but basalt material is typically used as an analog material in collisional studies. In these simulations, the collisional process was carried out to late times (typically several days), during which the gravitational interactions between the fragments could eventually lead to the formation of self-gravitating aggregates (as a representation of rubble piles) far from the largest remnant. These first simulations assumed perfect sticking of reaccumulated fragments, regardless of relative speed and mass. This treatment was improved by Michel et al. (2002), allowing for the dissipation of kinetic energy in such collisions and applying an energy-based merging criterion, as described previously. This improved treatment did not change the conclusion obtained with the more simplistic method because typical relative speeds between ejected fragments are most often below their mutual escape speed. Therefore, this new set of simulations confirmed the idea that the reaccumulation process is at the origin of large family members. Durda et al. (2007) and Benavidez et al. (2012) made a systematic study of collisional disruption of monolithic and rubble-pile basalt-like 100-km-diameter parent bodies, assuming perfect sticking during reaccumulation, over a large range of impact conditions, and then rescaled their results to compare with real families, showing again that the reaccumulation process is necessary to find any good solution. However, a caution about extending results from the disruption of 100-km-diameter parent bodies to observed families that originated from parent bodies very different in size from 100 km is in order and was acknowledged by Durda et al. (2007).

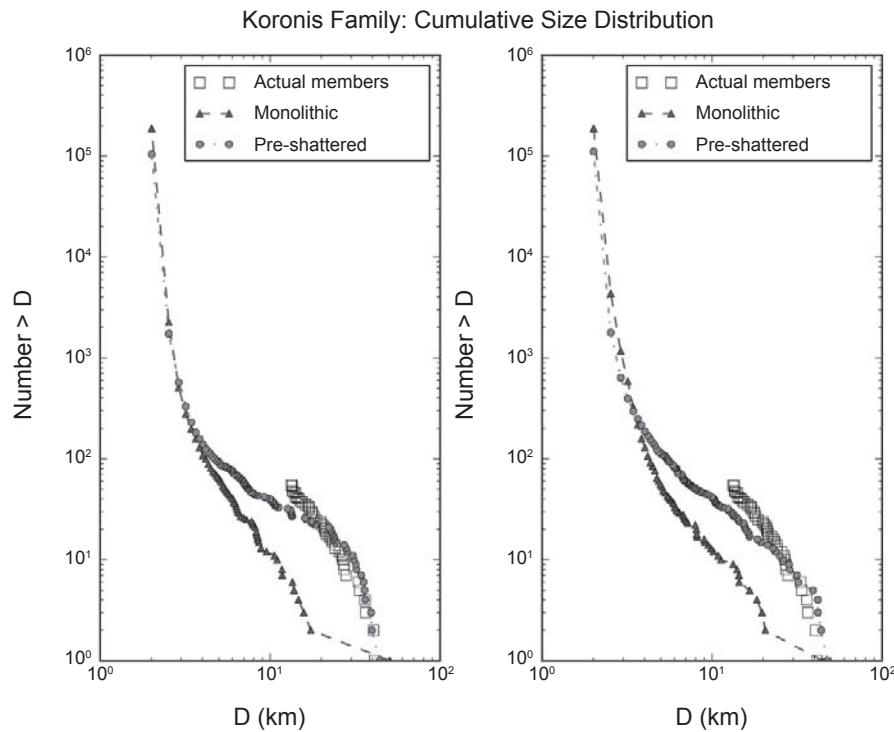

##### 4.1. The Size Distribution of Family Members

The role of geometric constraints accounting for the finite volume of the parent body in the production of family members was investigated by Tanga et al. (1999) and Campo Bagatin and Petit (2001). By filling the parent body with spherical (Tanga et al., 1999) or irregular (Campo Bagatin and Petit, 2001) pieces, starting from the largest member, they were able to reproduce the size distribution of some asteroid families to an encouraging level of agreement.

However, these models do not incorporate any physics, nor do they take into account fragment reaccumulation, and therefore they do not provide any explanation for how family members are formed nor any prediction for their internal properties. Moreover, ejection velocities are not addressed by this approach.

The first full numerical simulations of catastrophic disruption and gravitational reaccumulation by Michel et al. (2001) assumed a monolithic structure of the parent body represented by a sphere with material properties of basalt (no internal porosity was considered). These simulations already reproduced qualitatively the main properties of real family member size distributions. However, when looking into more quantitative details, it was found that the cumulative size distribution of simulated fragments was characterized systematically by a lack of intermediate-sized bodies and a very steep slope for the smaller ones (see an example in Fig. 1). Such characteristics are not always observed in the size distributions of real family members. In fact, for some families, the size distribution looks rather continuous. In their systematic study, Durda et al. (2007), using the same internal structures (monolithic, basalt) but considering 100-km-diameter parent bodies only, found a larger variety of size distributions in terms of power-law slopes and discontinuities, depending on the considered impact conditions.
