**5.1.1. Cratering regime.** Simple power-law relationships, so-called scaling laws, have been proposed to relate the size of the transient crater with impact parameters such as the mass and velocity of the impactor (see section 3). Those have been shown to be a theoretical consequence of the point-source assumption, as mentioned above. The scaling parameters in these equations (the so-called velocity exponent  $\mu$  and a proportionality factor that may be called K) have been determined by laboratory experiments, mainly in sand or other granular materials. One way to determine the scaling parameters is to vary the so-called gravity-scaled size of an impact event  $\pi_2 = (Lg)/v^2$ , with the diameter L of the impactor, or the gravity g, or the impact velocity v, over as large a range as possible. For example, one can increase the gravity using a geotechnic centrifuge and decrease the gravity using drop towers. The geotechnic centrifuge method was developed both for explosive cratering and hypervelocity impact cratering by Schmidt (1977) and by Schmidt and Holsapple (1980). Since gravity can be varied over 2 orders of magnitude, a 500-G centrifuge test models 1-G events with a 500× larger scale. A meter-sized test at 500 G has the same physics

as a 0.5-km event at 1 G. However, there is no effect of the increased gravity at those magnitudes except for materials with very little cohesion, so studies are primarily limited to granular materials such as sand. Although the properties of the target material such as porosity or internal friction are somewhat under the experimenter's control, independently varying these parameters is difficult.

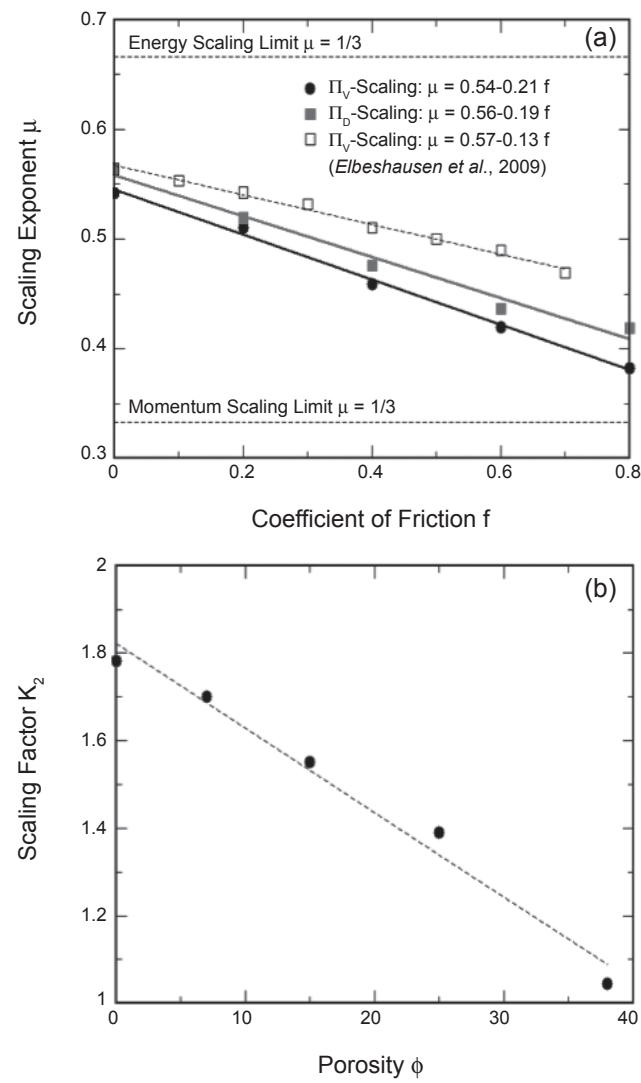

An alternative approach is to use numerical simulations to carry out numerical experiments that are not limited by experimental constraints in the laboratory. Of course, due to the numerous modeling questions mentioned above, those are not without their own uncertainties. And, as long as the point-source approximation is valid, they cannot contradict the theoretical scaling forms, but they can identify the unknown scaling coefficients. Also, they allow extensions of the parameter space from laboratory scale to natural dimensions under any given gravity regimes of planets, moons, and asteroids. The effect of material properties of the target such as porosity, friction, and cohesion can be independently investigated (Wünnemann et al., 2010), and the effect of the angle of incidence can be investigated as well (Elbeshausen et al., 2009). In these studies it was shown that the velocity exponent  $\mu$  depends on the coefficient of friction  $f$  of the target material (Fig. 6) and the scaling factor  $K$  may be expressed as a function of porosity  $\phi$ .

To incorporate the angle of impact  $\theta$  into the scaling equations, it was suggested by Chapman and McKinnon (1986) and others based on impact experiments in sand to replace the impact velocity  $v_\theta$  by the vertical component of the impact velocity  $v_\perp$ . For example, in this case, crater volume scales with the sine of the impact angle raised to the power  $2\gamma$  where  $\gamma = 3\mu/(2 + \mu)$ . Extensive parameter studies using models of impacts at different angles into granular targets with varying coefficient of friction (Fig. 7a) show that this approximation holds true only for a typical coefficient of friction of  $f = 0.7$  (Fig. 7c) (Elbeshausen et al., 2009). The vertical velocity component approximation also provides good estimates of crater volume and diameter for strength-dominated craters in cohesive ductile targets such as metals (Davison et al., 2011). For impacts in granular targets with a smaller coefficient of friction than is typical for sand, the size of the resulting crater is underestimated by this simple assumption (Fig. 7b). Details of the impact may not be so easily matched using this assumption.

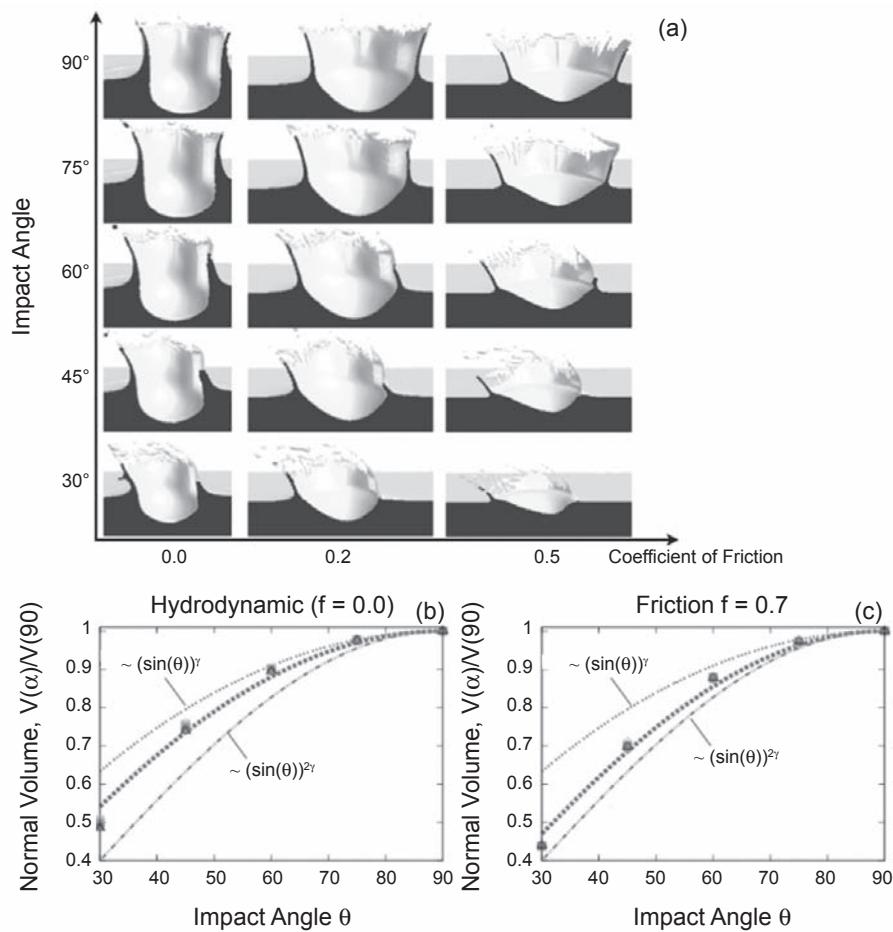

**5.1.2. Disruption regime.** To characterize the outcome of a disruptive collision, the critical specific impact energy  $Q_D^*$ , which results in the escape of half the target's mass in a collision, is often used. The parameter  $Q_D^*$  is called the catastrophic impact energy threshold (also called the dispersion threshold). The specific impact energy is often defined as  $Q = 0.5m_p v_p^2/M_T$ , where  $m_p$ ,  $v_p$ , and  $M_T$  are the mass and speed of the projectile and the mass of the target, respectively. The catastrophic disruption threshold  $Q_D^*$  is then given by the specific impact energy leading to a largest (reaccumulated) fragment  $M_{lr}$  containing 50% of the original target's mass. In recent studies (e.g., Stewart and Leinhardt, 2009; Leinhardt and Stewart, 2012), a more general definition of

the specific impact energy was proposed that also takes into account the mass of the impactor, which can be substantial in very-low-velocity impacts of near-equal-sized bodies. The corresponding radius  $R_{C1}$  is then defined as the spherical radius of the combined projectile and target masses at a density of  $1 \text{ g cm}^{-3}$ . According to this new definition, the catastrophic disruption threshold is then called  $Q_{RD}^*$ .

Values of  $Q_D^*$  (or  $Q_{RD}^*$ ) have been estimated using both laboratory and numerical hydrocode experiments (see, e.g., Holsapple et al., 2002; Asphaug et al., 2002). For high-velocity asteroid collisions, the first suite of numerical calculations aimed at characterizing the catastrophic disruption threshold in both the strength regime and the

**Fig. 6.** Scaling parameters  $\mu$  and  $K_2$  as a function of coefficient of friction  $f$  and porosity  $\phi$ . (a) The scaling exponent  $\mu$  was determined by numerical impact experiments into material with different coefficient of friction, zero cohesion, and zero porosity. The dashed line was taken from Elbeshausen et al. (2009). (b) The scaling factor  $K_2$  was determined by numerical impact experiments into material with different porosities, a coefficient of friction  $f = 0.8$ , and zero cohesion.

**Fig. 7.** Snapshots of the approximate transient crater for different impact angle and coefficient of friction. Relative change of the crater volume  $V_\theta$  normalized by crater volume for an equivalent 90° impact  $V_{90}$  with impact angle for (b)  $f = 0$  (fluid-like target rheology) and (c)  $f = 0.7$  (sand-like target rheology). Note: The results from numerical models over a range of different  $\pi_2$  values fall in between two lines calculated according to the vertical velocity component approximation [ $\sim -\sin(\theta)^{2\gamma}$ ; lower curve] and another line [ $\sim -\sin(\theta)^\gamma$ ]. Taken from Elbeshausen et al. (2009).

gravity regime was performed by Benz and Asphaug (1999), who used an SPH code (Benz and Asphaug, 1994, 1995) to simulate the breakup of basalt and icy bodies from centimeter scale to hundreds of kilometers in diameter. More recently, Leinhardt and Stewart (2009) computed  $Q_D^*$  curves using the hydrocode CTH (McGlaun, 1990) to compute the fragmentation phase and the N-body code *pdkgrav* to compute the subsequent gravitational evolution of the fragments. In this study, the dependency of  $Q_D^*$  on the strength of the target was investigated. In a recent study by Jutzi et al. (2010), the effect of target porosity on  $Q_D^*$  was investigated using an extended version of the SPH code (Jutzi et al., 2008). In this study, the size and velocity distribution of the fragments was computed as well, using the *pdkgrav* code. Benavidez et al. (2012) performed a study of a large number of collisions among  $R_t = 50$ -km rubble-pile bodies using the original SPH code by Benz and Asphaug (1994, 1995). As discussed in section 3, Leinhardt and Stewart (2012) proposed general scaling laws for collisions among gravity-dominated bodies.

In the chapter by Asphaug et al. in this volume, a recent systematic study of the relative effects of various asteroid properties on the disruption threshold  $Q_D^*$  (Jutzi, 2015) is presented.

## 5.2. Momentum Transfer in Small Impacts

The study of the momentum transferred in an specific impact on an asteroid as a function of impact conditions and the internal structure is crucial for performance assessment of the kinetic impactor concept of deflecting a potentially hazardous asteroid from its trajectory (see the chapter by Harris et al. in this volume). The momentum transfer is characterized by the so-called momentum multiplication factor  $\beta$ , which has been introduced to define the momentum imparted to an asteroid in terms of the momentum of the impactor

$$\beta = 1 + p_{ej} / (M_p v_p) \quad (16)$$

where  $p_{ej}$  is the escaping ejecta momentum, and  $M_p$  and  $v_p$  are the mass and velocity of the impactor, respectively (see,

e.g., *Holsapple*, 2004b). In the limiting case of an impact that produces no escaping ejecta,  $\beta = 1$ , and the momentum transferred corresponds to the momentum of the projectile (inelastic collision). However, in the case of an impact that produces a lot of material (ejected in the opposite direction) with velocities larger than the escape velocity, we can have  $\beta \gg 1$  due to the contribution of  $p_{ej}$ . Using the  $\beta$  factor, the resulting momentum of the target  $\Delta P_t$  (along the impact direction) can be obtained by

$$\Delta P_t = \beta P_p \quad (17)$$

where  $P_p = m_p v_p$  is the momentum of the projectile.

It is important to note that only fragments with ejection velocities larger than the escape velocity of the target asteroid,  $v_{eject} > v_{esc}$ , escape the body and contribute to the momentum transfer. Moreover, the ejected material is slowed down during its escape and its trajectory is changed due to the gravitational attraction of the target. Therefore, to compute the escaping ejecta momentum, the value and angle of the velocity at infinity have to be used (see, e.g., *Holsapple and Housen*, 2012; *Cheng*, 2012; *Jutzi and Michel*, 2014).

*Holsapple and Housen* (2012) presented scaling laws to extrapolate measurements of the momentum transfer in laboratory experiments to asteroid scales. Recent code calculations of the momentum transfer efficiency in impacts on asteroids for conditions typical for a kinetic impactor were performed by *Holsapple and Housen* (2013a) and *Jutzi and Michel* (2014). *Holsapple and Housen* (2013a) presented numerical simulations both for porous and non-porous materials, and obtained very good agreement with their laboratory results.

In the study by *Jutzi and Michel* (2014), the effect of different degrees and scales of porosity on the momentum multiplication factor  $\beta$  was investigated for a range of impact conditions.

Two kinds of porous target structures were considered by *Jutzi and Michel* (2014): (a) homogeneous — microporous only, and (b) heterogeneous — both micro- and macroporous. For both structures, the microporous part of the material has a porosity of 50%. For structure (b), in addition to the microporosity, macroscopic cracks with a size scale of  $\sim 0.3$  m are randomly distributed in the target. The resulting total macroscopic void fraction is 10%.

The impact simulations were performed using an SPH impact code (e.g., *Benz and Asphaug*, 1994, 1995; *Jutzi et al.*, 2008; *Jutzi*, 2015) as presented in section 4.5.2.

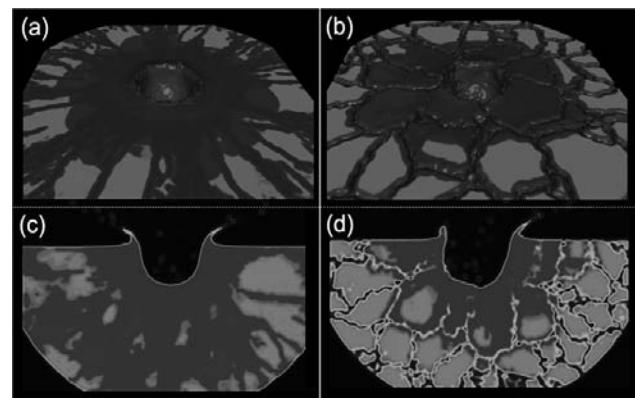

In Fig. 8, the outcome (in terms of damage) of an impact at  $10 \text{ km s}^{-1}$  is shown for the two target structures.

In Fig. 9, the results of the calculations of  $\beta$  are shown for the considered range of impact velocities ( $0.5\text{--}15 \text{ km s}^{-1}$ ) and the two target structures. At low-impact velocities, the amount of momentum transferred is smaller using structure (b) than structure (a). However, these differences disappear at high velocities. This means that for porous targets, inhomogeneities at the scales considered here have negligible effects on the amount of transferred momentum

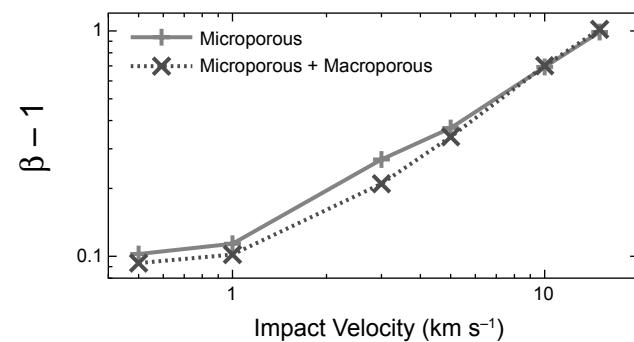

for velocities  $\geq 5 \text{ km s}^{-1}$ . That confirms the view expressed earlier that the exact form of the modeling of porosity will not matter for any phenomena with scales that are large compared to the size scale of that porosity.

While the effect of target inhomogeneities on the momentum multiplication factor  $\beta$  appears to be quite small, the effect of various material properties such as tensile or crushing strength was found to be more significant (*Jutzi and Michel*, 2014).

The results of this study verify that the momentum multiplication factor  $\beta$  is small even for very-high-impact velocities ( $\beta < 2$  for  $v_{imp} \leq 15 \text{ km s}^{-1}$ ) in the case of porous targets (with  $\sim 50\%$  porosity). This is consistent with scaling laws (section 3), which, in combination with the results of laboratory experiments, predict a small value of  $\beta \sim 1\text{--}2$  for porous materials and comparable impact velocities (see Table 3 in *Holsapple and Housen*, 2012). It is also consistent with the numerical simulations performed by *Holsapple and Housen* (2013a).

**Fig. 8.** (a,c) Damage (dark gray zones) produced by the impact at  $10 \text{ km s}^{-1}$  on a microporous target; (a) and (b) show the target from above, while (c) and (d) show a vertical slice. (b,d) Same for a target containing both microporosity and macroporosity. From *Jutzi and Michel* (2014).

**Fig. 9.** Momentum multiplication factor  $\beta - 1$  as a function of impact velocity for the two considered structures: (1) homogeneous microporous and (2) heterogeneous, microporous, and macroporous. From *Jutzi and Michel* (2014).

However, that is not true for nonporous targets. Values of  $\beta$  as large as 5 have been directly measured at impact velocities of  $v_{\text{imp}} \leq 5 \text{ km s}^{-1}$  (*Holsapple and Housen*, 2013a) for rocky targets. Furthermore, the scaling predicts a marked increase like  $U^{0.5}$  for those targets, so at  $v_{\text{imp}} \leq 20 \text{ km s}^{-1}$  those values might reach as much as  $\beta \sim 10$ . If so, that would significantly facilitate deflections by impacts.

An important question is how to scale strength (tensile strength and crush-curve parameters) of a porous material to larger sizes. The strength properties of real asteroid materials and their size dependency are not well constrained (e.g., what is the crush-curve of a 300-m asteroid with 50% porosity?), while they have a significant effect on the momentum transfer efficiency.

### 5.3. Selective Sampling in Catastrophic Disruptions

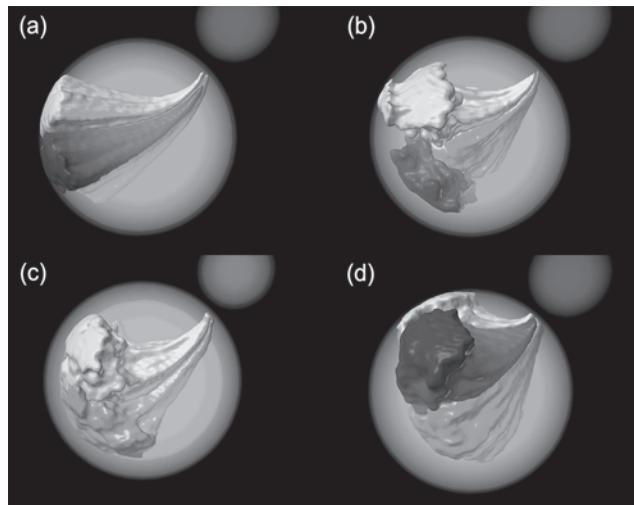

The catastrophic disruption of a large asteroid as a result of a collision with a smaller projectile and the subsequent reaccumulation of fragments as a result of their mutual gravitational attractions have been simulated numerically during the last decades, which allowed the formation of asteroid families to be successfully reproduced (see the chapter by Michel et al. in this volume). It is generally found that most large bodies formed during a catastrophic disruption consist of aggregates formed by reaccumulation of smaller fragments (e.g., *Michel et al.*, 2001). The original location within the parent body of the small pieces that eventually reaccumulate to form the largest offspring of a disruption as a function of the original internal structure of the disrupted asteroid is interesting to determine for several reasons. If reaccumulation is a random process, we expect the particles of a given large fragment to originate from uncorrelated regions within the parent body. Conversely, if the initial velocity field imposed by the fragmentation process determines the reaccumulation phase, the particles belonging to the same fragment should originate from well-defined areas inside the parent body. In addition, the position and extent of these regions provide indications about the mixing occurring as a result of the reaccumulation process. Motivated by the question of the origin of ureilites, which, in some petrogenetic models, are inferred to have formed at particular depths within their parent body, *Michel et al.* (2014) started to investigate this problem by simulating the fragmentation (and reaccumulation) of a large body with a diameter fixed at 250 km. This study was performed using a hybrid approach with an SPH shock-physics code (*Benz and Asphaug*, 1994, 1995; *Jutzi et al.*, 2008; *Jutzi*, 2015) and the n-body code *pkdgrav* as described in section 4. They considered four kinds of internal structures that may represent the internal structure of a large body in various early stages of the solar system evolution: fully molten, half-molten (i.e., a 26-km-deep outer layer of melt containing half the mass), solid except for a thin molten layer (8 km thick) centered at a 10-km depth, and fully solid. The properties of basaltic material were assumed for the solid component. They focused on the three largest offspring that had enough reaccumulated pieces to consider.

As found by *Michel et al.* (2004), who considered fully solid and preshattered bodies in the context of family formation, they found that the particles that eventually reaccumulate to form the largest reaccumulated bodies retain a memory of their original locations in the parent body. In other words, most particles in each reaccumulated body are clustered from the same original region, even if their reaccumulations take place far away. However, they also found that the extent of the original region varies considerably depending on the internal structure of the parent (Fig. 10). In particular, it seems to shrink with the solidity of the body. Although the covered parameter space in this first study was limited, this sort of investigation can provide some constraints on the internal structure of the parent bodies of some meteorites.

## 6. CONCLUSIONS

Numerical simulations provide an important tool that allows us to probe regimes unreachable by experimental methods. Collisions among asteroids take place in those regimes. To realistically model these events, the combined effects of gravity, strength, porosity, as well as shape and structural properties need to be taken into account. Therefore, high-fidelity physical models are required, and modeling asteroid collisions is extremely complex.

Our knowledge of the asteroid properties that are relevant in terms of impact modeling is still quite limited. Moreover,

**Fig. 10.** Original positions of the material that will reaccumulate and form the largest, second-largest, and third-largest fragments (plume-shaped objects shown in different levels of gray). The results for four different internal structures are (a) fully molten, (b) half-molten, (c) with a thin molten layer (10% of the total mass) at a 10-km depth (the third largest is hidden behind the visible two largest), and (d) fully solid. The transparent gray bodies indicate the original target and impactor, respectively. The impactor moves vertically down. In the investigated greatly disruptive regimes, all the material that is not in the largest fragments (i.e., the largest fraction of the parent body) is blown away, i.e., it will not reaccumulate (or only in very small fragments). Inspired by *Michel et al.* (2015).

there are known important shortcomings in the modeling that has been used to date, although that modeling is improving. It is important to keep that in mind in assessing the meaning of any numerical simulation.

An important step in the development of numerical methods (which includes the implementation of complex material models) is the validation against laboratory experiments. Although only very briefly mentioned in this chapter, experimental studies greatly contributed to our understanding of the collisional process at small laboratory scales and always give a necessary point of reference to test numerical methods. However, in comparisons to experiments, it is important to include more than one single scalar value, such as the crater size or the fragment mass from one experiment. In order for a numerical model to be a predictive tool, it should be able to reproduce multiple experiments in different regimes without adjusting any parameters.

Since the publication of *Asteroids III* a decade ago, there have been major advances in the modeling of asteroid collisions and impact processes. The numerical simulations will undoubtedly become of higher fidelity as our models improve, guided by experimental, theoretical, and scaling results.

---

Collisional and dynamical models of the main asteroid belt allow us to glean insights into planetesimal- and planet-formation scenarios as well as how the main belt reached its current state. Here we discuss many of the processes affecting asteroidal evolution and the constraints that can be used to test collisional model results. We argue the main belt's wavy size-frequency distribution for diameter  $D < 100$ -km asteroids is increasingly a byproduct of comminution as one goes to smaller sizes, with its shape a fossil-like remnant of a violent early epoch. Most  $D > 100$ -km asteroids, however, are primordial, with their physical properties set by planetesimal formation and accretion processes. The main-belt size distribution as a whole has evolved into a collisional steady state, and it has possibly been in that state for billions of years. Asteroid families provide a critical historical record of main-belt collisions. The heavily depleted and largely dispersed “ghost families,” however, may hold the key to understanding what happened in the primordial days of the main belt. New asteroidal fragments are steadily created by both collisions and mass shedding events via YORP spinup processes. A fraction of this population, in the form of  $D < 30$  km fragments, go on to escape the main belt via the Yarkovsky/YORP effects and gravitational resonances, thereby creating a quasi-steady-state population of planet-crossing and near-Earth asteroids. These populations go on to bombard all inner solar system worlds. By carefully interpreting the cratering records they produce, it is possible to constrain how portions of the main-belt population have evolved with time.

## 1. INTRODUCTION

The main asteroid belt is a living relic. It contains a record of what happened to the solar system in terms of bombardment since the planet-formation epoch. Ongoing collisional and dynamical evolution processes, however, are slowly obscuring the traces left behind. The goal of modeling efforts is to use all possible observational data to discern the initial conditions and evolution processes that occurred during and after the planet-formation epoch. For example, the questions one can probe with main-belt constraints include the nature

and mass of planetesimals inside Jupiter’s orbit, the timing of Jupiter’s formation, the distribution of volatiles in the inner solar system, the size distribution produced during planetary accretion, the presence of planetary embryos inside Jupiter’s orbit, the migration of the giant planets and whether sweeping resonance ever crossed the main belt, the degree of material mixing that occurred between the feeding zones, etc.

The problem is that our uncertainties about planet-formation processes and giant planet migration feed back into the assumptions made for our collisional-evolution models of the asteroid belt. If we do not know what happened when, it

is often difficult to impossible to find unique solutions. On the other hand, the main belt provides powerful constraints, and sometimes even order-of-magnitude solutions are useful at testing planet-formation scenarios. As a result, many main-belt-evolution scenarios have been investigated over the last several decades. The latest thinking on the primordial dynamical evolution of the main belt is discussed in the chapter by Morbidelli et al. in this volume.

A key issue for many evolution models concerns the so-called mass deficit of the main belt (e.g., Morbidelli et al., 2009). Consider that the total mass of the main asteroid belt, which is dominated by the masses of the largest asteroids, is  $\sim 5 \times 10^{-4} M_{\oplus}$  (Krasinsky et al., 2002; Somenzi et al., 2010; Kuchynka and Folkner, 2013). This value is tiny compared to the mass of solids thought to exist in the same region at the time of planetesimal formation. For example, the minimum mass solar nebula (Weidenschilling, 1977) suggests that 1–2.5  $M_{\oplus}$  of solid material once existed between 2 and 3 AU. If most of the solids ended up in planetesimals, the main-belt region could potentially be deficient in mass by a factor of >1000. These values have been used to argue that the asteroid belt has lost more than 99.9% of its primordial mass (e.g., Morbidelli et al., 2009). The critical unknown here is the efficiency and nature of planetesimal formation itself, which is discussed in the chapter by Johansen et al. in this volume.

If so much mass once existed in the primordial main-belt region, collisional evolution, dynamical removal processes, or some combination of the two were needed to get rid of it and ultimately produce the current main-belt population. For some time, many attempts were made to account for the mass deficit by collisions alone; see Davis et al. (2002) for a review of work up to the time of *Asteroids III*. Essentially, there are two key problems with this scenario. First, it is difficult for collisions alone to grind away the main-belt size distribution predicted by accretion models without blasting away Vesta's basaltic crust or producing size-frequency distributions (SFDs) that are inconsistent with the observed main-belt SFD (e.g., Davis et al., 1985). Second, collisional models employing disruption scaling laws based on numerical hydrocode simulations of asteroid collisions (e.g., Benz and Asphaug 1999) cannot break up enough  $D > 100$ -km asteroids to reproduce the observed population; too many large objects are left behind (e.g., Bottke et al., 2005a,b). Taken together, these outcomes suggest that either dynamical removal of asteroids has played a powerful role in allowing the population to reach its current state (see the chapter by Morbidelli et al. in this volume), or that the main-belt SFD for the largest asteroids has not changed very much since planetesimal formation.

For the former, several dynamical scenarios have been suggested to remove most of the primordial main belt's mass (see the chapter by Morbidelli et al. in this volume). For example, planetary embryos may have initially formed in the main-belt region (e.g., Petit et al., 2002, for a review; see also Chambers and Wetherill, 1998, 2001; O'Brien et al., 2006, 2007). As they gravitationally excited themselves and the surrounding planetesimals, most of these bodies escaped,

thereby naturally creating much of the main-belt mass deficit. In a second example, Jupiter gravitationally interacts with the gas disk and migrates across the main-belt region (Walsh et al., 2011). This so-called Grand Tack scenario allows Jupiter to do the job of scattering embryos and planetesimals out of the main-belt region. The key similarity of both examples is that planetesimals dynamically excited out of the main belt have the opportunity to slam into the survivors left behind (along with leftover planetesimals already on planet-crossing orbits) (Bottke et al., 2005b; O'Brien and Greenberg, 2005; O'Brien et al., 2006; Davidson et al., 2013). This allows these dynamical models to be at least partially tested against main-belt asteroid and meteoritical constraints.

An alternative scenario is to assume that planetesimal and planet formation works differently than has been assumed in existing scenarios, and that the quantity of planetesimals in the main-belt region was never more than a few times the present-day population (e.g., Levison et al., 2015a,b). This would remove the need for a mass deficit. This new scenario invokes a process called "pebble accretion" that describes how planetesimal growth rates are governed by the way in which small particles are affected by gas drag in the solar nebula near a growing body (see the chapter by Johansen et al. in this volume). In brief, planetesimals embedded in a population of "pebbles," whose sizes are debated, can grow very quickly because of a newly discovered mode of accretion aided by aerodynamic drag on the pebbles themselves. If a pebble's aerodynamic drag stopping time is less than or comparable to the time for it to encounter a growing body, such as a planetary embryo, then it is decelerated with respect to the planetary embryo and becomes gravitationally bound. After capture, the pebble spirals inward and is accreted. If pebble-accretion scenarios are found to be valid, early collisional evolution in a low-mass main belt might be dominated by leftover planetesimals that strike from planet-crossing orbits.

Beyond the earliest times, one must also consider whether the main-belt population was affected by giant planet migration taking place after the solar nebula had completely dissipated. In a popular suite of scenarios referred to as the Nice model (see the chapter by Morbidelli et al. in this volume), the giant planets undergo a gravitational instability long after the formation of the first solids. Ice giants like Uranus and Neptune migrate across a massive primordial disk of comets, scattering most across the solar system. Some of these bodies will slam into main-belt asteroids (Brož et al., 2013). As the gas giants migrate to their current orbits, secular resonances produced by the giant planets also jump to new positions, and some will interact with the primordial main-belt population. This may cause the primordial main belt to lose some of its mass (Gomes et al., 2005; Brasser et al., 2009; Morbidelli et al., 2010; Minton and Malhotra, 2009, 2011). At the same time, it may also trap some destabilized comets within this region on stable orbits (Levison et al., 2009). The new home for certain secular resonances may even destabilize a putative stable extension of the main belt that once existed between 1.7 and 2.2 AU (Bottke et al.,

2012). It is likely that evidence for or against these possibilities can still be found in the asteroidal impact record, provided we know what to look for there.

The question is how to test these concepts with what we know about asteroids and the main belt itself, and whether the constraints we know about today are sufficient to eliminate various planet-formation and evolution scenarios. To answer this, we first must examine the processes affecting asteroidal collisional evolution, and what would need to be incorporated into a comprehensive collisional-evolution model (section 2). Next, we need to discuss the constraints that can be reasonably brought to bear on this problem (section 3). Only then can we discuss what we have learned from existing models (section 4). We also refer the interested reader to the excellent reviews of historical collisional evolution work provided in previous *Asteroids* volumes by *Davis et al.* (1979, 1989, 2002), and to a much more limited literature review in *Bottke et al.* (2005a). As much as possible, we have tried to avoid duplication with these works while keeping this chapter self-contained.

## 2. PROCESSES AFFECTING MAIN-BELT EVOLUTION

At the most basic level, main-belt collisional-evolution models involve the solution of a straightforward differential equation, although the details can become complicated and somewhat messy from an accounting standpoint. The input is an initial SFD for the asteroid belt denoted as  $N(D,t)$ , with the bodies binned in logarithmic intervals as a function of diameter. The goal of the solution is to compute the time rate of change in the population per unit volume of space over a size range between diameter  $D$  and  $D + dD$ . In a schematic form, it can be written as

$$\frac{\partial N}{\partial t}(D,t) = -I_{\text{COLL}} + I_{\text{FRAG}} - I_{\text{DYN}} \quad (1)$$

Here  $I_{\text{COLL}}$  is the net number of bodies that leave between  $D$  and  $D + dD$  per unit time from collisions (i.e., it is a “sink” for bodies in the SFD). The net number of collisions taking place at every time step is calculated by determining how many projectiles from other size bins are capable of producing either a cratering or a catastrophic disruption event among bodies between  $D$  and  $D + dD$ . Note that other mass loss processes can be included here as well, such as the loss of material via nongravitational YORP torques, which can spin up asteroids fast enough that they shed mass (see the chapter by Vokrouhlický et al. in this volume and section 2.5 below).

The results of the  $I_{\text{COLL}}$  calculation are sent to the function  $I_{\text{FRAG}}$ , which describes the number of bodies entering a given size bin per unit time that were produced by the fragmentation of larger bodies (i.e., it is a “source” for bodies in the SFD). This allows large asteroids to act as a reservoir for smaller bodies, with collisional evolution or some other process liberating fragments over time.

Finally, the equation accounts for  $I_{\text{DYN}}$ , which is the number of bodies lost from a given size bin via dynamical processes, such as an object escaping through a dynamical resonance (i.e., it is a “sink” for bodies in the SFD). Note that  $I_{\text{DYN}}$  is often enacted over the entire main-belt SFD, which is reasonable for global dynamical mechanisms like sweeping resonances or migrating planets but is less accurate for bodies escaping from specific main-belt regions via dynamical resonances (e.g., the  $v_6$  secular resonance along the inner edge of the main belt; the 3:1 mean-motion resonance with Jupiter at 2.5 AU).

In the sections below, we discuss the many parameters and mechanisms needed to understand and create these functions within a collision evolution model.

### 2.1. Asteroid Collision Probabilities

A necessary component to determining the collisional evolution of a population is to compute the impact probabilities and relative velocities between all possible pairs of bodies. These values are used to estimate the interval between targets and projectiles of different sizes striking one another as well as the effects of those collisions. The most common value used in these cases is the intrinsic collision probability  $P_i$ , defined as the likelihood that a single projectile will hit the target over a unit of time and cross-sectional area, and the mean impact velocity  $V_{\text{imp}}$  between the pair (e.g., *Öpik*, 1951; *Wetherill*, 1967; *Farinella and Davis*, 1992; *Bottke et al.*, 1994).

To get these values for the present-day main belt, *Bottke et al.* (1994) took a representative sample of main-belt asteroids [e.g., 682 asteroids with  $D > 50$  km as defined by *Farinella and Davis* (1992)] and calculated  $P_i$  and  $V_{\text{imp}}$  between all possible pairs of asteroids, assuming fixed values of semimajor axis, eccentricity, and inclination ( $a, e, i$ ). A common approximation made here is that the orbits can be integrated over uniform distributions of longitudes of apsides and nodes because secular precession randomizes their orbit orientations over  $\sim 10^4$ -yr timescales. After all possible orbital intersection positions for each projectile-target pair were evaluated and weighted, they found that main-belt objects striking one another have  $P_i \sim 2.9 \times 10^{-18} \text{ km}^{-2} \text{ yr}^{-1}$  and  $V_{\text{imp}} \sim 5.3 \text{ km s}^{-1}$ . These values are fairly reasonable given what we know about the main-belt population today, and comparable values can be found in many works (e.g., *Farinella and Davis*, 1992; *Vedder*, 1998; *dell’Oro and Paolicchi*, 1998; *Manley et al.*, 1998). Estimates for different portions of the main-belt population striking one another have been reported as well (e.g., *Levison et al.*, 2009; *Cibulkova et al.*, 2014).

To model collisional evolution in the primordial asteroid belt requires that certain assumptions be made about the excitation of asteroid belt bodies at that time. For example, the process that caused the main-belt population to become dynamically excited (see the chapter by Morbidelli et al. in this volume) should have also driven many primordial main-belt asteroids onto planet-crossing orbits. While their orbits

were short lived, their higher eccentricity and inclinations would have allowed them to strafe the surviving main belt asteroids at  $V_{\text{imp}} > 10 \text{ km s}^{-1}$  for tens of millions of years (e.g., Bottke et al., 2005b; Davidson et al., 2013; Marchi et al., 2013). Moreover, if the primordial main belt once had considerably more mass, as discussed in section 1, these departed bodies could be responsible for a considerable amount of collisional evolution in the main belt.

A related issue is that the primordial main belt has likely been struck by sizable but transient populations on planet-crossing orbits, such as leftover planetesimals (Bottke et al., 2006, 2007), ejecta from giant impacts in the terrestrial planet region (Bottke et al., 2015b), comet-like planetesimals dispersed from the primordial disk during giant planet migration (Brož et al., 2013), and Jupiter–Saturn-zone planetesimals pushed into the inner solar system via giant planet migration and/or evolution (Walsh et al., 2011; Turrini et al., 2011, 2012). Most of these dramatic events are thought to take place during the first 500 m.y. of solar system history. The nature and evolution of these populations is uncertain, such that dynamical models are needed to set limits on what they were plausibly like (see the chapter by Morbidelli et al. in this volume). Under certain conditions, they could also account for abundant collisional grinding in the main belt.

In all cases, dynamical models are needed to allow the computation of  $P_i$  and  $V_{\text{imp}}$  between the impacting bodies and the main-belt targets. From there, it is a matter of estimating the initial sizes of the populations, how fast they disperse, and how the populations undergo collisional evolution among themselves.

## 2.2. Asteroid Disruption Scaling Laws

A second key issue to modeling asteroid collisional evolution concerns the disruption scaling law. This is commonly referred to as the critical impact specific energy  $Q_D^*$ , the energy per unit target mass delivered by the projectile required for catastrophic disruption of the target (i.e., such that one-half the mass of the target body escapes). A considerable amount has been written about the value of  $Q_D^*$  (e.g., reviews in Holsapple et al., 2002; Asphaug et al., 2002; Davis et al., 2002; see also Leinhardt and Stewart, 2009; 2012), and the latest on the computation of this value can be found in the chapters in this volume by Jutzi et al. and Michel et al. For these reasons, we only briefly review the main issues here.

Using  $Q_D^*$ , the diameter of a projectile  $d_{\text{disrupt}}$  capable of disrupting a target asteroid ( $D_{\text{target}}$ ) can be estimated as

$$d_{\text{disrupt}} = \left( 2Q_D^*/V_{\text{imp}}^2 \right)^{1/3} D_{\text{target}} \quad (2)$$

where  $V_{\text{imp}}$  is the impact velocity. We assume here that the target and projectile have the same bulk density, although that is by no means assured. Small asteroids are considered part of the “strength-scaling” regime, where the fragmentation of the target body is governed by its tensile strength,

while large asteroids are considered part of the “gravity scaling” regime, where fragmentation is controlled by the self-gravity of the target (see section 4.1). Laboratory experiments and hydrocode modeling work discussed in the references above suggest the transition between the regimes occurs in the range  $100 < D < 200 \text{ m}$  (Fig. 1).

Testing what impacts do to undamaged targets with basalt-like physical properties, Benz and Asphaug (1999) found that the mass of the largest remnant  $M_{\text{LR}}$  after a collision can be fitted as a function of  $Q/Q_D^*$ , where the kinetic energy of the projectile per unit mass of the target is denoted by  $Q$

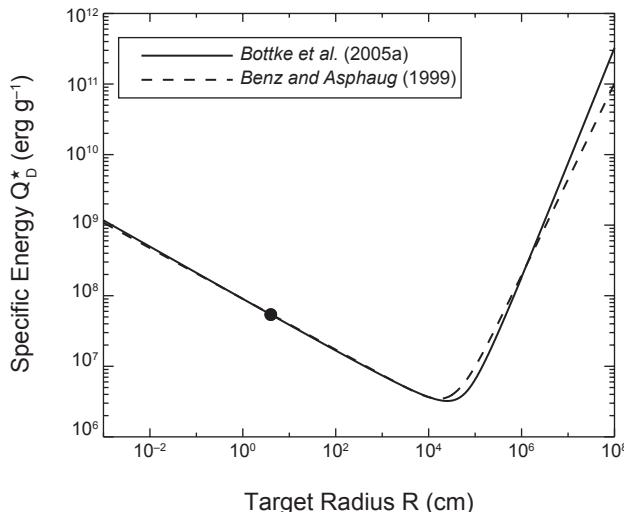

$$M_{\text{LR}} = \left[ -\frac{1}{2} \left( \frac{Q}{Q_D^*} - 1 \right) + \frac{1}{2} \right] M_T \quad (3)$$

for  $Q < Q_D^*$ , and

$$M_{\text{LR}} = \left[ -0.35 \left( \frac{Q}{Q_D^*} - 1 \right) + \frac{1}{2} \right] M_T \quad (4)$$

for  $Q > Q_D^*$ , where  $M_T$  is the target mass. Whenever  $M_{\text{LR}}$  in equation (3) turns out to be negative, one can assume that the target has been pulverized, such that all its mass is lost below some minimal mass threshold.

A missing aspect of this discussion is that asteroids have a wide range of physical properties and therefore may disrupt very differently than the idealized bodies used in numerical hydrocode runs. We refer the reader to the chapters in this

**Fig. 1.** The critical impact specific energy  $Q_D^*$  defined by Benz and Asphaug (1999). This function is the energy per unit target mass delivered by the projectile that is required for catastrophic disruption of the target, such that one-half the mass of the target body escapes. The dashed line is the function derived by Bottke et al. (2005a) for their modeling results. Both functions pass through the normalization point ( $Q_D^*, D$ ) set to  $(1.5 \times 10^7 \text{ erg g}^{-1}, 8 \text{ cm})$ , which was determined using laboratory impact experiments (e.g., Durda et al., 1998).

volume by Jutzi et al. and Michel et al., who discuss recent advances made in this area. Here we point out that all collisional models must, by necessity, make approximations to deal with complicated systems. This has led many modelers to assume that all asteroids (e.g., monoliths, rubble piles, etc.) follow the exact same  $Q_D^*$  functions for disruption. While this approach may be more accurate than one might expect (see results in the chapters in this volume by Jutzi et al. and Michel et al.), future collision evolution models will need to consider how specific asteroid types react to impacts. In addition, the influence of asteroid spin on  $Q_D^*$  has not been investigated so far in the hypervelocity impact regime, and it is likely that a spinning asteroid responds differently to an impact than a nonspinning one, as found in low-speed impacts between self-gravitating aggregates (e.g., Ballouz et al., 2014).

In practice, this will mean sorting all asteroids into broad categories that can be treated by individual  $Q_D^*$  functions. One possible way to divide them up would be by spectral signatures, such as the S-, C-, and X-complexes (see the chapter by DeMeo et al. in this volume). Within the complexes, bodies might share similar albedos (see chapters by Mainzer et al. and Masiero et al.), bulk densities and porosities (see chapter by Scheeres et al.), compositions, and so on. Differences between categories could then be dealt with in a logical fashion. For example, we know that C-complex bodies often have lower bulk densities and higher porosities than S-complex bodies, and studies of primitive carbonaceous chondrites suggest many are structurally weaker and have different grain structures as well (e.g., Britt et al., 2002). Whether this affects their  $Q_D^*$  function will then need to be determined by laboratory impact experiments and numerical hydrocode simulations of asteroid collisions. There will also be the issue of how to treat the exceptional cases (e.g., the X-complex include a wide range of asteroid types, internal structures, compositions, and bulk densities).

The hope is that this kind of work will eventually lead us to an understanding of the SFDs of different asteroid complexes and how they have changed over time. By getting the details right, it may be possible to ask more interesting questions about how the main belt reached its current state. Even the assumption that all asteroids should be placed into the S- or C-complexes, where their physical properties would be treated differently, would be an advance over current model assumptions.

### 2.3. Asteroid Fragmentation

One of the most difficult issues to deal with in any collisional evolution model is the treatment of the fragment SFD created when two bodies slam into one another. Given the wide range of parameters that could be involved in any collision, such as impact velocity, projectile and target sizes, impact angle, projectile and target properties, etc., it is a somewhat quixotic task to try to generate a “one size fits all” recipe capable of reproducing the outcomes of all meaningful cratering and catastrophic disruption events that could have ever taken place in the asteroid belt.

Comprehensive experimental work has been carried out over the last several decades on this subject. Studies based on hypervelocity laboratory impacts have provided threshold specific energies for shattering ( $Q_S^*$ ) among a wide range of materials, and scaling theories including strain-rate and gravity-scaling effects allow one to extrapolate those results to multi-kilometer-sized asteroids (Holsapple et al., 2002; chapter by Michel et al. in this volume). They show that  $Q_S^*$  and  $Q_D^*$  coincide in the strength regime, but  $Q_S^* < Q_D^*$  in the gravity regime and the minimum energy to disperse a given target can be expressed as the sum of the energy needed to shatter the body and the energy required to disperse the fragments. In this way, once the comparison between the impact specific energy and the value of  $Q_S^*$  is made, it is possible to determine whether the impact will be a cratering or a disruption event. In both cases the size distribution of the new fragments can potentially be calculated (e.g., Petit and Farinella, 1993). The critical quantity that discriminates cratering from shattering is the mass fraction between the largest fragment ( $M_{LR}$ ) and the target ( $M_T$ ), which is given by

$$f_{LF} = \frac{M_{LF}}{M_T} = 0.5 \left( \frac{Q_S^*}{E/2} \right)^{1.24} \quad (5)$$

In the case of a barely shattering impact event,  $f_{LF} = 0.5$ . Using  $Q_S^*$  instead of  $Q_D^*$  has the advantage of allowing one to calculate how many fragments are reaccumulated by the self-gravity of the non-escaping fragments (Campo Bagatin et al., 1994b).

One must also consider that many  $D < 100$ -km asteroids are likely to be second-generation gravitational aggregates. Campo Bagatin et al. (2001) tracked this aspect of collisional evolution, and found that the amount of reaccumulated mass for each object was enough that it could affect both the target body’s  $Q_D^*$  function as well as the fragment SFD created in an impact. Note that the lower size limit on gravitational aggregates is unknown; some meter-sized bodies may possibly be held together by cohesive forces (see the chapter by Scheeres et al. in this volume). Ultimately, little is known about the mass distribution of the fragments — aggregates themselves or single coherent components — coming out of a disrupting impact on a gravitational aggregate, although insights into this can potentially be gleaned from numerical hydrocode experiments of collisions on rubble-pile asteroids (Benavidez et al., 2012; see the chapter by Michel et al. in this volume).

Gravitational aggregates may also be produced by multiple subcatastrophic collisions, which may lead to the same result as a single shattering collision, provided their total energy is equivalent to the energy of the shattering event (Housen, 2009). This could mean some second-generation asteroids are gravitational aggregates with limited macro-porosity, due to the fact that fragments did not get enough kinetic energy to be jumbled and reshuffled. How these results feed into the creation of new fragment SFDs are uncertain. Improvements in this area, along the lines of an

updated *Campo Bagatin et al.* (2001) model, could help to better characterize collisional evolution in the main belt.

These issues influence the internal structure of asteroids. This may explain why mass and volume measurements of asteroids indicate a wide range of internal macroporosities for S- and C-complex asteroids (see the chapter by Scheeres et al. in this volume). Unfortunately, porosity is only a partial indicator of internal structure, as it is largely independent of the sizes of components. Porosity also hides the absolute sizes of components and their distribution. A porous gravitational aggregate might have a substantial microporosity (e.g., individual constituents with a fairy-castle structure) and/or a sizable macroporosity (e.g., large fragments and empty space near the contact points covered by regolith). The fact that many main-belt asteroids may have unusual internal structures makes it imperative that we obtain more ground truth on how real asteroids are affected by collisions.

Beyond this, it is important to recognize that our asteroid belt has been subject to an enormous number of stochastic events, and information about the fragments produced by ancient collisions has been lost by subsequent collisional and dynamical processes. This means the initial conditions for ancient family-forming events or even large cratering events (see the chapters by Asphaug et al. and Nesvorný et al. in this volume) may never be precisely known (see the chapters by Jutzi et al. and Michel et al.). A good example of this is the impact event that created the 400-km Veneneia basin on (4) Vesta; the basin has been partially buried/destroyed by the nearby Rheasilvia basin-formation event (*Schenk et al.*, 2012; see the chapter by Russell et al.).

Given these limitations, realistic modelers do the best they can with what they have. This means choosing parameters and formalism that are reasonable within the bounds of what is known and testing their results against the available constraints. The interpretation of even good matches, though, must always be met with some skepticism and wariness. Moreover, a careful modeler must also run simulations over numerous trials in an attempt to characterize how outcomes may have been affected by chance events (e.g., the disruption of a large asteroid at a strategic time or place may allow a model run to match constraints, yet this kind of event may not have happened in our asteroid belt).

To this end, modern collisional-evolution models have folded into their codes outcomes of numerical smoothed particle hydrocode (SPH) simulations that account for at least some of the parameters described above. For example, *Morbidelli et al.* (2009) constructed an algorithm that reproduced the fragment size distribution of the SPH results determined by *Durda et al.* (2004, 2007), who conducted a large number of collision simulations of projectiles of various masses and velocities striking 100-km-diameter asteroids. They found that most catastrophic collisions produce fragment SFDs that have a continuous, steep power-law size distribution starting from a single large fragment that is well separated in size from that of the largest remnant of the target.

The mass of the largest fragment and the slope of the power-law SFD in each of the experiments from *Durda et al.*

(2007) was described as a function of the ratio  $Q/Q_D^*$  that characterized each experiment

$$M_{LF} = 8 \times 10^{-3} \left[ \frac{Q}{Q_D^*} \exp^{-\left(\frac{Q}{4Q_D^*}\right)^2} \right] (M(i) + M(j)) \quad (6)$$

for the mass of the largest fragment and

$$q = -10 + 7 \left( \frac{Q}{Q_D^*} \right)^{0.4} \exp^{-\frac{Q}{7Q_D^*}} \quad (7)$$

for the slope of the cumulative power-law size distribution of the fragments. These equations represent empirical fits to the numerical hydrocode data. Note that comparable functions were created by *Cibulková et al.* (2014) from the rubble-pile impact simulation results of *Benavidez et al.* (2012). These equations were incorporated into their collisional-evolution models.

For fragment SFDs with very steep slopes, equations (5) and (6) can easily exceed the mass of the projectile and target, which is nonphysical. To avoid this problem, it is assumed that the fragment SFDs bend to shallower slopes at small sizes, although the precise diameter where this takes place is unknown; it is beyond the resolution limit of existing numerical hydrocode impact simulations.

It can be shown that the derived fragment SFDs from these simulations reproduce many attributes of observed asteroid families (*Durda et al.*, 2007). With that said, however, collisional outcomes and fragment SFDs are strongly affected by the target's gravitational forces; this means the impact outcomes onto 400-km targets differ from those of 100-km targets in terms of  $Q/Q_D^*$  (P. Benavidez, personal communication). The same is probably true for smaller targets as well. Major advances in this area will therefore come from those modelers who employ fragment SFDs appropriate for their target sizes.

A final interesting issue here is that analytical and numerical results suggest the final equilibrium main-belt SFD is often found to be relatively insensitive to the details of the fragmentation law (e.g., *Davis et al.*, 2002; *O'Brien and Greenberg*, 2003, 2005; *Bottke et al.*, 2005a,b; *Morbidelli et al.*, 2009). This statement is mainly based on experience, and it needs to be better quantified by modeling work. We suggest that while the fragmentation laws used are important, many are unlikely to dramatically change the equilibrium results. On the other hand, the choice of fragment SFD for given breakups will be important for investigating asteroid families and transient perturbations to the main-belt SFD.

## 2.4. Dynamical Depletion of Main-Belt Asteroids by the Yarkovsky Effect

As described in the chapter in this volume by Vokrouhlický et al.,  $D < 30$ -km asteroids in the main belt slowly drift inward toward or outward away from the Sun in semimajor

axis by Yarkovsky thermal forces. This allows some of them to reach resonances with the planets that drive them onto planet-crossing orbits, thereby allowing them to escape the main-belt region altogether. Additional mobility is provided by encounters with big asteroids like (1) Ceres and (4) Vesta, although the net effect of this mechanism is fairly modest (e.g., Carruba et al., 2003, 2013).

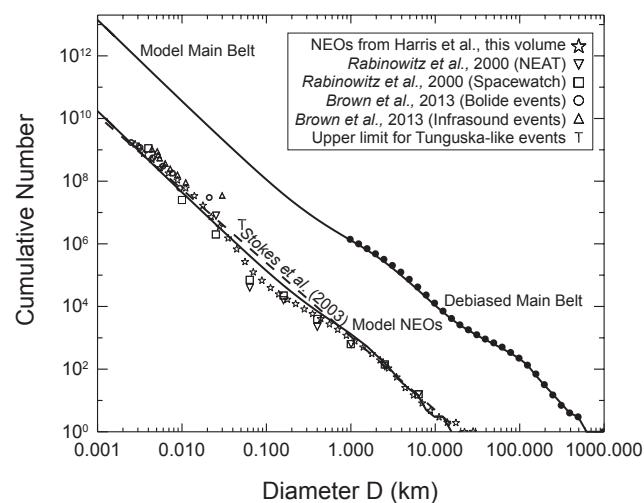

The Yarkovsky effect, working in concert with resonances, can therefore be considered a “sink” for small main-belt asteroids. Their depletion should feed back into the collisional evolution of the main belt itself (i.e., fewer smaller bodies means fewer cratering and disruption events among larger bodies). It also means that the near-Earth asteroid (NEA) population could be considered an short-lived component of the main-belt population. This allows the NEA SFD to constrain collisional and dynamical evolution within the main belt, provided the modeler understands the translation between the main belt and NEA SFDs (e.g., Morbidelli and Vokrouhlický, 2003).

The challenging part of this is to quantify the nature of small-body populations lost over time via the Yarkovsky effect and resonances. Consider the following:

- Every major main-belt resonance has a different character in its ability to produce long-lived near-Earth objects (NEOs) (e.g., Gladman et al., 1997; Bottke et al., 2006).
- The flux of asteroids reaching dynamical resonances may change over time as a consequence of asteroid family-forming events. Large asteroid families can produce enormous numbers of fragments, while smaller ones that disrupt in strategic locations next to key “escape hatches” may also influence the planet-crossing population for some interval (Nesvorný et al., 2002).
- The dynamical evolution of  $D < 1$ -km asteroids is poorly constrained because these bodies are below the observational detection limit of most surveys (e.g., Jedicke et al., 2002; see also the chapter by Jedicke et al. in this volume). Moreover, these bodies are also the most susceptible to YORP thermal torques, which can strongly affect their drift direction and evolution (see next section).

So far, no one has yet attempted to model all these factors and include them into an algorithm suitable for insertion into a collisional evolution code. It is a necessary but daunting task to do this correctly, given the current state of our knowledge of how the Yarkovsky/YORP effects modify the orbits, sizes, and shapes of small asteroids.

Instead, the best that has been done to date has been to generate loss rates for the asteroid belt that produce a steady-state population of NEOs (Bottke et al., 2005a; O’Brien and Greenberg, 2005; Cibulková et al., 2014) (Fig. 2). This approximation can provide interesting insights; for example, not including the Yarkovsky/resonance “sink” for small bodies may have a substantial affect on the collisional evolution of the main belt, with more projectiles left behind that can disrupt large main-belt asteroids (Cibulková et al., 2014).

**Fig. 2.** The estimated present-day main belt and NEO populations according to Bottke et al. (2005b) model runs (solid lines). For reference, we plot our results against an estimate of the NEA population made by Stokes et al. (2003), who assumed the  $D < 1$ -km size distribution was a power-law extension of the  $D > 1$ -km size distribution, and a population discussed in the chapter by Harris et al. in this volume. Our model main-belt population provides a good match to the observed main belt (solid black dots). Most diameter  $D \leq 100$ -km bodies are fragments (or fragments of fragments) derived from a limited number of  $D \geq 100$ -km breakups (Bottke et al., 2005a). Our NEO model population is compared to estimates derived from telescopic surveys (Rabinowitz et al., 2000), as well as satellite and infrasound detections of bolide detonations in Earth’s atmosphere (Brown et al., 2013). For reference, we also include an upper limit estimate of 50-m NEAs based on the airblast explosion that occurred over Tunguska, Siberia, in 1908. A mismatch between the NEA model and data is seen near  $D \sim 0.1$  km.

## 2.5. Asteroid Disruption by YORP Torques

The Yarkovsky-O’Keefe-Radzievskii-Paddack (YORP) effect is a thermal torque that, complemented by a torque produced by scattered sunlight, can modify the spin vectors of small asteroids (see the chapter by Vokrouhlický et al. in this volume). As an asteroid’s obliquity evolves, its orientation can strongly affect a body’s drift rate across the main belt, and therefore how quickly it reaches a resonance that can take it out of the main belt. YORP can also spin asteroids up or down. If the body has substantial unconsolidated material, or is a rubble pile, it must reconfigure itself to adjust to its new rotational angular momentum budget. In certain cases, this can cause the body to shed mass, potentially creating a satellite or an asteroid pair. Many of the latest aspects of the YORP effect are discussed in the chapters by Vokrouhlický et al. and Walsh and Jacobson in this volume.

YORP spinup may be so efficient at causing small asteroids to shed mass that this mechanism may dominate the production and elimination of bodies for  $D < 1$  km. This prospect is exciting, and we believe warrants continued

investigation using a wide range of models in the future. Indeed, recent main-belt modeling work that included collisional disruption and YORP mass-shedding mechanisms show the latter could explain the shape of the main belt SFD for subkilometer- and kilometer-sized bodies (*Marzari et al.*, 2011; *Jacobson et al.*, 2014; see also *Penco et al.*, 2004).

The goal of main-belt collisional models is to include all the major processes that affect mass loss from small bodies — collisions, Yarkovsky-driven removal of bodies, and YORP-driven mass shedding — in a self-consistent manner. So far, the models of *Bottke et al.* (2005a,b) and *Cibulková et al.* (2014) include the first two, while the models of *Marzari et al.* (2011) and *Jacobson et al.* (2014) include the first and third. Future models will have to include all these effects in the most accurate way possible, with their relative contributions sorted out using constraints. While this sounds straightforward, in practice the modeler must deal with numerous uncertainties, as well as all the feedbacks they produce.

As an example, consider the mismatch between the model and observed SFDs seen in Fig. 2. While a better fit is possible, and it should be a byproduct of the processes above, which one of them, if any, should dominate?

One could argue that varying the Yarkovsky depletion rates of asteroids from the main belt should solve the problem. Unpublished test runs performed by *Bottke et al.* (2005a,b) have shown that the shape of the main-belt SFD for subkilometer-sized bodies can be reproduced by assuming more asteroids escape over time than previously predicted. The central problem here is that the loss rates of subkilometer-sized bodies from the main belt are highly uncertain, with the coupling between Yarkovsky drift and the frequency/nature of so-called YORP-cycles only modestly well understood at this time (e.g., *Bottke et al.*, 2015a).

Alternatively, the mismatch might be readily fixed by including YORP-driven mass shedding, as suggested by *Marzari et al.* (2011) and *Jacobson et al.* (2014). We find this highly plausible, yet there is also much we do not yet understand when it comes to the details of YORP-driven mass shedding (see the chapter by Vokrouhlický et al. in this volume).

Consider that careful explorations of the YORP effect show there is a preference for asteroidal spinup vs. spindown (e.g., *Rozitis and Green*, 2012; *Golubov and Krugly*, 2012; *Golubov et al.*, 2014; see also the chapter by Vokrouhlický et al.). With this said, however, spindown must also exist in order to explain the relatively flat spin frequency distribution of small asteroids as well as why numerous very slow rotators exist (e.g., *Bottke et al.*, 2015a). There is also important work that shows that YORP torques are affected by small topographic changes on an asteroid. For example, *Statler* (2009) used numerical simulations to demonstrate that minor changes in an asteroid's shape, such as the formation of a small crater or even the movement of a boulder from one place to another, could modify the YORP torques enough to change the magnitude and sign of the spin rate. These changes produce a random walk in an asteroid's spin rate,

and has been coined the “stochastic YORP” effect. While more work is needed, stochastic YORP may prevent some small asteroids from undergoing mass shedding as often as predicted (*Cotto-Figueroa*, 2013; *Cotto-Figueroa et al.*, 2015; *Bottke et al.*, 2015a). This may explain why some small asteroids have shapes that suggest they have largely avoided substantial mass-shedding events. Conversely, certain bodies may return again and again to spinup-driven mass shedding, which may rapidly turn them into top-like shapes (see the chapter by Walsh and Jacobson in this volume). Probing the asteroidal shape dichotomy using numerical modeling work is an intriguing project for the future.

In the end, all these Yarkovsky and YORP-related issues will need to be better explored and quantified if we are to formulate superior main-belt-evolution models in the future.

## 2.6. Additional Processes

Some processes that affect planetesimal and planet formation have yet to be implemented into main-belt collisional evolution models. Key examples include (1) the implications of hit-and-run collisions, defined as the disruption and escape of portions of large projectiles striking still larger bodies (see the chapters by Scott et al. and Asphaug et al. in this volume); (2) planetesimal collisional evolution taking place side by side with accretion onto protoplanets/planetary embryos with all the appropriate dynamics and fragmentation events modeled correctly (e.g., *Levison et al.*, 2015a,b); (3) the effects of collisions on the dynamical evolution of an asteroid or planetesimal; and (4) the bombardment of main-belt asteroids by planetesimals forming and evolving within the terrestrial planet and gas giant regions (e.g., see the chapters by Morbidelli et al. and Scott et al. in this volume).

Some of these processes are difficult to include in a model until their effects have been evaluated, although they are almost certainly important for particular issues [e.g., hit-and-run collisions may explain the exposed core-like nature of (16) Psyche and (212) Kleopatra; see the chapters by Asphaug et al. and Scott et al. in this volume]. For other processes, their importance is still unclear because planet-formation models are incomplete and/or are lacking in key constraints (e.g., how much net collisional evolution is produced on indigenous main-belt asteroids via planetesimals from the terrestrial planet region?). We believe an exploration of processes (1)–(4) discussed above and their inclusion in future models will greatly improve the state of the art.

## 3. CONSTRAINTS ON COLLISIONAL-EVOLUTION MODELS

Given the large number of “knobs” that exist in collisional-evolution models, and the fact that these codes may provide the user with non-unique solutions, it is imperative to test results against as many constraints as possible. Given the breadth of predictions for such codes, this means accounting for how individual asteroids, asteroid families, and different asteroid populations have taken on their current

status. With sufficient constraints, bad parameter choices can be eliminated from contention.

On the other hand, it is important that one recognizes that our understanding of main-belt evolution is still limited, and the inclusion of faulty constraints into a code can also produce inaccurate results and poor predictions. Accordingly, most constraints should be treated with some caution, with the modeler and interpreter cognizant that both data and interpretation can and often do change with time.

With these caveats, we present a list of many of the constraints that should be considered when modeling the collisional evolution of the main belt.

### 3.1. Wavy Main-Belt Size-Frequency Distribution

One of the primary constraints for collisional-evolution models comes from the main-belt SFD. Improved estimates since the review chapter of *Jedicke et al.* (2002) were provided by pencil-beam studies of the main-belt population (*Gladman et al.*, 2009), the addition of asteroids colors from the Sloan Digital Sky Survey (SDSS) (e.g., *Parker et al.*, 2008), and new infrared data of many main-belt asteroids (see the chapters by *Mainzer et al.* and *Masiero et al.* in this volume). The inclusion of all these datasets into a single debiased SFD, however, has yet to be attempted, and it is beyond the scope of this chapter.

For basic purposes, one can derive an approximate main-belt SFD using the absolute magnitude H distribution provided by *Jedicke et al.* (2002), who combined results from the Sloan Digital Sky Survey (SDSS) for  $H > 12$  (*Ivezic et al.*, 2001) with the set of known main-belt asteroids with  $H < 12$ . To transform the H distribution into a size distribution, one can use the relationship between asteroid diameter D, absolute magnitude H, and visual geometric albedo  $p_v$  provided by *Fowler and Chillemi* (1992)

$$D = \frac{1329}{\sqrt{p_v}} 10^{-H/5} \quad (8)$$

A model main-belt SFD was made by *Bottke et al.* (2005a), who set  $p_v$  to 0.092 in order to match the observed asteroids described cited in *Farinella and Davis* (1992). This population is shown in Fig. 2. Overall, the observed and debiased main-belt SFD is wavy, with “bumps” near  $D \sim 3$  km and one near  $D \sim 100$  km. The reason for these bumps will be discussed in section 4.

For more precise constraints, and more model variables, one can treat different regions of the main belt separately. For example, *Cibulková et al.* (2014) divided the main-belt population into six distinct components: inner, middle, pristine, outer, Cybele, and high-inclination regions. This allowed them to track how each different regional SFD evolved in response to various collisional and dynamical processes. The observed SFDs in each region, however, have yet to be debiased, which means they must be treated as lower limits for modeling constraints.

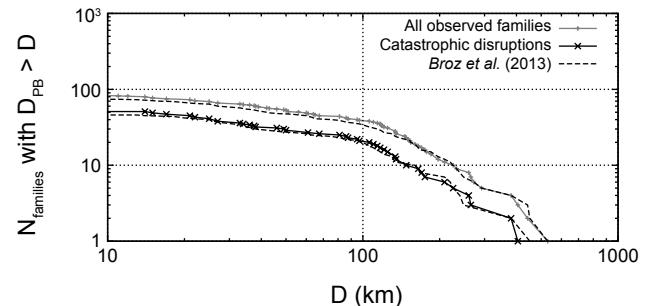

### 3.2. Asteroid Families

Asteroid families provide another powerful way to constrain asteroid collisional models. As discussed in the chapter by *Nesvorný et al.* in this volume, these remnants of cratering and catastrophic disruption events are identified in the main belt by their clustered values of proper semimajor axes  $a_p$ , eccentricities  $e_p$ , and inclinations  $i_p$ . The problem with using them to test our model runs is that estimates of ancient family ages can be imprecise and small families can also be eliminated over time by collisional and dynamical processes.

For this reason, the best starting constraints come from families where the parent body was large enough that their fragments could not be erased over 4 G.y. of evolution. We assume families formed prior to 4 G.y. ago were erased by sweeping/jumping resonances produced by late giant planet migration (see the chapter by *Morbidelli et al.* in this volume). Using results discussed in *Durda et al.* (2007) (see also *Cibulková et al.*, 2014), there are approximately 20 observed families created by catastrophic disruptions of parent bodies with sizes  $D_{PB} > 100$  km, where the ratio of the largest fragment’s mass to the parent body mass is  $M_{LR}/M_{PB} < 0.5$  (Fig. 3).

It is also useful to use the distribution of family parent body sizes to compare model to data. In one case, *Bottke et al.* (2005a,b) used results later published in *Durda et al.* (2007) to argue that the number of families formed over the last 3.5 G.y. from catastrophic breakups of parent bodies whose sizes were within incremental logarithmic-separated bins centered on diameters  $D = 123.5, 155.5, 195.7, 246.4, 310.2$ , and  $390.5$  km were 5, 5, 5, 1, 1, 1, respectively. New family identifications discussed in the chapter by *Nesvorný et al.* in this volume can be used to update these values.

Ideally, a good collisional model must account for all types of collisions, even relatively small cratering events. For the purpose of comparison with observations, one has to carefully select synthetic events that would still be observable. Even

**Fig. 3.** A production function [i.e., the cumulative number  $N(>D)$  of families with parent-body size  $D_{PB}$  larger than D] for all observed families (gray) and families corresponding to catastrophic disruptions (black), i.e., with largest remnant/parent body mass ratio lower than 0.5. Adapted from *Brož et al.* (2013) and updated according to the chapter by *Nesvorný et al.* in this volume. The families were assumed to form prior to 4 G.y. ago (see Fig. 4).

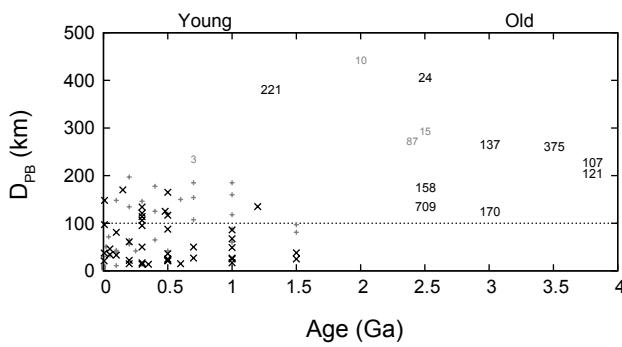

though this number ( $N_{\text{fam}} \sim 20$ ) appears well defined above, it is difficult to assess its uncertainty for the following reasons:

- Determining the size of the parent of an asteroid family depends on the observed fragment distribution, which has experienced collisional and dynamical evolution, and the nature of the precise breakup involved, which may be uncertain. The existence of interlopers within the family can also be hard to exclude.
- There are overlapping families that are difficult to separate unambiguously [e.g., several families exist in the Nysa/Polana region (M. Dykhuis, personal communication)].
- The method used for the parent body size determination in *Durda et al.* (2007) may exhibit some systematic issues since it involves a number of assumptions.

Taken together, the uncertainty of  $N_{\text{fam}}$  is at least the order of a few, if not more.

The distribution of the dynamical ages and sizes of families, as derived using the methods discussed in the chapter by Nesvorný et al. in this volume, may also provide another metric to estimate family completeness. For example, Fig. 4 shows estimates of the ages of cratering and catastrophic disruption events for families derived from different parent body sizes (Brož et al., 2013). We caution the reader that discerning these values for heavily evolved ancient families is problematic, and large uncertainties exist. We therefore use Fig. 4 as a guide to glean insights into interesting possibilities, not as the last word on this topic.

We focus here on asteroid families with parent body diameters  $D_{\text{PB}} > 100$  km; they are presumably more difficult to eliminate by collisional and dynamical processes. For families formed over the last 2 G.y., we find several with  $100 < D_{\text{PB}} < 200$  km and few with  $D_{\text{PB}} > 200$  km. The opposite is found for families older than 2 G.y.; only a few  $100 < D_{\text{PB}} < 200$ -km families exist, while several  $D_{\text{PB}} > 200$  km are found.

**Fig. 4.** The relationship between dynamical ages of families and the sizes of their parent bodies. Black labels, shown as x's and numbers, correspond to catastrophic disruptions, while cratering events, shown as crosses and numbers, are labeled in gray. Some of the families are denoted by the designation of the largest member. Adapted from Brož et al. (2013) and updated according to the chapter by Nesvorný et al. in this volume.

The difference between the two sets warrants additional study, but statistics of small numbers prevents us from saying they are highly unusual. The probability that two  $D_{\text{PB}} > 200$ -km families formed in the last 2 G.y. out of the seven identified with ages  $< 4$  G.y. is 23%. The number of  $100 < D_{\text{PB}} < 200$ -km families that formed at different times are also not unusual from a statistical standpoint. Overall, there are also approximately the same number of young ( $t_{\text{age}} < 2$  G.y.) and old ( $> 2$  G.y.) families produced by the catastrophic disruptions of  $D_{\text{PB}} > 100$ -km bodies.

The most intriguing issue here is that there are no identified  $D_{\text{PB}} < 100$ -km families that are  $> 2$  G.y. old. This hints at the possibility that some  $100 < D_{\text{PB}} < 200$ -km families older than 2 G.y. are so evolved that they escaped detection. If true, one could argue that something interesting was going on that was producing  $D_{\text{PB}} > 100$ -km families in the billion years or so after the completion of the major dynamical depletion events  $> 4$  G.y. (see section 1 and the chapter by Morbidelli et al. in this volume.).

Along these lines, one way to account for the unusual distribution of families in Fig. 4 is to assume that some small families are actually remnants, or “ghosts,” of much larger older families. A possible example might be the cluster of asteroids near asteroid (918) Itha (Brož et al., 2013). It exhibits a very shallow SFD, which could be a possible outcome of comminution and dynamical evolution by the size-dependent Yarkovsky effect. An excellent place to look for ghost families would be the narrow portion of the main belt with semimajor axis  $a$  between 2.835 and 2.955 AU. This pristine zone, which is bounded by the 5:2 and 7:3 mean-motion resonances with Jupiter, has a limited background population of small asteroids. We postulate it could resemble what the primordial main belt looked like prior to the creation of many big families.

An independent calibration of collisional models might also be based on very *young* families, namely younger (and larger) than some carefully estimated upper limit for which the respective sample is complete. Indeed, there are many examples of young families with well-determined ages: Veritas ( $8.3 \pm 0.5$ ) m.y. (Nesvorný et al., 2003), Karin ( $5.8 \pm 0.2$ ) m.y. (Nesvorný and Bottke, 2004), Lorre ( $1.9 \pm 0.3$ ) m.y. (Novaković et al., 2012), P/2012 F5 (Gibbs) ( $1.5 \pm 0.1$ ) m.y. (Novaković et al., 2014), etc. A collisional model then would have to reproduce the number of these events in the last  $\approx 10$  m.y. or so of the simulation.

### 3.3. Impact Basins on (4) Vesta

(4) Vesta is one of the most unique asteroids in the main belt. Not only is it among the largest asteroids, with a diameter of 525 km, but it is also has a largely intact basaltic crust that was put in place shortly after it differentiated some 2–3 m.y. after CAIs (see the chapter by Russell et al. in this volume). Decades of groundbased observations, combined with *in situ* observations of Vesta by the Dawn spacecraft, have shown that the spectral signatures found in Vesta’s crust are a good match to the howardite, eucrite, and diogenite

(HED) meteorite classes (see the chapter by Russell et al.). We do not consider the impact record on Vesta prior to the formation of this crust, although Vesta's abundance of highly siderophile elements may eventually allow us to infer what happened during this ancient period (e.g., Dale et al., 2012).

Vesta also has two enormous basins that dominate its southern hemisphere: Rheasilvia, a 505-km-diameter crater with an estimated crater retention age of 1 G.y., and Veneneia, a 395-km-diameter crater with a crater retention age of  $>2$  G.y. (Marchi et al., 2012). Rheasilvia, being younger, overlaps with and has largely obscured Veneneia (Schenk et al., 2012; Jaumann et al., 2012). The formation of each basin is also thought to have produced a set of fracture-like troughs, or graben, near Vesta's equator (Buczkowski et al., 2012). Studies of each trough group show they form planes that are orthogonal to the basin centers. Recent simulations of the formation of the Veneneia and Rhealsilvia basins using numerical hydrocodes suggest they were created by the impact of 60–70-km-diameter projectiles hitting Vesta near  $5 \text{ km s}^{-1}$  (Jutzi et al., 2013; see the chapters by Asphaug et al. and Jutzi et al. in this volume). These same events likely produced the majority of the observed Vesta family, a spread out swarm of  $D < 10$ -km asteroids in the inner main belt with inclinations and spectral properties similar to Vesta itself (see the chapter by Scott et al. in this volume).

Vesta shows no obvious signs that basins similar in size to Rheasilvia or Veneneia were ever erased or buried after its basaltic crust was emplaced; nothing notable is detected in Vesta's topography, and there are no unaccounted sets of troughs that could be linked with a missing or erased basin. This means Vesta is probably complete in Rheasilvia- or Veneneia-sized basins. This constrains both the size of many primordial populations as well as how long they could have lasted on Vesta-crossing orbits (e.g., main-belt asteroids, leftover planetesimals from terrestrial and giant planet formation, the putative late heavy bombardment (LHB) population, Jupiter-family comets, etc.).

As a working example, consider that if we use the main-belt asteroid population described in Bottke et al. (1994), where there are 682 main-belt asteroids with  $D > 50$  km, we find that the probability that Vesta has 0, 1, 2, or 3+ Rheasilvia/Veneneia formation events over the last 4 G.y. is 50%, 35%, 12%, and 3%, respectively. If Rheasilvia and Veneneia are actually both  $<2$  G.y. old, however, these values change to 70%, 25%, 4%, and 0.5%, respectively. The 4% probability for the observed situation is surprisingly small, and it suggests two possibilities: Veneneia's crater retention age was strongly affected by the Rheasilvia formation event, and its formation age is older than its crater retention age (Schenk et al., 2012), or the basins on Vesta's surface beat the odds. Note that testing modestly smaller projectiles to make the basins, such as  $D > 35$ -km asteroids (Asphaug et al., 1997), only increases the probabilities above by a factor of 2 or so.

These calculations become even more interesting if we assume the main-belt population was larger in its early history, and/or that it was hit by objects from outside the main

belt (see the chapter by Morbidelli et al. in this volume). Bottke et al. (2005a) argued the main belt experienced the equivalent of  $\sim 7.5$ – $9.5$  G.y. of collisional evolution over the last 4.56 G.y. (i.e., roughly translated as the number of impacts Vesta would get if it resided in the current main-belt population for this time; see section 4). For simplicity, we round this value to 10 G.y., which makes the probability of getting 0, 1, 2, or 3+ basins at any time in Vesta's history 17%, 30%, 27%, and 20%, respectively. This would place the Rheasilvia/Veneneia combination near the center of the probability distribution. If Rheasilvia/Veneneia formed  $<2$  G.y. ago, however, we not only have to explain their existence, but also the absence of ancient basins; large primordial populations are more likely to create ancient basins than young ones. The probability of these events taking place is only  $\sim 1\%$ .

Therefore, from a purely statistical point of view, one could argue that the main belt was probably more massive in the past, and that Veneneia's minimum age of  $\sim 2$  G.y. is not its formation age. An older age for Veneneia would also allow it to be the source for numerous Vesta family members with low inclinations, which need billions of years to reach these orbits via Yarkovsky drift and resonances (Nesvorný et al., 2008). Further work will be needed to see if the "facts on the ground" confirm or reject these predictions.

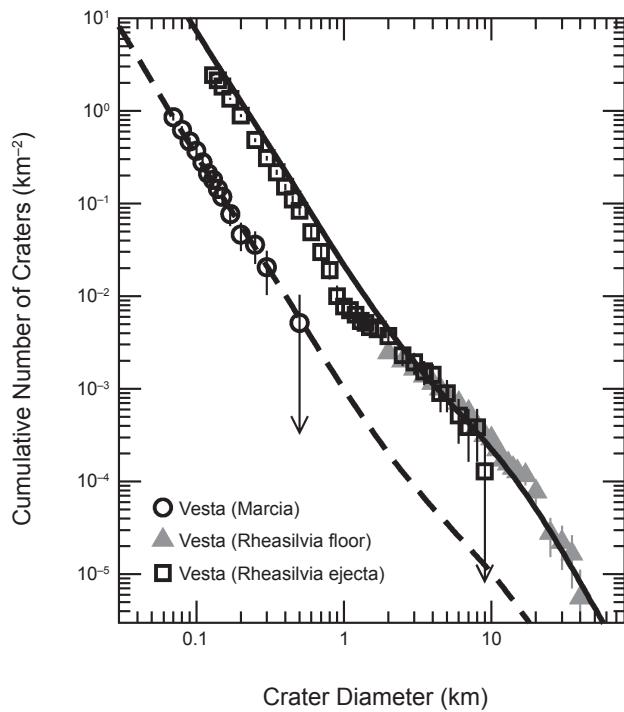

### 3.4. Near-Earth Asteroids, Asteroid Craters, and Lunar Craters

Asteroids in the main belt have struck other asteroids throughout the lifetime of the solar system. This means that projectile SFDs ranging from a few meters to multi-kilometer sizes can be constrained over hundreds of millions to billions of years by craters found on asteroids imaged by spacecraft missions (see the chapter by Marchi et al. in this volume). The main-belt SFD also produces planet-crossing asteroids via the combined Yarkovsky/YORP effects (see the chapter by Vokrouhlický et al.). This means that the observed planet-crossing asteroid population can also be used to provide main-belt SFD constraints. We focus here on the best-understood component of the population, namely the NEAs (see the chapter by Harris et al.). Finally, Earth-crossing asteroids in the NEA population have slammed into Earth and the Moon over billions of years, which means the crater SFDs and impact byproducts on these worlds can help us determine how the main-belt SFDs have evolved over these times.

The key issue for all these data is interpretation; the ages and SFDs of cratered terrains are often uncertain or complicated, and short-term changes in the flux or shape of impacting SFDs can be hard to decipher amid the integrated histories of cratered surfaces. For this reason, a full discussion of all cratering issues is beyond the scope of this section. Instead, we provide a brief summary of how asteroid and lunar craters, together with the debiased NEA population, can be used as constraints for main-belt collisional models, provided appropriate caution is employed by the reader.

The crater histories of the asteroids visited by spacecraft are reviewed in the chapters by Marchi et al. and Barucci et al. in this volume. They found that the crater SFDs that do the best job of showing off the main-belt production population are found on (951) Gaspra and (4) Vesta. Crater data for Vesta is shown in Fig. 5, while Gaspra crater data can be found in the chapter by Marchi et al. The cumulative crater SFD found on or near Vesta's Rheasilvia basin shows, from large to small craters, a wavy shape: a steep slope up to an inflection point at 20 km, a shallow slope to a roundoff near 4 km, an even shallower slope to 0.8 km, and a steep slope to 0.01 km, where the resolution limit is reached. The craters superposed on Vesta's Marcia crater and on Gaspra's surface have the same slope as that found on Rheasilvia for <0.8-km craters. If we assume the scaling relationship between asteroids and craters is a simple factor of 10 (Bottke and Chapman, 2006; Marchi et al., 2013), these values yield a wavy asteroid SFD with inflection points at ~2 km, 0.4 km, and 0.08 km. As a caveat, it is also possible that some aspects of the wavy crater SFD on Vesta are a byproduct of terrain properties (Marchi et al., 2012, 2014).

The nature of the NEA SFD is thoroughly discussed in this volume in the chapter by Harris et al., so we only discuss a few aspects of it here. Their best estimate of the NEA population is shown in Fig. 2. Its wavy shape is broadly similar to a scaled version of the crater SFD found on Vesta in Fig. 5,

**Fig. 5.** The crater SFDs found on the young terrains of Marcia crater and the floor and ejecta blanket of the basin Rheasilvia. Details can be found in the chapter by Marchi et al. in this volume. The fit is good except near  $0.7 < D < 2$  km, where the model steepens too quickly.

although some differences exist; recall that the main-belt SFD is modified en route to the NEA population by Yarkovsky/YORP-driven asteroid migration (e.g., Morbidelli and Vokrouhlický, 2003). The inflection points for the NEA population in Fig. 2, however, are at approximately the same sizes as derived above: ~2, 0.4, and 0.1 km. Our interpretation is that the broad shapes of the main-belt and NEA population have not been strongly modified for an extended period.

A similar analysis can be performed on the lunar crater SFD plotted in Fig. 1 of Ivanov et al. (2002). The broad shapes are the same as that above, with crater diameter inflection points at 64 km, 1.4 km, and 0.3 km. The middle inflection point at 1.4 km possibly straddles a slowly bending region between 1 and 3.5 km. Using crater-scaling-law relationships from Melosh (1989), these values roughly correspond to 2–3 km, 0.03–0.16 km, and 0.009–0.014 km. As before, these compare well to the values above.

In summary, the scaled asteroid and lunar crater data, together with the NEA population, all suggest a wavy main-belt SFD with inflection points near ~2–3, 0.4, and 0.1 km. Collectively, these results imply that the shape of the main-belt SFD for asteroid sizes smaller than 5–10 km has not substantially changed for billions of years.

If the shape of the main-belt SFD has remained the same over time, what can be said about the size of the population? Here we turn once again to the Moon, our benchmark for solar system chronology. Many nearside lunar terrains have been dated by returned samples. The crater populations found on these surfaces give us a sense of how the Earth-crossing impactor flux has changed with time (e.g., Stöffler and Ryder, 2001; Morbidelli et al., 2012). Given that this flux is fed by the main-belt population, changes in the lunar impactor flux over time should correspond at some level to what took place in particular regions of the main belt.

Studies of small lunar craters ( $D < 1$  km) on specific Copernican and Eratosthenian-era terrains suggest the impact flux of very small impactors has been fairly constant, within a factor of 2 or so, for the last 3.2 G.y. (e.g., Ivanov et al., 2002; Marchi et al., 2009; Hiesinger et al., 2012; but see also Robbins, 2014). For reference, the ages of the former era are often considered to be roughly 1 G.y. old, while those of the latter are defined by the ages of samples returned by the Apollo 12 astronauts (Stöffler and Ryder, 2001). This implies the main-belt population in the inner and central main belt feeding  $D < 0.05$ -km bodies to resonances may have been reasonably stable as well.

For larger impactors, the lunar data is more difficult to interpret, although it also hints at a steady state flux. For example, the best available crater SFD of the largest Copernican- and Copernican and Eratosthenian-era craters on the Moon are shown in Fig. 6 (McEwen et al., 1997; Ivanov et al., 2002). The Copernican and Eratosthenian-era craters are roughly a factor of 3 higher than the Copernican-era craters. If the ages of these eras suggested above are reasonable, these data would indicate there have been a fairly steady supply of kilometer-sized main-belt asteroids to the NEA population and the Moon over 3 G.y. (to a factor of 2 or so).

We caution that this interpretation may be subject to revision in the near future once data from the Lunar Reconnaissance Orbiter has been fully evaluated (e.g., Kirchoff *et al.*, 2013; Robbins, 2014). For example, asteroid-family-forming events in strategic locations could potentially affect the lunar impact flux for some period of time (Nesvorný *et al.*, 2002; Bottke *et al.*, 2007, 2015). Given our present state of knowledge, however, it is fair to say that deviations from a steady state over long time spans may be modest for most projectile sizes.

There are two main reasons these results are of critical importance for collision models:

1. Collisional models of the main-belt and NEA SFD need to achieve a quasi-steady-state for the last several billions of years (or have an alternative way to explain the above constraints). This likely rules out scenarios where a very large main-belt SFD is ground down over billions of years of comminution, with the observed SFD only achieved near the present time (see Davis *et al.*, 2002). Such models should produce strongly decaying lunar impact fluxes over the last 3 G.y., and they are not observed.

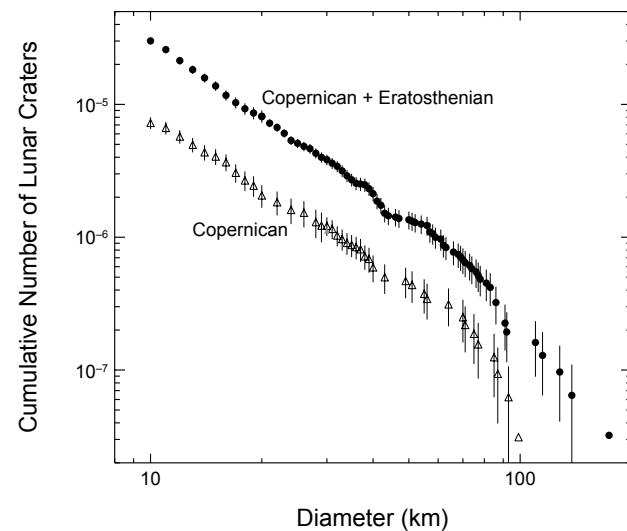

2. A steady-state main-belt SFD allows modelers to predict the ages of asteroid surfaces with reasonable accuracy, although caution should still be employed (see the chapter by Marchi *et al.* in this volume).

### 3.5. Main-Belt Binaries Formed by Impacts

The population of certain types of asteroid binaries may also constrain the collisional evolution of the main belt. Using numerical hydrocode simulations to model asteroid impacts on  $D = 100$ -km target bodies, Durda *et al.* (2004) found that large-scale cratering events can create fragments whose trajectories can be changed by particle-particle interactions and by the reaccretion of material onto the remnant target body. Under the right circumstances, impact debris can enter into orbit around the remnant target body, which is a gravitationally reaccreted rubble pile, to form a SMashed Target Satellite (SMATS).

Here we only discuss SMATS made by subcatastrophic collisions. We expect those SMATS to be rather isolated in space; while their formation events produce asteroid families dominated by small fragments, most of these bodies are readily removed or dispersed by collisional and dynamical evolution. As of a few years ago, detection limits of groundbased adaptive optics searches limited the discovery of SMATS to primary-to-secondary diameter ratios smaller than 25 (e.g., Merline *et al.*, 2002). This population is thought to be complete, so we focus on these binaries here. In a survey of 300 large main-belt asteroids, Merline *et al.* (2002) reported four  $D > 140$ -km bodies that had relatively large satellites (i.e.,  $D > 10$  km) that were not in asteroid families produced by catastrophic disruption events: (22) Kalliope, (45) Eugenia, (87) Sylvia, and (762) Pulcova.

Additions since that time to the SMATS record could include (216) Kleopatra and (283) Emma, whose primaries have diameters that are nearly 140 km. The secondary

**Fig. 6.** Lunar craters in the Copernican and Copernican and Eratosthenian eras as defined by Wilhelms *et al.* (1978) and McEwen *et al.* (1997). The absolute ages of these craters are often considered  $<1$  and  $<3.2$  G.y. old (Stöffler and Ryder 2001), although the age of the former is debated (e.g., Ryder *et al.*, 1991). The plotted Copernican-era craters are a combination of nearside craters (Wilhelms, 1987) and far-side rayed craters (McEwen *et al.*, 1997). These estimates may be revised using Lunar Reconnaissance Orbiter data in the near future.

sizes of Eugenia and Emma, however, are very close to our primary-to-secondary diameter ratio limit, and Kleopatra appears to have an iron rather than stony composition, such that the results of Durda *et al.* (2004) may not be applicable. This leaves the net value somewhere in the range of 3–6. The binary (90) Antiope is excluded here because it is a likely byproduct of the catastrophic disruption that produced the Themis family.

Using their runs, Durda *et al.* (2004) estimated that the expected frequency of SMATS-forming events by non-catastrophic collisions in the present-day main belt was  $f = 0.9\text{--}1.7 \times 10^{-11}$  yr $^{-1}$ . If one then assumes that the current population of  $D > 140$ -km bodies,  $N = 94$ , is similar to that from 4 G.y. ago, we would expect these production rates to yield 3–6 SMATs on average. These results are an excellent match to the 3–6 SMATs discussed above.

These results place upper limits on what happened during the primordial phase of the asteroid belt, depending on the planet formation evolution model invoked. For example, as described in the chapter by Morbidelli *et al.* in this volume, the main belt potentially had an early massive phase, where numerous SMATS should have been made. A dynamical depletion event at the end of this phase would then remove most of the excess mass as well as most of the newly formed SMATS. Effectively, this would make the remnant number of primordial SMATS the product of  $f$ ,  $N$ , and the time interval that the excess population existed in the main belt. For Nice model simulations (see the chapter by Morbidelli *et al.*),

where the main belt is only a few times more massive than the current population for  $\sim 0.5$  G.y., this would yield  $\sim 1$  extra SMAT on average, not enough to affect the results above.

On the other hand, SMATS provide powerful constraints against evolution scenarios where collision grinding alone removes most of the primordial mass of the main belt. This scenario is already problematic, as discussed above, but numerous collisions may produce a net amount of SMATS that exceeds observations. Similarly, massive planetesimal populations on terrestrial planet-crossing orbits may create numerous SMATS. Given that we see little evidence for an abundance of primordial SMATS, these models can potentially be tested on this basis.

### 3.6. Asteroid Spin Rates and Spin States

Asteroid spin rates are affected by collisions, so it is plausible they can be used as constraints on main-belt evolution. A problem with this is that many  $D > 50\text{--}100$ -km bodies may still have spins that were largely put in place by the planetesimal accretion process. A review of the spin rate literature for the largest asteroids can be found in *Bottke et al.* (2005a). For smaller bodies, the spin rates and obliquities of  $D < 30\text{--}40$ -km asteroids are likely dominated by the effects of YORP thermal torques (e.g., *Pravec et al.*, 2002; see the chapter by Vokrouhlický et al. in this volume). Given this, an unambiguous signal of collisions affecting spin vectors in the main belt may be limited to bodies whose evolutionary context is well understood.

The interested reader can consider the spin-evolution models of *Farinella et al.* (1992) and *Marzari et al.* (2011) for their views on this topic. They should also examine results from the numerical hydrocode simulations of *Love and Ahrens* (1997), who argued that small erosive collisions have a minimal effect on an object's spin, while catastrophic disruption events essentially destroy all "memory" of the target body's initial spin. The collisional signal we are looking for, therefore, may be limited to specific remnants of certain family-forming events.

An alternative way to obtain a model constraint may be found in the spin vectors of asteroids in the Koronis asteroid family. The Koronis family is thought to be one of the asteroid belt's most ancient families, with an estimate age of 2–3 G.y. (see the chapter by Nesvorný et al. in this volume). After years of painstaking observations of Koronis family members, including 21 of the 25 brightest Koronis family members, *Slivan et al.* (2003, 2009), *Slivan* (2002), and *Slivan and Molnar* (2012) reported that nearly all of the observed 15–40-km-diameter Koronis family members with prograde spins have clustered spin periods between 7.5 and 9.5 h and spin obliquities between  $39^\circ$  and  $56^\circ$ . Those with retrograde spins have obliquities larger than nearly  $140^\circ$  with periods either  $< 5$  h or  $> 13$  h. *Vokrouhlický et al.* (2003) demonstrated that all these spin states were a byproduct of YORP thermal torques. The prograde cluster was created by an interaction between YORP torques and spin orbit resonances, and are now called "Slivan states."

The predicted timescales for these objects to reach these spin states is several billions of years. During that time, collisions did not strongly affect their spin periods or their obliquities; if they had, we would see at least a few bodies with random spin vector values. Limits on this come from (243) Ida, a member of the prograde cluster with dimensions of  $53.6 \times 24.0 \times 15.2$  km; it was apparently unaffected by the formation of two  $\sim 10$ -km-diameter craters formed on its surface.

Statistically, we would expect catastrophic disruptions to be more rare than smaller, less-energetic impact events that can modify an asteroid's spin state. In the ancient Koronis family, however, the spin vectors of many large objects show no evidence that collisions have affected them. This presents a key challenge to collisional models that assume disruption events among 20–40-km bodies are relatively common; can this outcome be reconciled with the spin states of Koronis family members? A similar argument could potentially be developed regarding the anisotropic obliquities found among  $D < 30$ -km asteroids residing in the background main-belt population (e.g., *Hanus et al.*, 2013).

### 3.7. Additional Constraints

The constraints discussed above are far from complete, and many other datasets could be brought to bear in a collisional model. For space reasons, we do not include a discussion of (1) the cosmic-ray-exposure ages of stony meteorites (e.g., *Eugster*, 2003); (2) the orbital distribution of fireballs (e.g., *Morbidelli and Gladman*, 1998); (3) the population of V-type asteroids across the main belt (see the chapter by Scott et al. in this volume); (4) the crater records found on Mercury, Venus, Earth, and Mars (e.g., *Ivanov et al.*, 2002); (5) all asteroid families not discussed here (see the chapter by Nesvorný et al. in this volume); and (6) the shock degassing ages of meteorites (e.g., *Marchi et al.*, 2013). In fact, the subject of collisional evolution in the main belt is rich enough that data from numerous *Asteroids IV* chapters could probably be employed as well.

## 4. INSIGHTS FROM MODELING RESULTS

Existing collisional modeling work has provided us with insights into the nature of planetesimal formation, asteroid fragmentation and evolution, planet-formation processes, and the bombardment history of the inner solar system. Here we summarize some of those findings.

### 4.1. The Relationship Between the Main-Belt Size-Frequency Distribution and Asteroid Disruption Scaling Laws

The bump in the main-belt SFD near  $D \sim 2\text{--}3$  km (Fig. 2) is a byproduct of collisional evolution (*Campo Bagatin et al.*, 1994; see *Davis et al.*, 2002), and is driven by a change in the  $Q_D^*$  function near  $D \sim 0.2$  km. To trace its origin, we start with the classic work of *Dohnanyi* (1969) (later

expanded by *Williams and Wetherill*, 1994, and *Tanaka et al.*, 1996), who analytically modeled collisions among a SFD of self-similar bodies and found the steady-state SFD should follow a differential power law with an exponent of  $-3.5$ . Dohnanyi assumed that the strength per unit mass of the colliding bodies is independent of size. In reality, though, for bodies smaller than  $\sim 0.2$  km in diameter, material properties cause strength to decrease with increasing size, while for larger bodies, self-gravity makes it more difficult to shatter a body and disperse its fragments, leading to an increase in strength with increasing size (e.g., *Asphaug et al.*, 2002; *Holsapple et al.*, 2002; *Davis et al.*, 2002). This provides us with the classic  $Q_D^*$  function discussed above.

The dependence of the power-law index of the size distribution on these parameters was explored analytically by *O'Brien and Greenberg* (2003), and we repeat the main results here. First consider the steady-state of a colliding population of bodies whose strength is described by a single power law. The population is described by the power law

$$dN = BD^{-p} dD \quad (9)$$

where  $dN$  is the incremental number of bodies in the interval  $(D, D + dD)$ . While  $B$  should technically be negative as there are more small bodies than large bodies, it is defined to be positive here to avoid the physically unrealistic result of having negative numbers of bodies in a given size interval.  $p$  is the power-law index of the population. Equation (9) would plot as a line with a slope of  $-p$  on a log-log plot.

*O'Brien and Greenberg* (2003) considered the case where the impact strength  $Q_D^*$  is given by a power law

$$Q_D^* = Q_0 D^s \quad (10)$$

where  $Q_0$  is a normalization constant and  $s$  is the slope of equation (10) on a log-log plot. They find that, in collisional equilibrium, the power-law index  $p$  in equation (9) is given by

$$p = \frac{7 + s/3}{2 + s/3} \quad (11)$$

For  $s = 0$ , which corresponds to size-independent strength  $Q_D^*$ , this gives the classical Dohnanyi steady-state solution of  $p = 3.5$ . For the more realistic case where  $Q_D^*$  decreases with increasing size for small bodies and increases for larger bodies once gravity becomes important (as schematically shown in Fig. 1), *O'Brien and Greenberg* (2003) show that the strength- and gravity-scaled portions of the size distribution have power-law indices  $p_s$  and  $p_g$  that are only dependent on the slope of  $Q_D^*$  in the strength and gravity-scaled regimes  $s_s$  and  $s_g$ , respectively. The power-law index of the size distribution in the strength-scaled regime  $p_s$  has no dependence on the slope  $s_g$  of  $Q_D^*$  in the gravity-scaled regime, and vice versa;  $p_s$  is found by using  $s_s$ , and  $p_g$  is found by using  $s_g$ . Because  $s_s$  is usually negative and  $s_g$  is usually positive, equation (11) yields  $p_s > 3.5$  and  $p_g < 3.5$ .

While the general slope of the size distribution in the gravity regime is unaffected by  $Q_D^*$  in the strength regime,

the transition in slope of the size distribution will lead to waves that propagate through the size distribution in the gravity regime. In the derivation of  $p_g$ , it is implicitly assumed that all asteroids were disrupted by projectiles whose numbers were described by the same power law. However, for those targets just larger than the transition diameter  $D_t$  between the strength- and gravity-scaled regimes (i.e., near the small end of the gravity-scaled regime), projectiles are mostly smaller than  $D_t$ , and hence are governed by the strength-scaled size distribution. As these projectiles will be stronger and hence more numerous than would be expected by assuming that all bodies are gravity-scaled, they will lead to a depletion of bodies of diameter  $D_t$ . This underabundance of bodies of diameter  $D_t$  (a “valley”) leads to an overabundance of bodies that impactors of diameter  $D_t$  are capable of destroying (a “peak”), which in turn leads to another “valley” and so on. This results in a wave that propagates through the large-body size distribution, as can be seen in Fig. 2. The average power-law index  $p_g$  of the population in the gravity-scaled regime will not be significantly changed by the initiation of this wave; the wave oscillates about a power law of slope  $p_g$ . Analytical expressions for the amplitude of the waves, as well as the approximate positions of the “peaks” and “valleys” in the size distribution, are derived in *O'Brien and Greenberg* (2003). The waves will not continue on to larger bodies if they have long collisional lifetimes. The origin of the bump for  $D > 100$ -km bodies is discussed in the next section.

Finally, we note that removing all small bodies instantaneously from the population (i.e., creating a small body cutoff) can also launch a wave into the size-frequency distribution (*Campo-Bagatin et al.*, 1994; *Penco et al.*, 2004). The effect is minimized, however, if removal is more gradual. This was demonstrated by both *O'Brien* (2009), who found the depletion expected from Yarkovsky removal is too small to significantly perturb the main-belt size distribution (section 2.4), and by *Durda et al.* (1997), who found the same result when they modeled the expected dust distribution created by the main belt collisions and Poynting-Robertson drag.

#### 4.2. Large Asteroids as Byproducts of Planetary Formation

One of the most difficult issues to deal with concerning main-belt evolution is estimating the initial SFD created by planetary formation mechanisms. Given the current uncertainties surrounding planet formation, a enormous range of starting SFDs are theoretically plausible. This has caused many groups to winnow these possibilities down using collisional models.

For example, *Bottke et al.* (2005a,b) tested a wide range of initial SFDs and  $Q_D^*$  functions to determine which combinations work the best at reproducing the observational constraints discussed in section 3. They found that  $Q_D^*$  functions similar to those derived in numerical SPH experiments of asteroid breakup events (*Benz and Asphaug*, 1999)

tended to work the best (Fig. 1), although this made their  $D > 100$ -km asteroids very difficult to disrupt. Accordingly, they inferred that the shape of the main-belt SFD for  $D > 100$ -km asteroids was probably close to its primordial shape (Fig. 2). Interestingly, this prediction is consistent with several pioneering papers from the 1950s and 1960s (Kuiper *et al.*, 1958; Anders, 1965; Hartmann and Hartmann, 1968).

Next, they tested initial main-belt SFDs where the incremental power law slope of  $-4.5$  between  $100 < D < 200$  km had been extended to  $D < 100$ -km bodies (Fig. 7). This eliminated the observed bump near  $D \sim 100$  km. They found bodies in this size range were so difficult to disrupt that initial SFDs with these shapes could not reproduce constraints. They argued from this that the bump near 100 km in the main-belt SFD is primordial and that  $D < 100$ -km bodies probably had a shallow power law slope. Accordingly, this would indicate the planetesimal-formation process favors the creation of bodies near 100 km (or larger), with smaller bodies increasingly fragments produced by the disruption of large asteroids. These results may act as a guide for those studying planetesimal-formation processes (e.g., Morbidelli *et al.*, 2009; see the chapter by Johansen *et al.* in this volume).

### 4.3. Collisional Evolution of the Primordial Main Belt

To understand the history of the main belt, it is important to quantify how much collisional evolution has taken place there over its history. This means choosing a starting SFD and then evaluating what it takes to reach its present-day

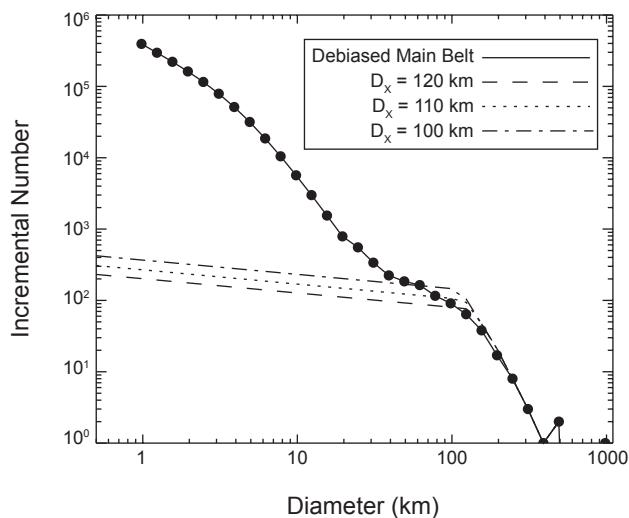

state. The problem is there are many different ways to get from start to finish, and the available constraints may be insufficient to tell us which pathways are favored.

In order to glean insights into this, one can adopt a simplistic but useful metric that can help us evaluate what different evolutionary paths might do. First, let us assume that the main belt is roughly self-contained in terms of collisions, such that we can largely ignore impacts from external sources like escaped main-belt asteroids, leftover planetesimals, comets, etc. Second, we assume the intrinsic collision probabilities and impact velocities of main-belt asteroids hitting one another have remained unchanged over its history. Third, we assume the main belt's SFD has been close to its current shape throughout its history, although it may have been larger in the past. We define this size to be a factor  $f_{MB}$ , the ratio of the main belt's SFD during some past interval of time defined as  $\Delta T$  over the present-day main-belt SFD. Together, these values allow us to estimate the degree of collisional evolution experienced by the main belt in terms of the time exposed to different population sizes.

This metric allows to play with evolution scenarios. The simplest example is the nominal case where the current main-belt SFD ( $f_{MB} = 1$ ) undergoes collisional evolution over its lifetime ( $\Delta T = 4.56$  G.y.). The two values multiplied together yield 4.56 G.y. of collisional grinding. In a more complicated example, we assume a dynamically excited primordial main belt had  $f = 300$  for 3 m.y. (0.003 G.y.). At that point, most of the population was lost via escaping embryos or a migrating Jupiter, which reduced it to  $f_{MB} \sim 5$  for  $\sim 0.5$  G.y. Then, at  $\sim 4$  G.y., 80% of the bodies were lost via sweeping resonances driven by late giant planet migration, which left the surviving population close to its current state ( $f = 1$ ) for the next  $\sim 4$  G.y. Taking all of the multiples, one can say that collectively the survivors experienced  $(0.9 + 2.5 + 4) = 7.4$  G.y. of collisional evolution. This pseudo-time tells us that this main belt roughly experienced the collisional evolution equivalent of a  $f_{MB} = 1$  main belt going through 7.4 G.y. of comminution.

Using a collisional model that took advantage of these concepts, as well as the constraints above, Bottke *et al.* (2005a) found median pseudo-times of 7.5–9.5 G.y. for their best-fit runs, with error bars of a few million years on each end of this range. An example of one of their runs is shown in Fig. 8. Their interpretation was that the main-belt SFD obtained its wavy shape by going through an early time interval where the main-belt survivors were exposed to many more projectiles than are observed today, with most of those bodies due lost to dynamical processes. Thus, the wavy main-belt SFD could be considered a “fossil” produced in part by early collisional evolution in the primordial main belt.

This pseudo-time range above can be used to explore dynamical-evolution scenarios, particularly those that create abundant main-belt populations. For example, using our simple metric, one could replace the middle component, which roughly corresponds to the “Jumping Jupiter” version of the Nice model (Morbidelli *et al.*, 2010; Marchi *et al.*, 2013; see also Nesvorný, 2011; Nesvorný and Morbidelli, 2012),

**Fig. 7.** The debiased main-belt size-frequency distribution as defined in the main text (solid line). The dashed curves show possible initial shapes of the primordial main belt SFD (Bottke *et al.*, 2005a). They found a best fit in their runs for an elbow near  $D_x \sim 110$ – $120$  km. It is likely that the primordial population was larger than the SFDs shown here, with most of the mass eliminated by dynamical processes.

with the original Nice model, where  $f_{MB} \sim 20$  for  $\sim 0.5$  G.y. (Gomes et al., 2005). This change yields  $(0.9 + 10 + 4) = 14.9$  G.y., a pseudo-time outside the favored range. While it cannot be ruled out statistically, it does suggest that collisional evolution needs to be explored in greater depth here.

Another interesting property of Fig. 8 is that once it achieves the shape of the current main belt's SFD, it tends to keep that shape for an extended time. This would explain why the main-belt SFD could remain in a near-steady-state condition for billions of years. While it would be constantly changing and losing bodies by collisional, dynamical, and

YORP spinup processes, it would also be steadily replenished by new large breakup events. This means the vast majority of disruption events produce too few fragments to push the main-belt SFD out of equilibrium for very long. This result also explains why the nonsaturated crater populations on Gaspra, Vesta (i.e., the Marcia and Rheasilvia terrains), and the Moon appear to have been hit by a projectile population with a similarly shaped SFD for an extended period (see section 3.4).

#### 4.4. Processes Affecting Small Asteroids

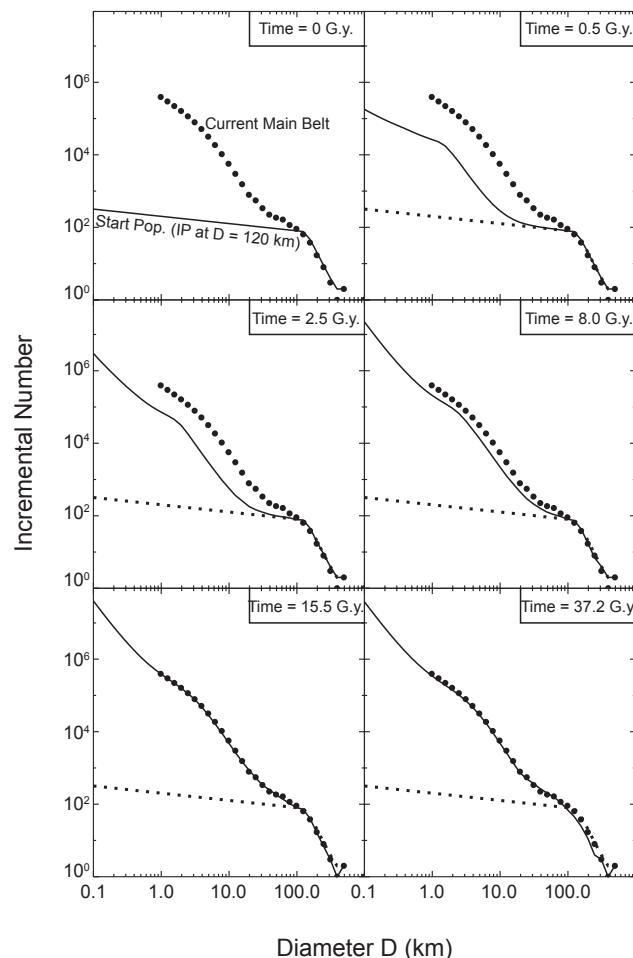

A comparison between the model predictions of Bottke et al. (2005b) and the observed NEO population discussed in the chapter in this volume by Harris et al. (Fig. 2) is intriguing for a different reason (see also O'Brien and Greenberg, 2005). The model does a reasonable job of fitting the observed data for small and larger NEOs, but there is a distinct mismatch near  $D \sim 0.1$  km. The same kind of discrepancy is found between the model main belt and small craters on Vesta at the same approximate location when the craters are scaled back to projectiles (see chapter by Marchi et al. in this volume) (Fig. 5).

This difference suggests the model may be missing something (see section 2.5):

1. YORP spinup torques produce such efficient mass shedding as asteroids sizes approach  $D \sim 0.1$  km that they can influence the shape of the main-belt SFD (Marzari et al., 2011; Jacobson et al., 2014). This same mechanism, however, would need to shut off for  $D < 0.1$  km. The reason why YORP mass shedding approaches termination is unknown, but we can think of several possibilities: (i) the physical nature and/or internal structure of small asteroids may be different from large asteroids, with smaller bodies less likely to be rubble-piles; (ii) small asteroids may be more susceptible to being held together by non-gravitational cohesive forces; or (iii) the thermal properties of the small asteroids are different than those of large asteroids and/or small asteroids become isothermal enough that the YORP mass shedding is less pronounced.

2. The Yarkovsky effect is more efficient at delivering small main belt asteroids to resonances than predicted by Bottke et al. (2005b). As more  $D \sim 0.1$  km objects are evacuated from the main-belt population, a steady-state deficit of small bodies may be created in both the main belt and NEO populations near this size. The reason for this increased delivery efficiency may be related to the YORP shut down discussed above. If YORP becomes less efficient, bodies may become less likely to experience YORP cycles that can cause them to random walk in semimajor axis. In turn, this would enhance their escape rate out of the main belt.

These possibilities illustrate the importance of understanding all the physical processes that affect small bodies in the inner solar system; they feed back in interesting ways, and they may ultimately affect how we interpret the ages of surfaces on both asteroids and the terrestrial planets. We look forward to seeing this investigated in the future.

**Fig. 8.** Six snapshots from a representative run where Bottke et al. (2005a) tracked the collisional evolution of the main-belt size distribution for a pseudo-time of 50 G.y. This run uses a starting population with  $D_x = 120$  km. The bump near  $D \sim 120$  km is a leftover from accretion, while the bump at smaller sizes is driven by the transition at  $D \sim 0.2$  km between strength and gravity scaling regimes in  $Q_D^*$ . The model main belt achieves the same approximate shape as the observed population at  $t_{pseudo} = 9.25$  G.y. (not shown). The model closely adheres to the observed population for many gigayears after this time. Eventually, comminution eliminates enough  $D > 200$ -km bodies that the model diverges from the observed population.

#### 4.5. Monolithic vs. Rubble-Pile Structures

Recent collisional modeling work by *Cibulková et al.* (2014) has also taken a more sophisticated look at the evolution of six different main-belt regions (Fig. 9): inner, middle, “pristine,” outer, Cybele zone, and high inclination. Their goal was to fit the SFDs and asteroid families formed in all these zones. The observed SFDs in these regions were computed from the available WISE satellite data (*Masiero et al.*, 2011; see the chapter by Mainzer et al. in this volume). They also assumed the bodies were either monolithic asteroids or rubble piles, with the fragment SFDs derived from *Durda et al.* (2007) and *Benavidez et al.* (2012), respectively. Their model also allows for dynamical depletion due to the Yarkovsky effect.

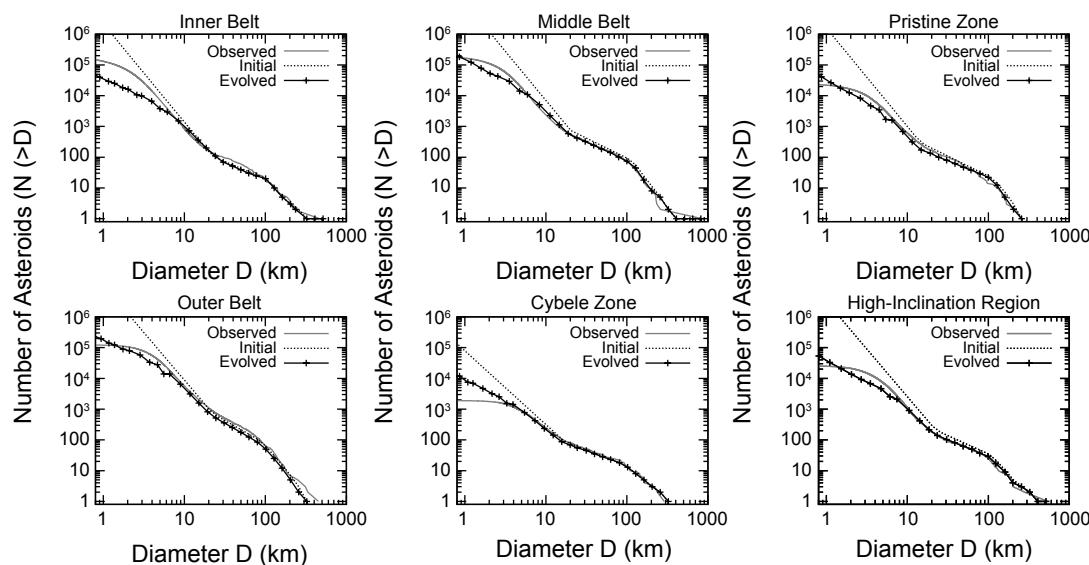

*Cibulková et al.* (2014) found a number of intriguing results. First, treating all asteroids as weak rubble piles as defined by *Benavidez et al.* (2012) led to SFDs that are too shallow below  $D < 10$  km, as well as a factor of 2 more large families produced than are observed. This does not necessarily mean that asteroids are not rubble piles; an alternative would be that their disruption law is close to that derived for monolithic objects. New models of how porous rubble-pile asteroids break up suggest this may be the most likely answer (see the chapter by Jutzi et al. in this volume). Second, *Cibulková et al.* (2014) also found that individual breakups are unlikely to change the SFDs of the regions they investigated because small fragments, while numerous, were

quickly destroyed on a  $\sim 100$ -m.y. timescale. This is consistent with the main belt staying close to an equilibrium state.

Finally, even at the current limit of observational completeness (3 to 6 km, depending on the main belt zone), the frequency of collisions becomes comparable to the dynamical removal of bodies by the Yarkovsky effect and major mean-motion resonances (*Bottke et al.*, 2005a,b) or rotational disruption induced by the YORP effect (*Jacobsen et al.*, 2014). Regarding the former effect, removal rates used by *Bottke et al.* (2005b) or those in *Cibulková et al.* (2014) seem to be compatible with observations, namely the observed SFDs of main-belt asteroids and NEAs. The same may also be true for the latter process, although this will need to be examined in greater detail with the implications of *Statler* (2009) included. At this time, it is not clear which process dominates.

#### 4.6. Connections Between Asteroid Families and Meteorites

One of the most perplexing issues involving meteorite delivery concerns the fact that we currently have many tens of thousands of meteorites in worldwide collections, yet this population could represent as few as  $\sim 100$  different asteroid parent bodies:  $\sim 27$  chondritic,  $\sim 2$  primitive achondritic,  $\sim 6$  differentiated achondritic,  $\sim 4$  stony-iron,  $\sim 10$  iron groups, and  $\sim 50$  ungrouped irons (e.g., *Burbine et al.*, 2002). If we remove the stony-iron, iron, and differentiated meteorites,

**Fig. 9.** Observed size-frequency distributions (gray lines) for six parts of the main belt compared to simulated initial (dashed) and final SFDs (black), after 4 G.y. of collisional evolution. This particular simulation shows the best-fit model out of more than 200,000 models started with various initial conditions. We assumed the scaling law of *Benz and Asphaug* (1999) and a monolithic structure of bodies. The largest differences can be seen for the inner and outer belt; they can be attributed to a dynamical removal of small bodies ( $D < 0.1$  km) caused by the Yarkovsky effect, which then cannot serve as projectiles for larger bodies ( $\approx 1$  km). Note that it is not easy to improve these results (e.g., by increasing the normalization of the outer belt; this would feed back and affect the other subpopulations). Figure adapted from *Cibulková et al.* (2014).

this number is reduced to as few as  $\sim 30$  parent bodies. This large difference in numbers is even more puzzling given current meteorite delivery scenarios, where nearly any small main-belt fragment can potentially reach a resonance capable of taking it into the terrestrial planet region via the Yarkovsky effect (see the chapter by Vokrouhlický et al. in this volume). Presumably, this would suggest that our meteorite collections should have samples from thousands upon thousands of distinct parent bodies.

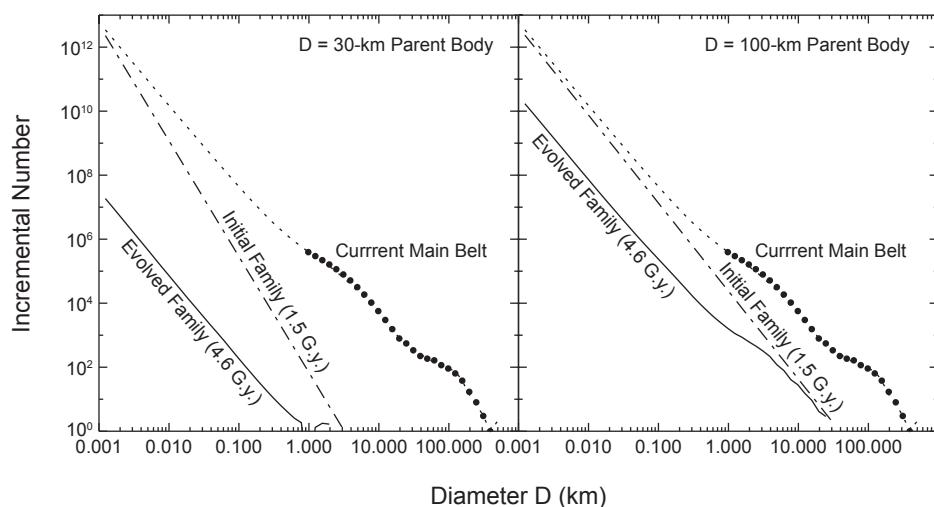

An important missing component here is information on how collisional evolution has shaped meteorite delivery in the asteroid belt. Using the models discussed above, it is useful to apply what we have learned to the issue of stony meteoroid production, evolution, and delivery to Earth. First, one can consider what happens when a body undergoes a cratering or catastrophic disruption event. A fragment SFD is created ranging from meteoroid-sized bodies all the way to multi-kilometer-sized asteroids (or more). Subsequent collisions onto bodies in the SFD act as a source for new meteoroids that are genetically the same as those created in the previous generation. This collisional cascade guarantees that some meteoroids from this family, representing a single parent body, will be provided to the main-belt population, resonances, and possibly to Earth for an extended interval. At the same time, dynamical processes and collisions onto the newly created meteoroids act as a sink to eliminate them from the main belt.

An example of this process is shown in Fig. 10. It shows what happens when fragment SFDs produced by  $D = 30$ -km and 100-km parent bodies are placed in the main belt

$\sim 3.1$  G.y. ago. For fragments derived from the 30-km body, the initial meteoroid population (i.e., the population of meter-sized bodies) drops by a factor of 100 and  $10^5$  within 130 m.y. and within 3.1 G.y., respectively. Thus, meteoroid production by  $D < 30$ -km parent bodies decays away so quickly that breakup events of this size from billions of years ago are unlikely to deliver meaningful numbers of meteoroids to Earth today. For the 100-km parent body, the decay rate is significantly slower, with the meteoroid population only dropping by a factor of 100 over 2–3 G.y. This suggests that many meteoroids reaching Earth today could come from prominent asteroid families with sizable SFDs, even if those families were created billions of years ago.

Bottke et al. (2005c) used these ideas to estimate how many stony meteorite classes should be in our collection. They did this by computing the meteoroid decay rates taken from different parent body sizes (Fig. 11) and combining them with the estimated production rates of asteroid families over the last  $\sim 4$  G.y. This calculation made many simplifying assumptions: (1) meteoroids from all parts of the main belt have an equal chance of reaching Earth, (2) all  $D > 30$ -km asteroids disrupted over the last several billion years have the capability of producing a distinct class of meteorites, and (3) once a family's meteoroid production rate drops by a factor of 100, an arbitrary choice, it was unlikely to produce enough terrestrial meteorites to be noticed in our collection.

They found that asteroid families produced by the breakup of  $D > 100$ -km bodies have such slow meteoroid decay rates that most should be providing some meteoroids today, regardless of their disruption time over the last 3 G.y. Among the

**Fig. 10.** The collisional and dynamical evolution of two asteroid families with simple fragment SFDs produced by the disruption of  $D = 30$ - and 100-km parent bodies (Bottke et al., 2005c). Both were inserted into the collision evolution model at 1.5 G.y. after solar system formation. The meteoroid population is represented by the number of bodies in the  $D \sim 0.001$ -km size bin. The solid lines show the families at present (4.6 G.y.). The smaller family has decayed significantly more than the larger family. Note the shallow slope of the  $D = 100$ -km family for  $0.7 \leq D \leq 5$  km. This shape mimics that of the background main-belt population over the same size range.

smaller parent bodies ( $30 < D < 100$  km), they found that, on average, the interval between disruption events across the main belt was short enough that many have disrupted over the last billion years or so, enough to provide some meteoroids as well. They did not examine large cratering events, such as the Rheasilvia formation event on Vesta, but presumably they would factor into this as well, with the biggest events acting like the disruption of a sizable parent body.

Overall, they found that stony meteorites were plausibly coming from  $\sim 45$  different parent bodies. This value is fairly close to the actual value of  $\sim 30$  parent bodies. A few reasons that the model estimate may be on the high side include (1) some disruption events must occur within existing families, so no unique meteorite class would be created; (2) some outer main-belt meteoroids may have great difficulty reaching Earth because they only have access to resonances that are orders of magnitude less efficient at delivering meteoroids to Earth than inner-main-belt resonances (Gladman *et al.*, 1997; Bottke *et al.*, 2006); and (3) we have not factored in the different fragment SFD actual families can have. We conclude that most stony meteorites are byproducts of a collisional cascade, with some coming from asteroid families produced by the breakup of  $D > 100$ -km bodies over the last several billion years and the remainder coming from smaller, more recent breakup events among  $D < 100$ -km asteroids that occurred over recent times (i.e.,  $\ll 1$  G.y.).

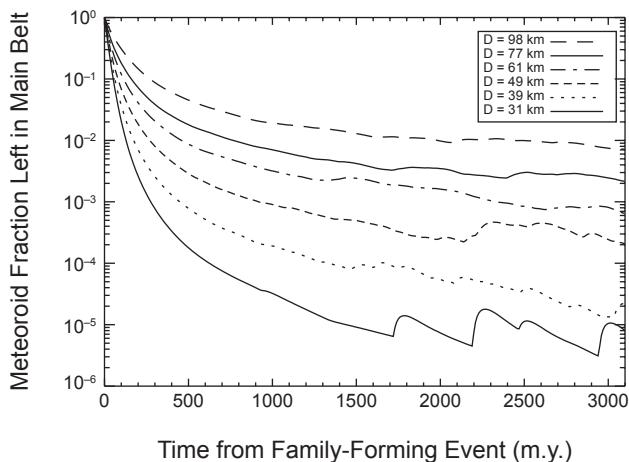

#### 4.7. Cometary Impacts on Main-Belt Asteroids During the Late Heavy Bombardment

An interesting quandary comes from the predicted bombardment of comets on main-belt asteroids during the Nice model (see the chapter by Morbidelli *et al.* in this volume). Ac-

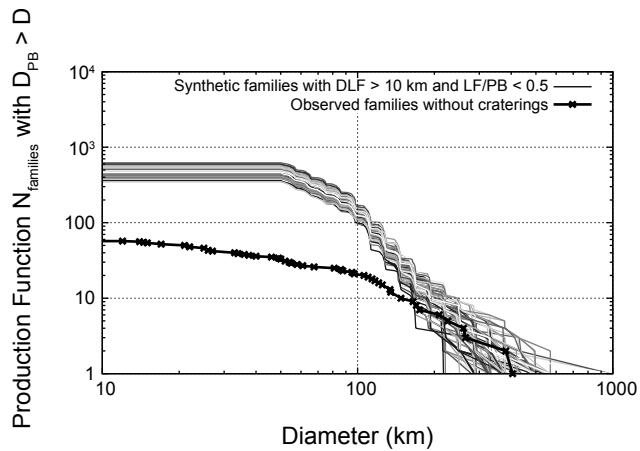

cording to Brož *et al.* (2013), a massive  $25 M_{\oplus}$  disk of transneptunian comets might contain  $10^{12}$   $D > 1$ -km comets. Using numerical simulations of Vokrouhlický *et al.* (2008), they estimated the collision probabilities and impact velocities for a comet hitting main-belt asteroids to be  $P_i \sim 6 \times 10^{-18} \text{ km}^{-2} \text{ yr}^{-1}$  and  $V_{\text{imp}} \sim 10 \text{ km s}^{-1}$ . Coupled with models describing the loss of asteroids during resonance sweeping (Minton and Malhotra, 2010), they estimated that the LHB could potentially disrupt more than 100 parent bodies with  $D_{\text{PB}} > 100$  km, depending on the assumptions made (Fig. 12).

These values would violate many of the constraints provided in section 3, and they present an intriguing challenge to the main tenets of the Nice model. One option here would be to reject the Nice model altogether, although this would also mean giving up the successes it has had in explaining various solar system attributes (see the chapter by Morbidelli *et al.* in this volume).

The other possibility is that there are aspects of the Nice model or our collision models that need revision. For example, the disk of transneptunian comets may have different initial conditions and/or evolution properties than have been previously assumed, such that the collision probabilities between comets and asteroids are lower than expected (D. Nesvorný, personal communication). It is also possible that numerous transneptunian comets disrupt when they enter the inner solar system (e.g., Levison *et al.*, 2001), with possible mechanisms being volatile pressure buildup, amorphous/crystalline phase transitions, spinup by jets, etc. Brož *et al.* (2013) examined this possibility by arbitrarily assuming that all comets disrupt at perihelion distance,  $q_{\text{crit}} < 1.5$  AU. On average, this led to the correct number of catastrophic disruptions for  $D_{\text{PB}} = 200$ – $400$ -km bodies, but it still pro-

**Fig. 11.** Decay rates of meteoroid populations from asteroid families with simple power-law fragment SFD produced from parent bodies between  $30 < D < 100$  km. All families were inserted in the collisional model at 3.1 G.y. ago. The meteoroid population in the smallest families decrease by a factor of 100 over a few 0.1 G.y. while the largest take several gigayears to decay by the same factor.

**Fig. 12.** The outcomes of the bombardment of the main asteroid belt by transneptunian comets, as modeled by Brož *et al.* (2013). The plot shows the family production functions [i.e., the cumulative number  $N_{\text{fam}}(>D)$  of families with parent-body size  $D_{\text{PB}}$  larger than  $D$ ] and a comparison to the observed one. Here we show 100 individual simulations (differing only by random-seed values) using different grayscale colors.

duced a factor of 2–3 more disruptions for  $D_{PB} \approx 100$ -km bodies than observed. It is possible that this excess could be removed by subsequent collisional and dynamical evolution. All these values assume, of course, that collisions between low-density porous comets and asteroids are understood, when in reality no hydrocode simulations have ever been run using this set up. Finally, it could be that the main belt can accommodate more early collisions than predicted here. The constraints we have on the early era are extremely limited. All these topics remain exciting areas for future research.

## 5. CONCLUSIONS

Considerable progress has been made over the last several decades in interpreting how the main belt reached its current state by collisional and dynamical evolution, but there is still much work to do. At this time, no model has yet included all the important processes affecting asteroid evolution. Even after this accomplished, these models will still have to be successfully tested against all the known constraints, including new ones that are discussed in other chapters. Still, it is fair to say that many existing models have done a good job of matching the constraints discussed in section 3, and their predictions have made it possible to glean insights into how the main-belt population reached its current state (see section 4).

We expect that major advances will also come from the inclusion of new and better constraints that can help modelers rule out solutions. A few of the entries on our wish list for new data, beyond advances in the fields of planetesimal and planet formation, include (1) increased information on the main-belt population for  $D < 1$ -km bodies (e.g., albedos, colors, spectroscopy, sizes, etc.); (2) a substantiated chronology for lunar and terrestrial crater populations, with crater SFD information verified for a wide range of surface ages; (3) a thorough examination of the main belt for ghost families; (4) more information on small asteroids that enable better predictions of Yarkovsky drift rates and YORP torques for  $D < 1$ -km asteroids; (5) additional nonsaturated crater SFDs from asteroid surfaces; (6) more discoveries of very young families, enough that we convince ourselves we have a complete set for a given time period.

In regard to modeling work, the next major steps forward will probably come from next-generation codes that can track how asteroid populations move across the main belt via Yarkovsky/YORP forces while also undergoing comminution and YORP-driven mass shedding. This would allow the collisional cascade in the main belt to be treated as accurately as possible, from disruption all the way to the fragments reaching resonances. Additional information on asteroid collisions at all sizes from numerical hydrocode simulations would be extremely useful, as would laboratory and numerical experiments completed on a wide range of asteroid compositions and internal structures. This would allow new codes to accurately account for the varying  $Q_D^*$  functions and fragment SFDs that asteroid families of different composition might have.

Finally, it is imperative that collisional models employ the best estimates of how the main-belt and external small-body populations have dynamically evolved with time. The history of our solar system is etched into the main-belt population in enumerable ways, and the only way to read these markings and tell the story of our home is to unite models of collisional and dynamical evolution from the formation of the first solids all the way to the present day.

Impact craters are a ubiquitous feature of asteroid surfaces. On a local scale, small craters puncture the surface in a way similar to that observed on terrestrial planets and the Moon. At the opposite extreme, larger craters often approach the physical size of asteroids, thus globally affecting their shapes and surface properties. Crater measurements are a powerful means of investigation. Crater spatial and size distributions inform us of fundamental processes, such as asteroid collisional history. A paucity of craters, sometimes observed, may be diagnostic of mechanisms of erasure that are unique on low-gravity asteroids. Byproducts of impacts, such as ridges, troughs, and blocks, inform us of the bulk structure. In this chapter we review the major properties of crater populations on asteroids visited by spacecraft. In doing so we provide key examples to illustrate how craters affect the overall shape and can be used to constrain asteroid surface ages, bulk properties, and impact-driven surface evolution.

## 1. INTRODUCTION

Until the space age, craters had only been observed on a single astronomical body, the Moon. It was only with the analysis of the first lunar samples, however, that it finally became clear that the vast majority of lunar craters (and a recognizable minority of terrestrial craters) were caused by cosmic impacts and were not generally of volcanic or other endogenic origin (e.g., Wilhelms, 1993). Three decades later, when the Galileo spacecraft flew past (951) Gaspra, then a few years later past (243) Ida, craters were found on asteroids. During the subsequent two decades, spacecraft flybys and dedicated orbital missions have recorded crater populations on many additional asteroids.

While hypervelocity impact by asteroids and comets or by their debris will produce impact craters on any solar system body with a solid surface, there is a fundamental difference between craters on small bodies and those on larger planets and satellites: Instead of cratering on semi-infinite surfaces, asteroidal cratering occurs on smaller bodies generally with minimal gravity. So the ejecta from an impact explosion travel far and often escape into independent orbits around the Sun, becoming individual small asteroids.

Collisional fragmentation and cratering are major evolutionary processes for asteroids since the earliest epochs of solar system history and learning about the visible record of surficial cratering can provide vital clues about their evolution and interactions with the space environment. Cratered terrains provide snapshots of collisions that occurred eons ago, and in turn, inform us about the origin of the impactor populations that have shaped the surfaces of all but the most geologically active bodies. Moreover, craters excavate deep to reveal underlying layers, perhaps differing from surface materials, while some of the escaped material can eventually land on Earth as meteorites.

The fundamental observable property of a crater is its size, and the fundamental property of a population of craters concerns the ratio of the number of small craters to large craters, i.e., the size-frequency distribution (SFD). As with crater populations on larger planets and satellites, there are additional factors that interfere with a direct inference of the projectile population from the observed crater SFD. These include *saturation* of craters (the maximum number of craters that can be accommodated on a given surface), formation of *secondary* craters (craters made by impact of ejecta rather than from the *primary* cosmic projectile impacts), as well

as often size-dependent processes that erase craters or alter their morphology (downslope mass wasting, pit-formation by volatile release, etc). Crater SFDs are also affected by the properties of the target material (e.g., hard rock, rubbly megaregolith, icy or volatile-rich material); these can vary not only spatially across the target body's surface but also in the vertical dimension, so that scaling of impactor size to crater size may actually vary across the surface and with impactor size. Furthermore, energetic collisions may drastically alter the bulk properties of asteroids and scramble their surfaces by producing surface features such as troughs, ridges, and grooves.

All these issues may initially manifest themselves as problems due to our limited knowledge of asteroid properties, but, if one regards them as potentially decipherable challenges, they may eventually enable crater studies to reveal many properties of asteroid interiors, surfaces, and geological processes.

In this chapter, we attempt to summarize the most up-to-date understanding of asteroidal cratering processes, emphasizing presentation and interpretation of the more recent spacecraft data [e.g., from (4) Vesta, (21) Lutetia, and (25143) Itokawa], while also updating interpretations of earlier results from Gaspra, Ida, (253) Mathilde, (433) Eros, and some smaller targets of opportunity.

## 2. CRATER STATISTICS

The identification of impact craters is a challenging process. One may think that craters should resemble nice, sharp bowls, but observations of craters on terrestrial bodies and asteroids readily show that this is naive. In reality, cratered landscapes evolve over time under various forces, such as cratering itself, mass wasting, and other endogenic geological processes, which especially hamper our ability to identify old, degraded craters. Furthermore, there is no unanimously accepted standard procedure to map craters, and researchers need to rely on their own bag of tricks. For instance, when a group of experienced mappers were given the same image from which to count craters, it was found that the results could differ by a factor of 2 (Robbins *et al.*, 2014).

In this section we introduce the topic of crater statistics, and crater SFDs, which are a primary diagnostic tool for understanding cratering. Furthermore, we discuss how crater SFDs can reveal important processes that modify or alter the *production* population of craters — i.e., the crater SFD per unit time that results from the mainly asteroidal projectile population — and are a powerful tool to infer relative and absolute ages of various terrains along with aspects of their bulk mechanical properties.

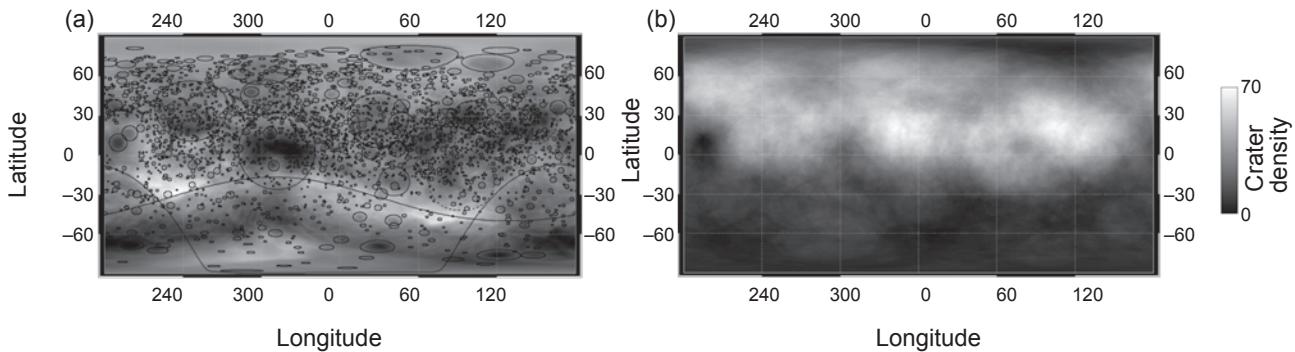

### 2.1. Crater Size-Frequency Distributions

In this section we review crater SFDs of asteroids visited by spacecraft. As mentioned above, the identification of impact craters can be cumbersome, particularly when they are degraded and heavily modified by post-formation

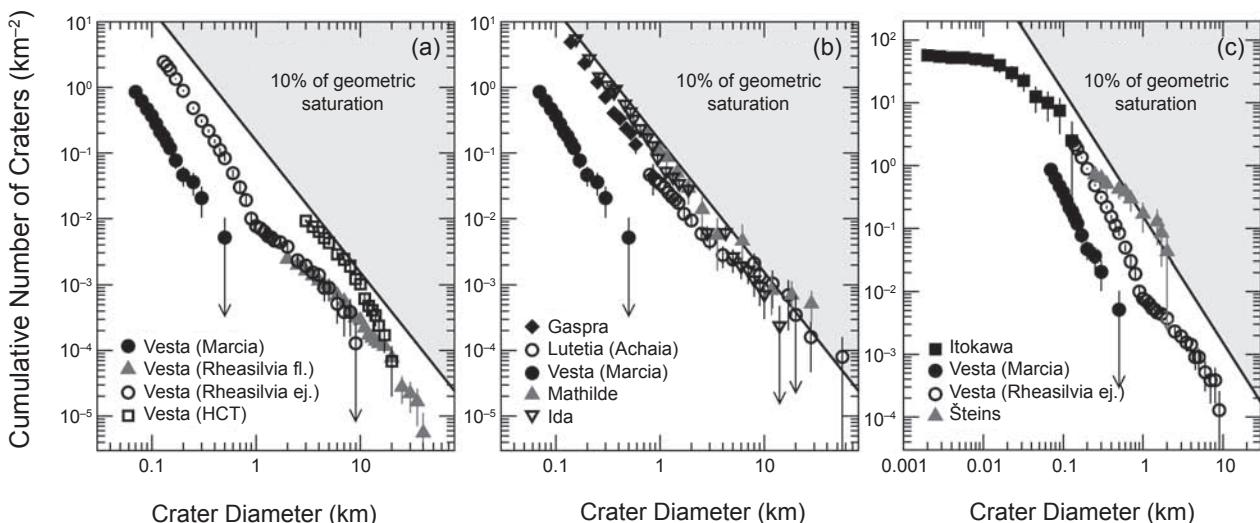

processes. In addition, oddly shaped asteroids often show large facets that sometimes are interpreted to be the result of impact sculpting or to be a consequence of their rubble-pile structure. Here we take the approach of showing selected examples from the various asteroids to illustrate key processes, rather than presenting a global compilation of every measured crater SFD. In doing so we opt to show crater SFDs from selected references along with some newly measured crater SFDs, and remind readers that there are additional, and sometimes different, counts in the published literature (e.g., Schmedemann *et al.*, 2014). An important and often neglected factor that makes cratering on asteroids different from cratering of terrestrial body surfaces is the fact that the physical sizes of visited asteroids vary by more than 3 orders of magnitude. As a result, craters form and evolve under very different conditions. Here we start our discussion with the largest bodies and continue with smaller asteroids.

**2.1.1. Large asteroids.** Vesta is the largest asteroid so far visited by a spacecraft (see the chapter by Russell *et al.* in this volume). The NASA Dawn mission orbited Vesta for more than one year, gathering images of 98% of the surface. The large surface and coverage makes Vesta the best example so far to study cratering on a large asteroid. In addition, Vesta formed within a few million years after the first solar system solids (e.g., McSween and Huss, 2010), implying that its surface has been subject to extensive cratering throughout nearly all of solar system evolution. As anticipated, the surface of Vesta exhibits an extremely diverse set of crater populations. The significant population of craters (~10–15) larger than 50 km, including a few old degraded structures, witnesses the heavy collisional history, recorded primarily in the northern hemisphere (Marchi *et al.*, 2012a). The southern hemisphere, on the contrary, has been obliterated by the two largest impact structures, the ~400-km Veneneia and ~500-km Rheasilvia basins. As a result, the overall spatial distribution of craters is rather heterogeneous and shows a marked north-south asymmetry. This is easily seen in the global crater distribution, and in the resulting global average crater density (Fig. 1). The formation of Veneneia and Rheasilvia had major effects on the whole surface, as manifested by the extensive troughs and voluminous ejecta blanketing (Schenk *et al.*, 2012; Buczkowski *et al.*, 2012; Yingst *et al.*, 2014). Mapping of these and other geological features led to the development of a well-defined time-stratigraphic system (Williams *et al.*, 2014). In this system, the youngest epoch — Marcian — begins with the time of formation of the freshest of the large craters, the ~70-km Marcia. The second youngest epoch — Rheasilvian — begins with the formation of the Rheasilvia basin. The relative youthfulness of Marcian and Rheasilvian terrains offers a unique opportunity among asteroids to study the least-processed populations of craters produced by asteroidal bombardment (Marchi *et al.*, 2014) and also reveals the small main-belt asteroid SFDs. Figure 2a shows the crater SFDs of selected Marcian and Rheasilvian terrains.

The crater SFDs of older vestan terrains are not easily interpretable because they exhibit odd shapes (for details,

**Fig. 1.** Vesta's global crater catalog. (a) The map shows a cylindrical projection of all mapped craters larger than 4 km in diameter (more than 2500 are shown on the map) overlaid on a digital terrain model. The two lines encompassing the south pole are the projections of best-fit circles to Rheasilvia and Veneneia basins. (b) Crater areal density (in units of number of craters per  $10^4 \text{ km}^2$ ). The map is produced averaging craters over a radius of 80 km. Due to limited imaging coverage at high northern latitudes, the map is not reliable for latitudes above  $\sim 75^\circ\text{N}$ .

**Fig. 2.** Selected crater SFDs of various asteroids. The data are shown in the form of cumulative numbers of craters per unit area as a function of crater diameter. The thick black lines indicate the level of empirical saturation corresponding to 10% of geometric saturation (Gault, 1970; Melosh, 1989, p. 192) (see section 2.2). (a) Crater SFDs of representative terrains within the Marcian and Rheasilvian units on Vesta. Marcia crater SFD is obtained from high-resolution counts within the rim of Marcia crater (from Marchi et al., 2014). The SFDs for craters on the floor of Rheasilvia basin and on its proximal ejecta blanket update those presented by Marchi et al. (2014). (b) A comparative view of crater SFDs of Lutetia [Achaia region, from Marchi et al. (2012b)], Ida (Chapman et al., 1996a), Gaspra (Chapman et al., 1996b), Mathilde (Chapman et al., 1999), and the Vesta heavily cratered terrain (HCT) [count updated from Marchi et al. (2012a)]. For a better comparison with (a), Marcia crater SFD is plotted here again. (c) Crater SFDs of Itokawa (Hirata et al., 2009), and Šteins (Marchi et al., 2010). For a comparison with crater counts shown in (a) and (b), the crater SFDs of Marcia and Rheasilvia are also shown.

see Yingst et al., 2014), and also differ from the arguably more pristine Marcian and Rheasilvian crater SFDs. It is probable that the formation of large basins such as Rheasilvia and Veneneia (and possibly also older ones) altered crater populations on older terrains (see section 2.2). Here we present data from just a relatively small region where the highest crater density has been observed, the so-called heavily cratered terrain (HCT) (Fig. 2b). The plot also indicates a curve corresponding to empirical crater saturation, i.e.,

approximately the highest crater density that can be accumulated on a given surface (Hartmann, 1984) (see also section 2.2). Therefore, Vesta HCT seems to be close to or has reached the empirical saturation level.

Interestingly, asteroid Lutetia provides some similarities with Vesta. First, given its large size ( $\sim 100 \text{ km}$ ), it may be a primordial object (i.e., not a fragment of some still larger body) according to models of collisional evolution of the main belt (Morbidelli et al., 2009). Furthermore, its surface

shows significant features that were used to map and develop a time-stratigraphic system (*Thomas et al.*, 2012; *Massironi et al.*, 2012). However, the relatively small size and partial surface imaged (40%) did not permit detailed investigations of most of the surface. An exception is the relatively flat, coherent unit, called Achaia (Fig. 2b), which has a crater SFD showing a peculiar kink at crater sizes between ~5 and 8 km (*Marchi et al.*, 2012b; see the chapter by Barucci et al. in this volume). Craters larger than ~8 km are close to the Vesta HCT and saturation, while craters smaller than ~5 km are significantly depleted. The latter has been interpreted as due to resurfacing or a variation of the mechanical properties with depth (see the chapter by Barucci et al.).

The smooth appearances of Achaia and Vesta HCT — suggesting the presence of significant regolith — resemble the surface of asteroid Ida, although on a very different size scale. The Ida crater SFD is also close to the saturation curve, over the size range from ~0.2 to 10 km. A similar conclusion applies to asteroid Mathilde for craters smaller than ~10 km, while for craters larger than ~10 km the crater density is well above the empirical saturation curve. A comparative plot of their crater SFDs is given in Fig. 2b. In conclusion, except for large craters on Mathilde, heavily cratered surfaces of mid- to large-sized asteroids seem to cluster in proximity to the empirical saturation density.

In between the two extremes of low crater density represented by Marcian and Rheasilvian terrains on Vesta and the most heavily cratered terrains, we find a range of other terrains. Examples are the asteroid Gaspra (excluding the large facets of uncertain origin), or the Achaia region on Lutetia for craters smaller than 5 km. All these distributions (except for the kinked Achaia crater SFD) share relatively similar slopes, if one considers the statistical uncertainties associated with the measurements.

**2.1.2. Small asteroids.** Smaller asteroids, however, do not fit the above picture. Consider for instance the well-studied case of Itokawa (a similar discussion about Eros can be found in section 2.2.4). The crater SFD at sizes larger than ~0.02 km has a characteristic slope somewhat shallower than the slopes observed on other asteroids (see Fig. 2c). Unexpectedly, however, the crater SFD has a considerably shallower slope at smaller sizes (<0.02 km) than both that of nonsaturated terrains (e.g., Marcia and Rheasilvia on Vesta), and likely saturated ones (Ida, Mathilde). Moreover, craters become increasingly rare on Itokawa at smaller sizes and, indeed, the surface becomes dominated by boulders. As a result, the Itokawa crater SFD becomes almost flat in a cumulative plot below ~0.01 km (see Fig. 2c). Eros exhibits a similar behavior, with slight shallowing of the crater SFD below ~0.1 km and more pronounced shallowing below ~0.05 km (see section 2.3 for more details on Eros). Several possible interpretations for the lack of small craters were discussed by *Chapman et al.* (2002) for Eros and by *Michel et al.* (2009) and *Michel and Richardson* (2013) for Itokawa, including a decrease in the slope of main-belt asteroids' SFD, erasing of small craters, armoring by boulders, and a cratering hiatus. Similar decreasing frequencies of smaller craters were also

seen on (2867) Šteins and (4179) Toutatis, although with poorer imaging resolution (*Besse et al.*, 2012; see the chapter by Barucci et al. in this volume). The shallow sloped crater SFDs do not match those of the relatively pristine Marcia and Rheasilvia craters, suggesting that one or more specific processes on small asteroids are responsible. Although several of the ideas listed above may be partly applicable, the dominant cause is likely to be seismic shaking, discussed in detail below (section 2.2.4). Unfortunately, image resolutions of larger asteroids (e.g., Vesta, Lutetia) do not allow for a comparison with Eros and Itokawa high-resolution counts (<0.1 km). However, there is a hint that the Marcia crater SFD does not start bending to a shallower slope near 0.1 km diameter. The main-belt SFD at these impactor sizes (<0.01 km) is unconstrained by direct observations, although there are some indirect arguments against the shallow slope being an attribute of the asteroidal SFD. *Marchi et al.* (2014) showed that a current model main belt SFD matches reasonably well the Marcia crater SFD, and such a model does not yield a significant change in slope for smaller asteroids (*Bottke et al.*, 2005). Furthermore, according to recent evolution models (e.g., see the chapter by Bottke et al. in this volume), the near-Earth objects (NEO) SFD slope at this size is roughly similar to that of the main belt, and the observed NEO SFD (see the chapter by Harris et al. in this volume) does not show such a shallower slope.

## 2.2. Temporal Evolution of Crater Size-Frequency Distributions

Cratered surfaces provide time-integrated snapshots of the accumulation of craters over a certain period. Therefore, the total number of craters superposed on a given terrain should monotonically increase over time. Thus, the number of observed craters — in ideal conditions — constrains the age of the terrain (see section 2.3). In practice, however, crater topography is reduced over time by a number of surface processes, and eventually old, degraded craters fade away. As a result, the temporal evolution of a cratered terrain is rather complex and its correct interpretation involves considering various production and obliterating mechanisms.

The production of craters is primarily due to the flux of incoming asteroids and, as such, is susceptible to temporal variations reflecting variation in the impact rates and/or impactor SFD. Crater obliteration is a natural result of the degradation of the topography over time. Contrary to what is observed on geologically active terrestrial bodies, the primary cause for obliteration on asteroids is related to the bombardment itself. Basically, a newly formed crater obliterates smaller previously existing craters. Additional processes tend to magnify the erasure and extend it to larger distances. An interesting aspect is crater saturation, as anticipated in the previous section.

A newly formed crater obliterates smaller previously existing craters, or parts of larger craters, by geometrical overlap (cookie cutting), by spreading ejecta on top of them, by seismic shaking, and by sandblasting. As the integrated areas

of superposed craters approach the surface area, the chances that an earlier crater can still be recognized drop toward zero. A steady-state is eventually reached (“saturation” in jargon) where the crater spatial density cannot further increase. The manner of saturation depends on the slope of the SFD of the crater production function, reflecting that of the impactor population (cf. Richardson, 2009). A shallow-sloped impactor SFD destroys preexisting craters primarily by resetting of the surface by the creation of very large craters and their ejecta deposits, as well as by seismic shaking, whereas a steeply sloped impactor SFD erodes the topography of preexisting craters in a kind of sandblasting effect dominated by tiny projectiles. We expand on these mechanisms below.

Numerical codes simulating the random formation of craters on a surface and the various obliterating mechanism have been developed (Chapman and McKinnon, 1986; O’Brien et al., 2006; Richardson, 2009; Marchi et al., 2012c). Here we present a series of global- and regional-scale cratering simulations to illustrate the basic processes. In these simulations old craters are obliterated by the four primary mechanisms mentioned above.

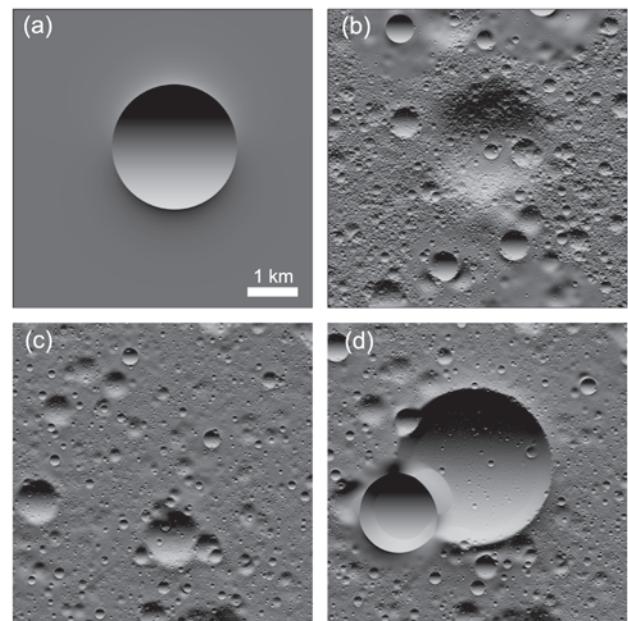

### 2.2.1. Crater erasure mechanisms: Cookie cutting.

Cookie cutting describes the most direct way that new craters destroy old craters, by overprinting and geometric overlap (Woronow, 1977). When an impactor strikes a cratered surface, any preexisting smaller craters within the excavation and collapse regions of the new crater are totally obliterated. For cookie cutting to occur, however, the new crater (or a few of them) must be a sizable fraction of, or larger than, the preexisting crater. If the overlapping craters are too small, an original large crater may still be recognized as a topographic depression and counted, although its rim and other short-wavelength topography are gone.

If a production function SFD of craters has a shallow cumulative power-law slope with exponent that is larger than  $-2$ , then large-crater cookie cutting tends to dominate the crater erasure process and crater density steady-state values will continue to reflect, or follow, the shape of the production population, as large regions are continuously reset and then repopulated with small craters (Richardson, 2009). In this case, the terrain reaches what Chapman and McKinnon (1986) described as a *quasi-equilibrium* state, one in which large portions of the surface are frequently reset by the formation of large craters, and thus the newer cratering continues to reflect the production population, even after a long period of bombardment (Woronow, 1977; Chapman and McKinnon, 1986). In this process, the crater population will gradually approach *empirical saturation* levels of  $\sim 5\text{--}10\%$  geometric saturation (Gault, 1970) as small craters accumulate on the surface, only to be suddenly pushed back down again by the cookie-cutting effect of the next large crater to form (see Fig. 3).

### 2.2.2. Crater erasure mechanisms: Sandblasting.

The term sandblasting can be used to describe the process by which many small impacts can gradually erode away topographic features (Chapman, 1976), such that the numerous small craters degrade larger craters to the point that they are

**Fig. 3.** A demonstration of (a),(b) crater sandblasting and (c),(d) cookie-cutting in a small-scale lunar surface simulation. Beginning with a pristine, large crater in (a), the surface is bombarded with a steeply sloped impactor population rich in small impactors. Individual impacts have very little effect on the large crater’s topography and visibility. However, over time and cumulative impacts (b), the large crater is eroded and filled in, as the numerous small impacts redistribute the material making up the walls and rim of the large crater. In (d), a pair of large, simple craters have cookie-cut out (erased) all of the much smaller craters that previously occupied their location in (c). In this manner, large craters can severely alter small crater populations and counts over the affected region.

not recognizable as a crater by a crater counter (Soderblom, 1970). The multiple small craters rearrange the material that had formed the topography of the larger old crater so that its topography relaxes back toward the mean elevation of the terrain.

If a production function SFD of craters has a steep cumulative power-law slope with exponent less than  $-2$ , then small-crater sandblasting tends to dominate the crater-erasure process (Richardson, 2009). In this case, the terrain will display classic behavior (Gault, 1970), with the smallest craters reaching crater-density equilibrium conditions first at between 5 and 10% of geometric saturation (with a cumulative power-law slope of about  $-2$ ), and with successively larger crater sizes reaching equilibrium over time (see Fig. 3).

**2.2.3. Crater erasure mechanisms: Ejecta burial.** The ejecta from a fresh crater can obliterate old craters beyond its rim by burying them. In other words, if the newly produced ejecta blanket is thicker than the depth of a preexisting crater at that location, the crater will be buried, and thus will be invisible to a crater counter. This concept has been employed to estimate the thickness of ejecta deposits from lunar craters (Moore et al., 1974). On a low-gravity asteroid

this process may be less efficient because ejecta are more widespread, but Vesta and Lutetia clearly show significant ejecta reaccumulation (Schenk *et al.*, 2012; Thomas *et al.*, 2012). On Eros, however, Cheng *et al.* (2001, 2002) consider the presence of ejecta, especially for small craters, as minimal, whereas Blitz *et al.* (1999) consider ejecta from larger craters as a major contributor to the several tens of meters of regolith on many parts of Eros. Associated with ejecta burial is the poorly understood scouring process of ballistic sedimentation (Oberbeck, 1975). Ballistic sedimentation involves high-energy deposition of ejecta onto the surface beyond the crater rim that mobilizes regolith where the ejecta land (Melosh, 1989).

**2.2.4. Impact-induced seismic shaking on asteroid surfaces.** The Ranger images of the Moon revealed downslope flow of material on lunar slopes in the form of slides, slumps, and creep processes, and impact-induced seismic effects were proposed as a potential cause (Titley, 1966). Cintala *et al.* (1978) published two of the primary reasons why impact-induced seismic shaking of a small body is an important surface modification mechanism. First, the small volume of the target body concentrates seismic energy from an impact within the body even though it has dispersed throughout the body. Second, the low surface gravity  $g_a$  of asteroids (frequently less than one-thousandth that of Earth) permits relatively small seismic accelerations to destabilize material resting on slopes, where destabilization begins at 0.2–0.5  $g_a$  for loose regolith (Lambe and Whitman, 1979).

Elastic stresses and seismic effects of large impacts on small bodies were first modeled by Fujiwara (1991) and Ivanov (1991), who investigated the formation of the Stickney impact crater on Phobos. Asphaug and Melosh (1993) also performed hydrocode modeling of the impact that produced the Stickney crater, and as a byproduct estimated the resulting velocities imparted to a hypothetical regolith layer resting on the surface, an effect called *seismic jolt* (Nolan *et al.*, 1996). More extensive seismic jolt estimates for large impacts on small asteroids [e.g., Gaspra (Greenberg *et al.*, 1994) and Ida (Greenberg *et al.*, 1996)] indicated that they can severely affect their cratering records, erasing most craters below a few hundred meters in diameter when a loose, mobile regolith layer exists.

The high-resolution, global-coverage of Eros by the Near Earth Asteroid Rendezvous (NEAR)-Shoemaker spacecraft greatly advanced studies of seismic shaking. In addition to clear indications of downslope regolith motion, the Eros cratering record also showed a particularly large number of degraded craters, along with a severe paucity of small craters ( $<0.1$  km in diameter), that were thought to possibly be the result of seismic shakedown (Veverka *et al.*, 2001; Chapman *et al.*, 2002). Richardson *et al.* (2004, 2005) used a series of linked seismic and geomorphic models to investigate the detailed process of impact-induced seismic shaking on Eros-like bodies. They developed a basic theory for propagating seismic energy in a highly fractured asteroid, drawing upon previous lunar crust seismic propagation theory (Toksöz *et al.*, 1974). Synthetic seismograms were then applied to a model

of regolith resting on a slope, and the resulting downslope motion computed for a full range of impactor sizes. This computed downslope regolith flow was then used in a fully three-dimensional model of the body's surface, with craters formed by impacts and then erased by the effects of superposing craters, ejecta coverage, and seismic shakedown. These simulations agreed with the observed Eros cratering record, including the observed paucity of small craters (see section 2.3). More recent simulations (Richardson, 2013) showed that for an Itokawa-like body with an extremely small gravity field ( $<0.1$  mm s $^{-2}$ ), impact-induced seismic shaking is especially effective at degrading and erasing craters on very short timescales, such that the surface for an asteroid like Itokawa should be maintained clean of all but the very most recent impact craters, with all others reduced to little more than a collection of vague, filled circular features, as observed (Abe *et al.*, 2006).

An important feature of impact-induced seismic shakedown is its extreme dependence on the size and surface gravity of the asteroid under bombardment, a direct result of the fact that seismic accelerations of greater than about 0.2–0.5  $g_a$  are required in order to effectively produce downslope regolith flow. Lesser seismic accelerations are incapable of breaking the bonds of particle friction and cohesion and causing movement under the force of gravity. Richardson *et al.* (2005) examined this feature in detail, showing that for a body less than 5 km in diameter, impactors of less than a few centimeters in diameter (at typical asteroid impact speeds) are capable of producing a global seismic event producing accelerations larger than  $g_a$  across the asteroid's surface. For a body in the size range of 10–30-km mean diameter (like Eros), a global seismic event requires an impactor of a few meters in diameter. There is an upper limit on asteroid size for experiencing global, surface-modifying, seismic effects from individual impacts; it is about 70–100 km (depending upon asteroid seismic properties). Larger asteroids will experience only localized (regional) seismic effects from individual impacts.

Beyond effects on small craters, there are catastrophic seismic effects of large impacts, exemplified on Eros and Šteins. NEAR-Shoemaker images of Eros (Thomas and Robinson, 2005) revealed differences in crater densities and scattered boulder densities that pointed to Shoemaker, the most recent large impact crater on Eros (~7.6 km diameter), as the source of these disparities. In particular, craters smaller than ~0.6 km in diameter showed a proportional decrease in numbers as the straight-line, chord distance (through the interior of the asteroid) decreased, a decrease that could not be fully attributed to visible ejecta coverage as a result of the impact. This gradient in crater density as a function of linear distance from the center of Shoemaker crater indicated that (1) the interior of Eros was coherent enough to permit the efficient passage of seismic energy to broad regions on the surface of the body, and (2) this energy was sufficient to produce noticeable degradation and/or erasure of craters smaller than ~0.6 km in diameter as a function of seismic proximity to the large impact.

As a second example, Šteins is particularly interesting from the standpoint of seismic shaking in that it lies midway in size (at ~7 km long) between the ~34-km-long Eros studied by NEAR-Shoemaker, and the ~0.5-km-long Itokawa studied by Hayabusa. As described earlier, the surface of Šteins shows a noticeable paucity of small craters below about ~0.6 km in diameter, increasingly so as one moves to smaller sizes. Marchi et al. (2010) ascribed this general paucity of small craters to one or a combination of two possibilities, either the cumulative effects of (small) impact-induced seismic shaking, or the gradual reshaping of the asteroid due to spinup and spindown caused by the Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) effect (Rubincam, 2000). In addition, observed heterogeneities in the small crater distribution may be due to a singular impact event: the formation of the relatively fresh ~2-km-diameter Diamond crater, which had disruptive effects for the rest of the surface (Jutzi et al., 2010a), probably similar to those the formation of Shoemaker crater apparently had on the surface of Eros.

### 2.3. Model Production Function and Age Determination

We provide crater-retention age estimates for some of the crater SFDs presented in section 2.1, and discuss the effects of crater obliteration (section 2.2) for selected cases (see the chapter by Barucci et al. in this volume for additional examples).

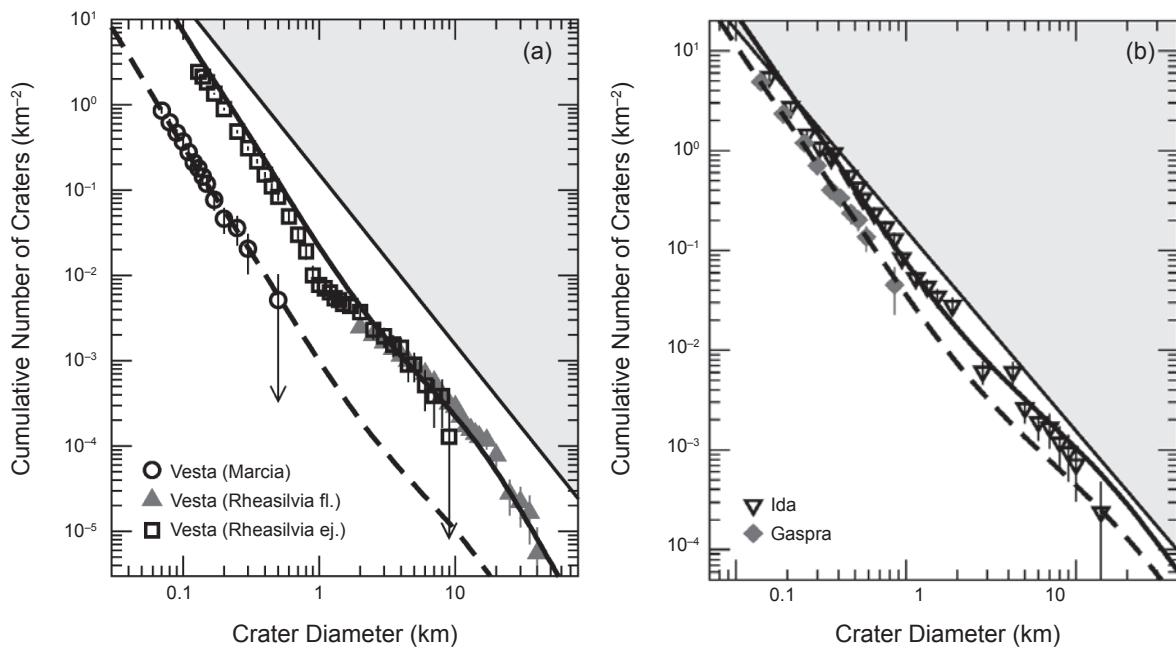

The assessment of cratering ages requires knowledge of impactor SFD, impact rate, and a crater-scaling law (i.e., a relationship between impactor sizes and crater sizes). These inputs are used to derive the model production function (MPF), i.e., the number of craters per unit time per unit surface (O'Brien et al., 2006; Marchi et al., 2010, 2011, 2012a,b). Among the available crater-scaling laws, we implemented the one by Holsapple and Housen (2007). The advantage of this formulation is that it is of general purpose and can be applied to both strength and gravity regimes. Furthermore, it allows full control of target physical properties, which may differ among various asteroids and across a body. On the other hand, crater size may depend strongly on input parameters (mostly the strength of the target,  $Y$ ), so the cratering-retention age may vary depending on the assumptions. Here we restrict our analysis to outline how to obtain crater-retention ages and how they depend on the assumed parameters. An important aspect to bear in mind is that assessing crater-retention ages is a multiple-step problem and, whenever possible, geological analyses need to be implemented to narrow down the possible range of target properties.

We consider two main cases. The first is the so-called *hard rock* (HR) case. The crater-scaling law for hard rock has been extensively applied to terrestrial planets and asteroids (Mosh, 1989), and therefore offers a good term of comparison. Here we adopt a rock strength of 20 MPa (Asphaug et al., 1996). There is little doubt, however, that the HR scaling does not generally apply to asteroids, particularly for small

craters formed in regolith or craters formed on a rubble-pile asteroid that are much larger than the components of the rubble. For this reason, we also implement an additional crater scaling for weaker materials; we adopt a scaling [for so-called *cohesive soils* in Holsapple and Housen (2007)] that has been calibrated using impact experiments on various weaker terrestrial materials, including alluvium, whose strength is below or on the order of 100 kPa at most. Here we assume that this scaling is applicable to craters in the size range of tens to hundreds of meters, and we adopt a nominal strength of 2 MPa, justified by the fact that the craters under analysis reach a significant depth where an increased strength with respect to laboratory experiments is expected (we also use different strength values for specific cases). This choice seems reasonable given that lunar regolith has a strength of ~1 kPa (at 2 m depth), and the strength increases with depth. Larger craters, however, reach a much greater depth, and it is uncertain whether both the hard rock or weaker scaling — or neither — apply. Our current understanding of asteroid evolution suggests that all except large ones undergo major collisional evolution during their lifetimes (Bottke et al., 2005), to the point that most are probably rubble piles. Larger asteroids (such as Vesta) are certainly not rubble piles; however, their upper layers may well be moderately to highly fractured, like megaregolith on the Moon. We generally refer to these situations, as well as to the loose-material case, as *rubbly material* (RM), for which we apply the cohesive soil expression by Holsapple and Housen (2007) for various values of strength as indicated.

Impact rates and velocities were specifically computed for each asteroid, using a model main-belt population from Bottke et al. (2005). Current impact rates have been extrapolated back in time following a recent model of main-belt evolution (O'Brien et al., 2014). In the following discussion we will not consider Mathilde, because the crater-scaling law for highly porous bodies is highly uncertain. Also, for the sake of simplicity we will not provide error bars for the best-fit ages. The formal analytical best-fit age uncertainties are typically on the order of a few percent. However, the uncertainty resulting from the impactor population and crater-scaling law can be as low as ~20–30% for statistically robust crater SFDs (such as Rheasilvia), and it can be even larger for oddly shaped crater SFDs and/or with low statistics (such as Šteins).

**Cratering retention ages** — For the interesting case of Vesta, we obtain an age of ~1 Ga for Rheasilvia floor's crater SFD. This age is obtained both using the HR and RM ( $Y = 2$  MPa) scaling laws. The quality of the fit is almost identical and only one of them is shown in Fig. 4. The MPF slightly overestimates the number of craters on the smooth ejecta unit. This is not surprising because of the different crater size range and nature of the terrains. The difference can be entirely due to variation in the properties of the terrains. It is also possible that the assumed impactor SFD overestimates the real main-belt population. The dip at crater sizes ~0.7–2 km is interesting and may represent a real feature in the impactor SFD. Applying the same scaling laws, we

**Fig. 4.** Examples of model production function (MPF) best fits (solid and dashed thick black curves) for some of the crater SFDs presented in Fig. 2. (a) Vestan terrains, (b) Ida and Gaspra. Note that the change in slope of the MPF is primarily due to similar changes in slope in the assumed impactor SFD. The crater-scaling law may also introduce minor modifications in the MPF from one asteroid to another depending on the target strength and gravity, particularly for large craters on large asteroids that may approach the gravity regime. For details on the parameters used for the fits see the text. The thick solid line that bounds the gray area defines the empirical saturation level as in Fig. 2.

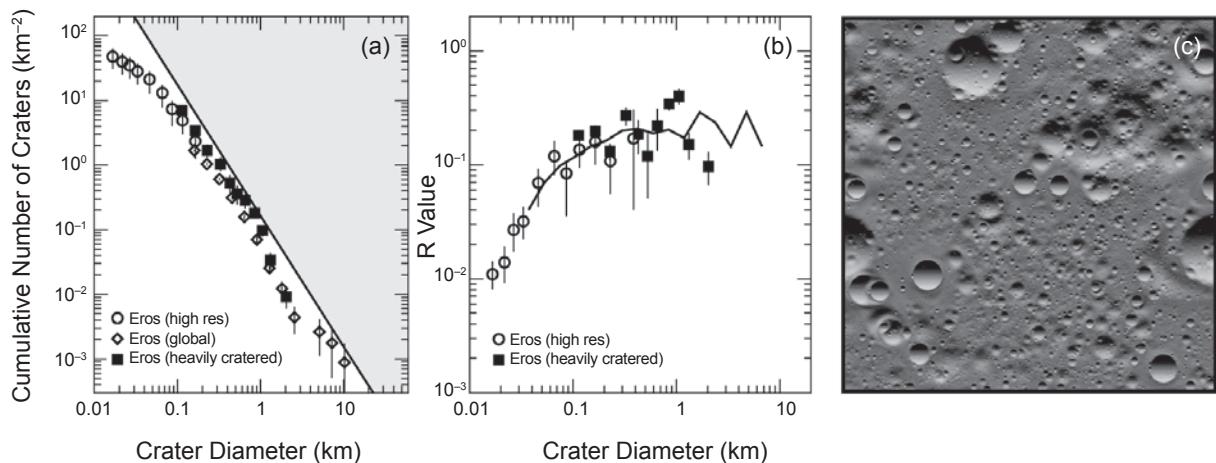

derive an age of  $\sim 50$  Ma for the Marcia smooth unit (Fig. 4). It should be noted that the target strength has a significant effect on small crater formation (crater size  $\sim Y^{(0.2-0.3)}$ ), and a strength variation of a factor of 10 results in a factor of 2–3 variation in the cratering age.

It is more difficult to derive an age for the heavily cratered terrain. A nominal fit using RM ( $Y = 2$  MPa) scaling law gives an age of  $\sim 4.2$  Ga. This should be regarded as a lower limit, given that crater obliteration is expected to be important for old terrains. An attempt to correct for this process, following the numerical approach outlined by O'Brien *et al.* (2006), gives an age of  $\sim 4.4$  Ga. These ages are certainly very uncertain; nevertheless, it is possible that much of the collisional history of Vesta may still be recorded in its HCT.

For Gaspra, we obtain an age of  $\sim 1.5$  Ga for both HR and RM ( $Y = 2$  MPa) scaling laws, which may increase to  $\sim 1.8$  Ga if crater obliteration is considered (Fig. 4). In the case of Ida we obtain an age of 3.3 Ga (HR) and 2.8 Ga (RM,  $Y = 2$  MPa), ignoring crater obliteration. Both ages become  $\sim 3.5$  Ga if we correct for crater obliteration, and the crater SFD seems to be close to or in saturation (Fig. 4).

The case of Eros is interesting for several reasons. First, it is a near-Earth object, yet it is generally believed that most observed craters formed while Eros was in the main belt, prior to being deflected into a near-Earth orbit. Here we assume, therefore, average main-belt impact rates, and derive an age of about 1.5 Ga for both HR and RM ( $Y = 2$  MPa) scaling

laws. This age is derived without crater obliteration and it is based on the fit of craters  $>0.4$  km (using the global catalog shown in Fig. 5a). Figure 5a also provides two additional crater SFDs: (1) a highly cratered terrain ( $D \sim 0.1\text{--}2$  km), and (2) a high-resolution count on a smaller area ( $D \sim 0.01\text{--}0.2$  km). Interestingly, the global crater SFD lies below the heavily cratered crater SFD for craters in the size range  $\sim 0.2\text{--}1$  km. This depletion has been ascribed to erasure due to the formation of Shoemaker crater, as mentioned in section 2.2.4 (Thomas and Robinson, 2005). The global crater SFD is used here for age dating because it provides better statistics at large crater sizes, but it should be noted that the Eros surface is not uniform. The difference between our age estimate with a previous age estimate (Richardson *et al.*, 2005) of  $\sim 0.4$  Ga can be understood in light of the different assumptions. In particular, they implemented a different scaling law that results in a much larger crater for the same impactor. Therefore, the resulting age is younger. In fact, we obtain a similar age implementing RM scaling and  $Y = 200$  kPa. On the other hand, Richardson *et al.* (2005) also argued (based on the largest craters) that the cratering age may be as old as 1–2 Ga. The second aspect of interest is the availability of high-resolution measurements that allow validation of the seismic models. Figures 5b,c show that the downslope regolith migration resulting from impact-induced seismic shaking can explain the paucity of small craters. A similar model also provides a good fit to Itokawa crater SFDs.

**Fig. 5.** (a) Various Eros cumulative crater SFDs from Chapman et al. (2002) (high resolution), Veverka et al. (2001) (heavily cratered), and Thomas and Robinson (2005) (global). The latter is an average over the whole surface, including regions where small craters were erased by formation of Shoemaker, and therefore it contains fewer craters than the heavily cratered counts in the size range 0.1–1 km. The thick solid line that bounds the gray area defines the empirical saturation level as in Fig. 2. (b) Same distribution as in (a) but now depicted in relative-density plot fashion (*Crater Analysis Techniques Working Group*, 1979), which is better suited to show fine-scale variations in the distributions, showing the increased paucity of small craters as one goes below about 0.1 km crater diameter. The solid curve shows the crater counts for the model simulation shown in (c).

### 3. CRATER MORPHOLOGICAL PROPERTIES

Crater morphological properties, e.g., depth-to-diameter ratio, can be used to address degradation processes operating on asteroids. Early observations of lunar terrains (Gilbert, 1893) revealed that craters with diameters below a few tens of kilometers (so-called *simple* craters) have bowl-shaped profiles with the maximum depth at the center of symmetry of the crater. Larger craters (so called *complex* craters) show progressively higher raised central peaks surrounded by flatter crater floors. The final crater shapes are attained during the so-called *modification* stage (e.g., Gault et al., 1968) that takes place when the excavation cavity has reached its maximum radial extension, and surrounding highly fractured rocks collapse within the cavity pulled by gravity. The transition from simple to complex craters scales as  $\sim 1/g_a$  (Pike, 1980); therefore, on asteroids it takes place at much larger crater sizes (see section 2) compared with terrestrial bodies. Due to the low gravity of asteroids, the crater-modification stage is probably largely affected by target mechanical properties (e.g., strength) and the asteroid's overall shape. Once a crater is formed, additional degradation processes are responsible for the evolution of its morphology, as discussed in section 2.

In general, crater morphologies on asteroids are not fundamentally different from the ones observed on terrestrial bodies, except that craters on all but the largest asteroids generally form in the strength regime, and they are also simple craters (except the largest craters on the largest asteroids, e.g., Rheasilvia basin on Vesta). Also, the morphology of a crater approaching the physical size of the asteroid

significantly differs from the final shape described above. We review key morphologic parameters of asteroidal craters, such as depth-to-diameter ratios, which can be measured from individual images or from digital terrain models. Additional useful data are the ellipticity, particularly for craters on slopes, and the overall shape of large depressions that approach an asteroid's physical size.

#### 3.1. Crater Depth-to-Diameter Ratio

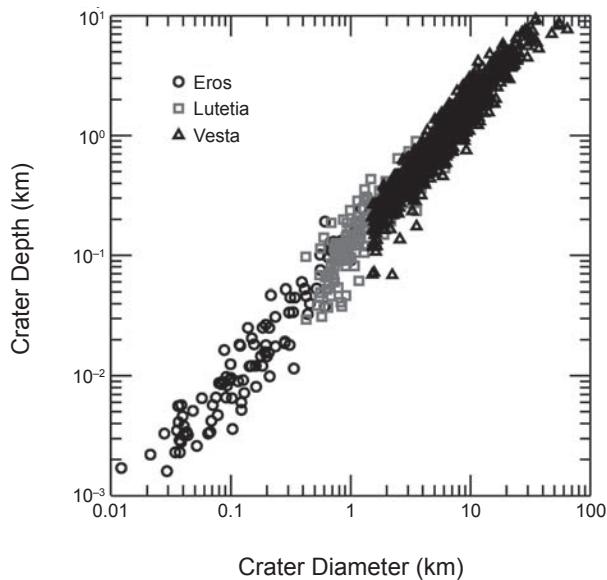

Here we discuss in detail asteroid crater morphology by presenting selected examples from Itokawa, Eros, Lutetia, and Vesta. For all these bodies, crater morphologies are assessed from imaging. Crater diameter is obtained by fitting an ellipse to the crater rim and taking the length of the largest axis (in case of nongeoreferenced images) or the average of the two axes (for georeferenced images). It can be measured very precisely, with a typical uncertainty of twice the spatial resolution. Depth can be obtained directly if the spacecraft carried an altimeter, i.e., the NEAR-Shoemaker mission at Eros and the Hayabusa mission at Itokawa. However, in most cases, depth is measured with less-accurate indirect techniques such as measuring the length of rim shadows cast inside the crater, or using a digital terrain model (DTM) reconstructed by stereo-photogrammetry (e.g., Vesta) or stereo-photoclinometry (e.g., Lutetia) from the images. Comparisons of the different imaging-based methods show that the shadow technique tends to overestimate the depth while photoclinometry underestimates the depth, especially for the smallest craters. Stereo-photogrammetry is the most accurate technique, but requires multi-imaging of the surface with

very specific illumination conditions, not always achievable (especially during flybys).

In addition, for oddly shaped asteroids it is important to try to take into account preexisting topography under the crater when measuring the depth. Due to the non-equilibrium shape of most asteroids, their topographic excursions are generally significant with respect to the radius of the body.

Craters on asteroids display a wide range of shapes, from sharp bowls to very subdued and degraded depressions. This translates into a wide range of crater depths ( $h$ ). For simple craters this ratio follows a near linear law,  $h/D \sim k$ , where  $k$  for asteroids is approximately 0.15 (Grieve, 2007). Figure 6 shows an example of this linear relationship for Eros, Lutetia, and Vesta. Variations are generally interpreted as reflecting different states of degradation of the surfaces, but different physical properties of the target may also play a role. Consider two examples: target properties (porosity, strength), and impact velocity. Craters in highly porous material generally have a higher depth-to-diameter ratio than those in low-porosity material [e.g., Mathilde (Housen and Holsapple, 2003)]. An interesting characteristic of craters on asteroids, as distinct from the Moon and terrestrial planets, is that they appear deprived of impact melts due to the lower average impact speeds (e.g., Keil et al., 1997; Marchi et al., 2013); therefore, they better show the morphology of the floor and walls.

**3.1.1. Small craters.** For asteroids visited by space missions, the overall properties of  $h/D$  distributions (weighted toward fresher craters, but including somewhat degraded craters, as well) look very similar. Ranging from  $\sim 0.12$  to  $\sim 0.20$  (excepting Itokawa), their mean values are centered

**Fig. 6.** Distributions of crater depth vs. crater diameter for asteroids Eros, Lutetia, and Vesta. Although the three asteroids are very different, one can notice similar behavior in their crater morphologies. The average relation between crater depth and diameter is close to a linear law with a slope of  $\sim 0.15$ , although degradation state is an important contributor.

close to  $\sim 0.15$  (Carr et al., 1994; Sullivan et al., 1996; Veverka et al., 1999, 2000; Besse et al., 2012; Vincent et al., 2012, 2014), slightly below the canonical value of  $\sim 0.2$  for planetary surfaces (Melosh, 1989, and references therein). Smaller, rubble-pile asteroids (e.g., Itokawa) tend to have shallower craters than larger bodies (e.g., Lutetia, Vesta).

Small craters exhibit a range of measured  $h/D$ , while larger craters tend to have similar  $h/D$  ratios. In general, the dispersion in  $h/D$  values decreases with increasing crater diameter. This may be the result of several factors: (1) Measurement uncertainty is larger for smaller craters, especially when their diameters are only a few times the image resolution, but the dispersion in  $h/D$  is still visible when removing craters smaller than  $10\times$  the resolution; (2) fresh craters are more likely to be found among small craters than larger ones, thus small craters can be found in all states of degradation while very young large craters are generally absent; and finally (3) small craters are most efficiently altered, even to the point of erasure, by post-formation processes, such as ejecta blanketing from nearby craters or seismic shaking (see section 2), whereas the largest craters remain visible, despite degradation, throughout the history of the asteroid's surface (unless large craters are saturated).

Relationships between strength, gravity, and formation regime were tested on Vesta by Vincent et al. (2014). The transition between strength and gravity regime is given by  $D_{\text{trans}} = 0.8 Y/(\rho g_a)$  (Asphaug et al., 1996), or  $D_{\text{trans}} \sim 25$  km for Vesta ( $Y = 20$  MPa,  $\rho = 2600$  kg m $^{-3}$ ,  $g_a = 0.25$  m s $^{-2}$ ), typically where we start to see a narrowing of the  $h/D$  distribution toward the typical ratio of 0.15. The transition between simple and complex craters scales with the inverse of the gravity, so simple craters should transition to complex craters for  $D \sim 160$  km for Vesta. The transition size is fuzzy and, indeed, a crater as small as the  $\sim 70$ -km-diameter crater Marcia shows evidence of incipient central peak formation.

If the average initial  $h/D$  is similar for all asteroids, recent work on high-resolution images and DTMs has shown that this picture might be too simple, either because of the low resolution of previous studies or the limited number of craters observed. While the overall distribution is generally peaked near a particular value, more complete statistics show that the average  $h/D$  can differ from region to region. This is very prominent on Vesta, where a double peak is visible in the global distribution of  $h/D$  (Vincent et al., 2014) with about a 25% difference between the peaks at 0.15 and 0.19. The same effect can be seen on Lutetia, with up to a 40% difference in average  $h/D$  between different regions (Vincent et al., 2012).

It is also valuable to compare the cumulative probability distribution of  $h/D$  for different regions and bodies. Figure 7 shows an example of such comparison for Lutetia and Vesta. On both bodies measurements were obtained on the oldest, heavily cratered regions found on the northern hemisphere and on younger regions of Vesta mostly from the southern hemisphere, as well. By comparing the cumulative probability distributions of these broadly different terrains we find that the oldest regions of Vesta and Lutetia display very similar distributions, while younger vestan areas significantly

lack shallow craters. Overall, *Vincent et al.* (2014) found a very good correlation between h/D variations and vestan geologic units (*Yingst et al.*, 2014). This is interpreted as evidence of the resurfacing event triggered by the giant impacts in the southern hemisphere of Vesta, which reset the polar surface and partially erased craters even approaching the equatorial regions.

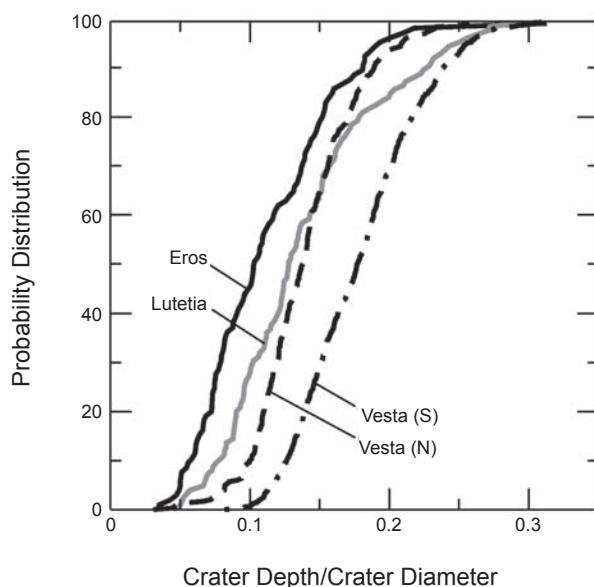

Although most small craters on asteroids resemble those observed on rocky planets, there are a few peculiar morphologies that seem more common on asteroids. For instance, many examples of what are termed bimodal craters were discovered and analyzed on Eros (*Mantz et al.*, 2004), Lutetia (*Vincent et al.*, 2012), and Vesta (*Krohn et al.*, 2014). They are characterized by a sharp rim on one side and a less-defined rim on the other, often associated with important mass wasting. Those craters are typically found on slopes with respect to the gravity field, with the sharper rim always on the more elevated side. This peculiar morphology is explained by slumping of material from the upper rim toward the lower

rim combined with failure of the lower rim. Material accumulates on the lower edge of the impact feature, smoothing the topography. As discussed earlier, such features are more common on asteroids due to the stronger changes in topography and gravity with respect to the general curvature of the body. Figures 8a,b present a few examples of these craters.

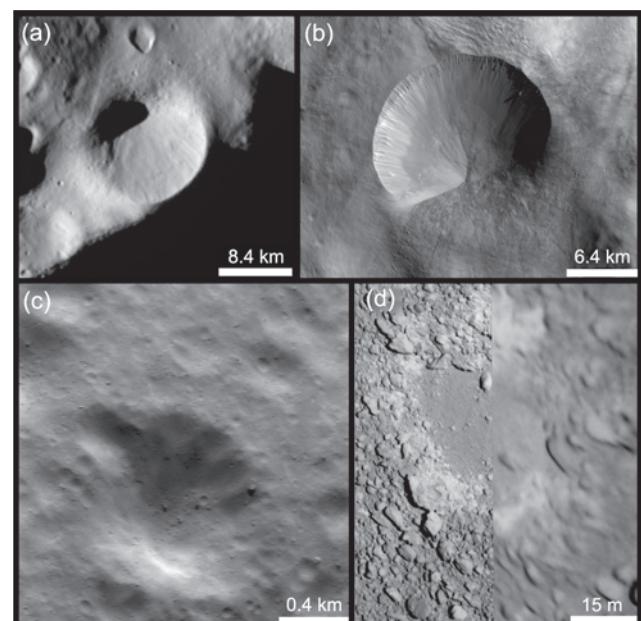

In areas with relatively homogeneous physical properties, variations in crater morphology cannot be due to variations in such properties. Additionally, for surfaces unaffected by a massive, local resurfacing event, we can assume that differences in h/D for craters of similar sizes can measure the degradation rate, as the variation of degradation state is only a function of age. For instance, the dispersion of h/D for small craters on regions of similar physical properties on Vesta implies a degradation rate of  $\sim 10^{-7}$  m yr<sup>-1</sup> (*Vincent et al.*, 2014), comparable with an estimate of boulder erosion on Lutetia (*Kueppers et al.*, 2012), but considerably higher than for the Moon (*Fassett and Thomson*, 2014).

The morphologies of craters on Eros have been investigated by several authors (*Veverka et al.*, 2000; *Chapman et al.*, 2002; *Robinson et al.*, 2002). Measurements that make use of the NEAR Laser Rangefinder data and a careful assessment of crater freshness indicate that many of the freshest craters on Eros typically possess h/D near 0.2 for D > 100 m (Fig. 6). These ratios match results reported on the Moon (*Pike*, 1977) and Ida (*Sullivan et al.*, 1996). For D < 100 m, fresh craters on Eros are shallower than those on the Moon. The average h/D of all craters on Eros indicate that most are degraded (Fig. 8c) and follow a pattern akin to what is observed on Vesta, Šteins, and Lutetia.

Craters on Itokawa are very different from most other asteroidal craters. The best defined craters (*Hirata et al.*,

**Fig. 7.** Cumulative distribution function of h/D on Eros, Lutetia, and Vesta (N: northern hemisphere, S: southern hemisphere), emphasizing the relative differences in the distribution of depth to diameter ratios. One can see that old surfaces like Lutetia or the northern hemisphere of Vesta tend to have significantly more shallow craters than recently reset areas such as the southern hemisphere of Vesta. This degradation with age is even more pronounced in the case of Eros where additional effects such as seismic shaking smooth the topography. About 80% of Eros' craters have h/D less than the typical value of 0.15, 70% on Lutetia and Vesta N, and only 20% in Vesta S. Asteroidal h/D average values are 0.12 for Gaspra (*Carr et al.*, 1994), 0.15 for Ida (*Sullivan et al.*, 1996), 0.2 for Mathilde (*Veverka et al.*, 1999), 0.14 for Eros (*Veverka et al.*, 2000), 0.08 for Itokawa (*Hirata et al.*, 2009), 0.12 for Šteins and Lutetia (*Besse et al.*, 2012; *Vincent et al.*, 2012), and 0.15 and 0.19 for Vesta N and Vesta S, respectively (*Vincent et al.*, 2014).

**Fig. 8.** Peculiar crater morphologies on asteroids. (a) Bi-modal crater on Lutetia and (b) Vesta. (c) Eroded impact crater on Eros, and (d) a shallow impact feature on Itokawa.

2009) are generally very shallow, with h/D ratios below 0.1 (Fig. 8d). Seismic shaking on this small body, as discussed in the previous section, would surely rapidly degrade any craters that formed on its surface. But, in addition, two other factors might contribute to causing these low h/D ratios: (1) The presence of numerous large blocks can depress crater formation as the impact energy fractures a boulder rather than excavating a depression (Chapman *et al.*, 2002) or otherwise leading to formation of flat shallow craters (e.g., Güttsler *et al.*, 2012), and (2) the large curvature of Itokawa relative to some of the diameters of the large candidate craters proposed by Hirata *et al.* (2009) can yield very shallow craters, with the crater floor exceeding the height of the crater rims in some rare instances (Fujiwara *et al.*, 1993; Asphaug *et al.*, 1996). The shallow nature of many of Itokawa's craters can therefore be attributed in part to factors influencing their initial formation as well as to subsequent degradation by seismic shaking.

Finally, it is worth considering the spatial variation of crater morphologies across small body surfaces. Most of the differences can be linked to aging processes (erosion, infilling, rim collapse, seismic shaking). However, when statistics are significant enough to build a map of h/D or measure it on various regions of an asteroid, it appears that regions of similar age can show different average h/D. This was determined on Lutetia and Vesta (Vincent *et al.*, 2012, 2014), where a link between variations of crater morphologies and geological units might indicate differences in their physical properties.

**3.1.2. Large craters.** The largest craters on asteroids can have diameters approaching or even exceeding the asteroid's radius (see Fig. 9). Most of these craters can be grossly approximated as simple bowl-shaped craters, with a few exceptions (e.g., the Rheasilvia basin on Vesta). For these simple giant craters where their h/D can be measured, this ratio is typically less than 0.2 (Thomas *et al.*, 1999). An important reason why many of these giant craters are shallow is illustrated by measurements of h/D of three giant Eros craters both along and perpendicular to the greatest radius of curvature of the asteroid. For example, Himeros crater has an h/D of 0.17 along the long axis of Eros, but a much

shallower h/D of 0.1 when measured perpendicular to the long axis of the asteroid. These craters are shallower when the local radius of curvature is more important.

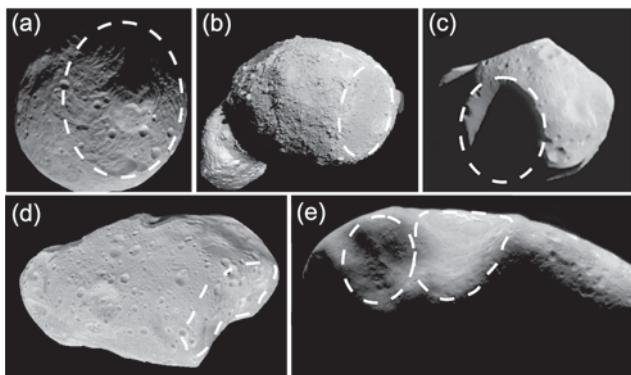

The asteroid Mathilde is unique in that it possesses five giant craters on its imaged side, none of which have led to its disruption. Equally remarkable, given what is now apparent on Eros and Vesta, none of these craters seem to disturb their neighbor. These observations have been attributed to Mathilde's high porosity of 50% (Cheng and Barnouin, 1999; Housen *et al.*, 1999), which can better absorb the energy of these impacts, making the asteroid harder to disrupt and each crater less likely to influence its neighbor.

The  $500 \pm 20$ -km Rheasilvia basin is unique among asteroidal craters (Thomas *et al.*, 1997; Schenk *et al.*, 2012). It possesses a broad central uplift whose height is similar to its rims. The central uplift is remarkably broad compared with other craters on the Moon or Mercury and exhibits extensive slumping and sliding in its interior. In addition, radial curved ridges near the central mound may be the result of Coriolis forces acting on inward-collapsing material during the modification stage (Otto *et al.*, 2013). However, unlike similar-sized craters on other planets, little impact melt is observed, probably due to the comparatively low impact velocities in the asteroid belt, which do not efficiently generate melt (e.g., Keil *et al.*, 1997; Marchi *et al.*, 2013).

To date only the relatively recent, giant craters Rheasilvia on Vesta and Shoemaker on Eros show quantitative evidence for resurfacing a significant fraction of the surface of either asteroid. In the case of Rheasilvia, its ejecta have hidden most craters within tens of kilometers of its rim and influenced the crater SFD and h/D of craters further beyond (see Fig. 1) (Marchi *et al.*, 2012a; Schenk *et al.*, 2012). Unlike Rheasilvia, Shoemaker crater probably removed craters mainly by seismic shaking (Thomas and Robinson, 2005). Indeed the density of craters ranging from  $\sim 0.2$  to  $\sim 1$  km diameter increases with radial distance from the center of Shoemaker crater rather than with distance from the crater rim, as would be expected for ejecta. Furthermore, the density of the largest blocks seen on Eros that have been attributed to ejecta from Shoemaker crater (Thomas *et al.*, 2001) do not correspond with the locations where the dearth of craters on Eros has been observed.

#### 4. LINEAR SURFACE STRUCTURES AND BLOCKS

Asteroids possess various types of linear surface structures (Jaumann *et al.*, 2012; Pockter *et al.*, 2002; Sullivan *et al.*, 1996; Thomas *et al.*, 2012; Thomas *et al.*, 1979; Veverka *et al.*, 1994). They have been identified on most asteroids visited by spacecraft with the possible exception of Šteins (Besse *et al.*, 2012; see the chapter by Barucci *et al.* in this volume) and Mathilde, which possess some limited evidence for them (Thomas *et al.*, 1999), although those two asteroids were imaged with relatively poor resolution. In most cases, when sufficiently good image resolution is available, the genesis of these lineaments can be attributed in part, and

**Fig. 9.** Examples of larger features on asteroids. (a) Vesta, (b) Itokawa, (c) Mathilde, (d) Gaspra, (e) Eros.

sometimes entirely, to a source crater. Lineaments can concur to obliterate preexisting topography, including craters (Prockter et al., 2002; Jaumann et al., 2012), indicating that the formation of lineaments by large impacts can drastically reset the surface of an asteroid (see section 2). The large extent of many lineaments, and their link to the largest craters on asteroids, even when these lineaments are located far from these craters, indicate that internal properties of most of the asteroids visited must be capable of transmitting sufficient impact energy through their interior to cause near-surface failure that can be linked to a parent crater.

#### 4.1. Types of Lineaments

Lineaments on asteroids have various styles (Fig. 10). The most common are shallow troughs, grooves, and pit chains (Thomas and Prockter, 2010). Shallow troughs are linear depressions, with a flat floor and no raised rim. Grooves are usually V-shaped, while pit chains comprise a series of small depressions that are somewhat circular, with uniform sizing and spacing. Less commonly observed lineaments include fractures and broad flat troughs (Figs. 10e,f). Fractures have been reported only on Eros, perhaps because the imaging resolution for other asteroids did not easily permit their identification. The morphology of the observed fractures looks like a fan of cracks emanating from a ridge (Buczkowski et al., 2008; Prockter et al., 2002). On Vesta, broad troughs appear to be graben, with their floor tilting toward the dominant fault (Buczkowski et al., 2012). Such tilting is fairly common for graben that form in sedimentary environments on Earth, and may reflect the abundance of regolith on Vesta.

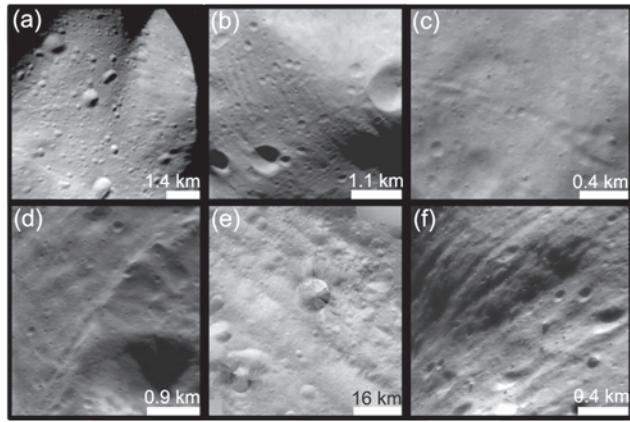

Ridges are another linear structure seen on asteroids that is also less common than negative relief linear features (Fig. 10d) indicative of extension. Ridges, however, appear to have formed through some displacement along a preexisting

zone of weakness, either because of translation and/or compression. Rahe Dorsum on Eros is one of the best examples of such a structure.

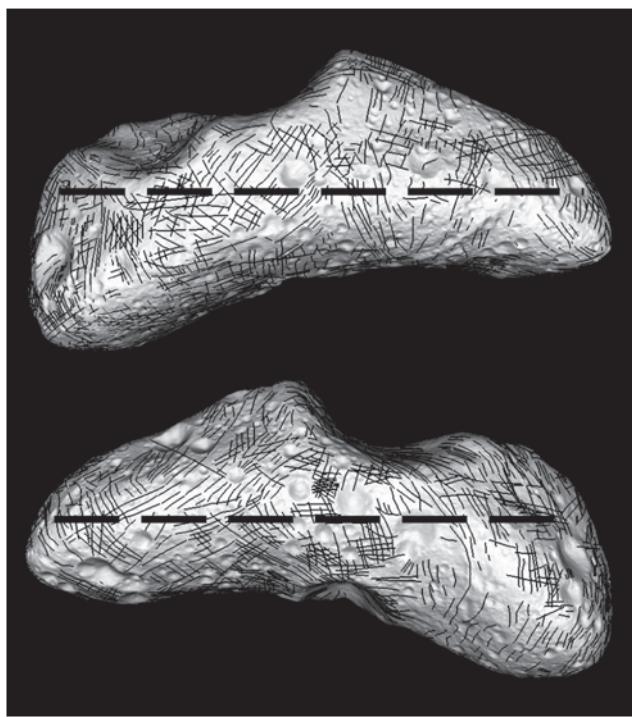

Shallow troughs have been observed on Ida, Gaspra, Eros, Lutetia, and Vesta. Grooves have been reported on Gaspra, Eros, Lutetia, and Vesta, while pit chains have been found on Steins, Eros, Lutetia, and — with extraordinary richness — on Vesta (Carsenty et al., 2013). Broad flat troughs are on Eros, Lutetia, and Vesta, while ridges are on Gaspra, Eros, Lutetia, Vesta, and even rubble-pile asteroid Itokawa. In the latter case, these appear to be very limited in length (Barnouin et al., 2014).

#### 4.2. Cratering Origin of Lineaments

Studies of the asteroids Eros, Vesta, and Lutetia show that there is a close correlation between the observed lineaments and craters, as had been suspected but not easily confirmed by earlier investigations of Ida and Gaspra (Thomas and Prockter, 2010). A detailed mapping of more than 1500 lineaments on Eros indicates that the longest, dominant set of lineaments is likely associated with the formation of large craters. Most of these long lineaments, sometimes in excess of tens of kilometers, are circumferential about impacts in the regions separating Himeros from Psyche crater. Fitting planes to the surface expressions of these lineaments provides the normal vectors to these planes, which preferentially point to either Himeros or Psyche crater (Fig. 11). It is difficult to assign which crater is directly responsible for most of the lineaments because they are essentially 180° away from each other on the opposite sides of the asteroid. Interestingly, many of the circumferential lineaments appear subdued, and are probably not very young. Although it is impossible to distinguish whether or not Himeros crater formed before Psyche, the large size of Himeros, and its degraded appearance relative to Psyche, suggest that it might have formed first. In such a scenario, it is plausible that Himeros could have initially generated most of the long circumferential lineaments, probably due to impact-generated tensile hoop stresses (Asphaug et al., 1996). Later craters such as Psyche, and perhaps Shoemaker, may have only reactivated them, causing the subdued appearance of many of the lineaments. Such a possibility is consistent with a recent numerical study, which models self-consistent dynamically interacting crack distributions and pressure-dependent granular flow of a highly damaged material (Tonge and Ramesh, 2015). These calculations investigate the evolution of porosity and damage in an asteroid. Damage is usually expressed on the surface of an asteroid as cracks. These calculations show for the simplest case where Eros is assumed to be a basaltic monolith that Himeros could easily create a 20–25% porous Eros, and generate lineament distributions comparable to those we see today. Furthermore, the model indicates that subsequent formation of Psyche and Shoemaker craters would have had minor global effects, with little change to the overall asteroid porosity and global surface cracking. These later craters limit their damage to local regions near the craters. However, the

**Fig. 10.** Common lineaments observed on asteroids: (a) grooves on Ida, (b) pit chains on Eros, (c) shallow troughs on Lutetia. Less common linear structures: (d) ridges seen on Eros, (e) broad troughs on Vesta, and (f) heavy modification of topography (a crater rim) on Eros by grooves and fractures.

**Fig. 11.** Global distribution of lineaments on Eros. The dashed black line indicates the average planes derived from a subset of about 1500 lineaments. Perpendicular to the dashed lines are seen the large craters Himeros (above line) and Psyche (below line), which are possible sources for some of the lineaments. The two views correspond to a rotation of 180° in longitude.

calculations also indicate that for a rubble-pile Eros struck by a projectile with the same size and speed as employed for the strong case, any global link between surface cracks to Himeros' formation is lost. Cracks are formed at all scales and in all directions, with little directional connection to the parent crater.

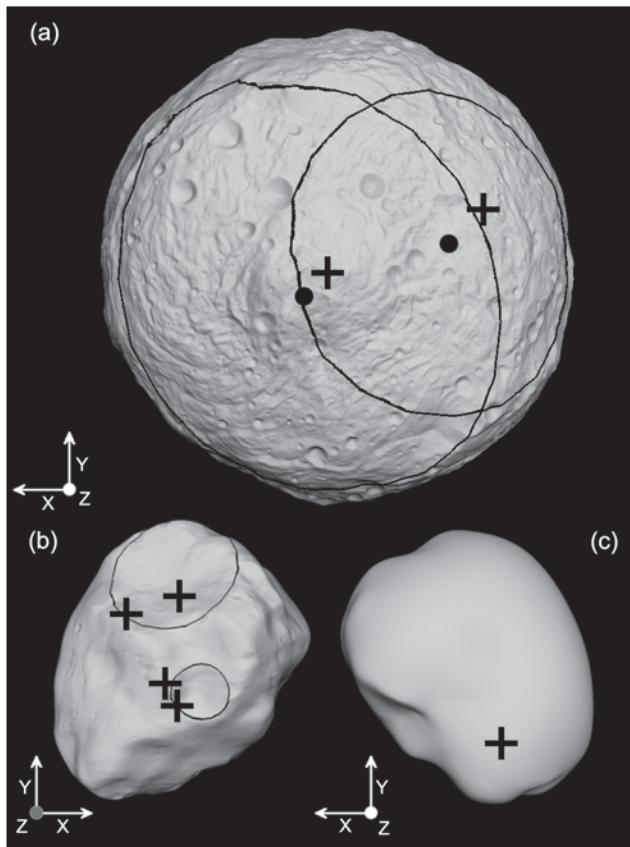

The internal structure of Eros is, however, not known. The largest lineament on Eros, Rahe Dorsum, along with two other sets of smaller lineaments that are either parallel or in conjugate orientation to Rahe Dorsum, seem to have no parent crater and could be a remnant from Eros' original parent body (Buczkowski *et al.*, 2009). Their presence suggests that Eros must have been somewhat damaged to begin with, perhaps as the result of the collision on a larger parent body. Such a view is substantiated by analyses that indicate that Eros is probably best represented by a lunar-like megaregolith covered by a regolith, but with some large interlocking aggregates or fragments, to account for the low measured porosity (Robinson *et al.*, 2002). Such large-scale fragments may also explain the presence of the long lineaments described above. Support for this scenario may come from a smaller subset of lineaments that are radial to many of the smaller ( $\leq 5$  km) craters (Buczkowski *et al.*, 2008), indicating that the characteristic size for the putative internal rubbles is likely to be comparable to or larger than

these craters. Therefore, although a monolithic Eros seems unlikely, it still may have significant internal coherence to explain some of the surface features.

The analysis of the three-dimensional orientation used to understand the origin of structural lineaments on Eros was also employed on Vesta and Lutetia. In the case of Vesta, the two main sets of impressive circumferential lineaments are related to the formation of the two south polar basins Rheasilvia and Veneneia (Jaumann *et al.*, 2012) (Fig. 12a). The older set is clearly related to the older Veneneia, while the younger features are associated with the younger Rheasilvia. These faults are much more impressive than on Eros, with absolute vertical and horizontal displacements comparable with the size of Eros itself. Preliminary numerical investigations (Buczkowski *et al.*, 2012) suggest that these likely reflect the differentiated internal structure of Vesta, which results in shock impedance differences that can accentuate the formation of large surface faults. Furthermore, a stronger metallic interior core may also contribute to localize seismic energy (Bowling *et al.*, 2014). The formation of circumferential lineaments on Vesta was also investigated with the help of laboratory experiments and three-dimensional CTH simulations (Stickler *et al.*, 2015). The results show that large impacts induce widespread subsurface damage, and that surface lineaments may be the manifestation of faulting due to shear localization in subsurface failure planes. Furthermore, the offset of the pole of the lineaments to the crater center can be used to constrain the geometry of the impact, such as the impact angle, which for the case of Rheasilvia was inferred to be at least  $\sim 50^\circ$  from the normal to the surface (Stickler *et al.*, 2015). This process may also explain the set of pit chains seen prevailing in the east-west direction that is parallel to the major set of faults due to the formation of Rheasilvia basin.

On Lutetia, the analysis of the lineaments (Besse *et al.*, 2014) shows that both radial and circumferential lineaments observed can be attributed to craters, as proposed in recent modeling (Jutzi *et al.*, 2013). Most of the circumferential features can be attributed to the north crater complex (formed by two to four overlapping large craters; see the chapter by Barucci *et al.* in this volume), but two other sets of lineaments have also been identified (Figs. 12b,c). One set can be linked to the 60-km Massilia crater, and the other to the southern region of the asteroid not imaged by the Rosetta mission (roughly corresponding to Massilia's antipodes). Given the apparent link between many of these lineaments and craters on Eros, Vesta, and Lutetia, this last set of lineaments on Lutetia could indicate the presence of another sizable crater in the southern hemisphere, although we cannot rule out its association with Massilia crater.

Asteroidal ridges do not seem to be directly related to any particular craters. While some studies have invoked an internal process for their formation (Greenberg, 2008), others indicate that these might be the result of collisional processes that are associated with the formation of the asteroids. As mentioned previously, Buczkowski *et al.* (2009) show that on Eros, the Rahe Dorsum has a set of conjugate fractures that are likely formed coevally with the Dorsum. Neither one

**Fig. 12.** Location of poles (black pluses) defined by best fit planes to circumferential lineaments seen on (a) Vesta (modified from Jaumann et al., 2012) and (b),(c) Lutetia (modified from Besse et al., 2014). The black lines mark major craters. The center of the large Rheasilvia and Veneneia basins on Vesta are also indicated (black dots) to highlight the slight misalignment with the poles of the equatorial troughs system associated with both basins.

of these features is obviously associated with any surface crater, which may suggest that they resulted from cracking during the disruption of Eros' parent body. Itokawa has a set of ridges that circumscribe the large lobe (but not the small lobe) that also do not have any obvious association with any of the known candidate craters located on the surface of the asteroid (Barnouin et al., 2008, 2014). These ridges may reflect some displacement along the edges of interior chunks in the body of Itokawa that were mobilized at some point in Itokawa's formation and evolution.

#### 4.3. Impact-Derived Surface Blocks

Besides forming craters and contributing to lineament formation, impacts also generate blocks on the surfaces of most small bodies. While large cratering events are the sources of many blocks on asteroids, some surface blocks may result from the disruptive origins of the asteroids, creating rubble piles, and may provide additional constraints on their makeup (Lee et al., 1986, 1996; Thomas et al., 2012; Kueppers et al.,

2012; Thomas et al., 2001; Nakamura et al., 2008; Michikami et al., 2008; Mazaroei et al., 2014; Carsenty et al., 2014).

High-resolution imaging data (<100 m/pixel) from asteroids Vesta, Lutetia, and Eros confirm the assumptions made in earlier efforts at Ida (Lee et al., 1996) that blocks on asteroids are the result of impact cratering. In many instances, the SFDs of blocks found to be associated with craters (e.g., Chapman et al., 2002; Kueppers et al., 2012), possess similar cumulative power-law exponents (slopes) with an average value of about  $-4$ . Although a preliminary analysis of the block distributions on Itokawa's surface (Michikami et al., 2008) found a shallow slope of  $-3$ , a recent more complete evaluation of all the largest blocks ( $>5$  m) on Itokawa (Mazrouei et al., 2014) show little difference from distributions derived from crater ejecta. The range of observed slopes on asteroids is comparable to that found for the block distributions of lunar impact craters, which cluster between  $-3$  and  $-4$  (e.g., Bart and Melosh, 2010). However, the blocks on Itokawa may more likely be the result of impact disruption and reaccretion (e.g., Fujiwara et al., 2006) rather than crater ejecta, despite the similar sloped SFDs. Despite the overall agreement, it is important to realize that lunar block SFDs often exhibit slopes as shallow as  $-2$  and, in a few cases, also as steep as  $-5$  (Bart and Melosh, 2010). Such a significant spread in the slope can be due to differences in terrain properties and/or preservation. In fact, it should be noted that once blocks are exposed on the surface, they undergo erosion and breakup as a result of a number of processes, such as small impacts and thermal fatigue (e.g., Delbo et al., 2014), which may alter their SFD.

The overall similarity of the asteroidal block SFDs likely reflects a common formation process, a similar range of material properties, and similar preservation. Most of these blocks appear to be derived by impact cratering (Lutetia, Eros) or disruption (Itokawa) of preexisting regolith and rubble that was created by brittle fracture. That some individual fragments fail brittlely is suggested by several studies (Nakamura et al., 2008; Michikami et al., 2010) that show that the blocks on Itokawa possess morphologies, shapes, and aspect ratios very similar to fragments generated in small-scale laboratory experiments produced by brittle failure of individual rocks (Tsuchiyama et al., 2011). Once blocks are exposed on the surface they follow similar evolutionary pathways, probably as a consequence of thermal fatigue and impacts, so they maintain similarities in their size distributions.

#### 4.4. Implications for the Internal Structures

The analyses of lineaments on Vesta, Lutetia, and perhaps Eros indicate that these objects must possess some internal ability to transfer impact energy over long global distances. Even the rubble-pile asteroid Itokawa has ridges, which indicate the presence of localized aggregates that have slid past each other, although not at the global scales seen elsewhere. Blocks observed on Vesta, Lutetia, Eros, and Itokawa provide further evidence for the presence of subsurface rocks that have been broken brittlely by impacts. Gaspra and

Ida also possess lineaments, and the latter also has surface blocks. Ida's measured density of  $2600 \pm 500 \text{ kg m}^{-3}$  is similar to that for Eros given its proposed composition, and suggests that its interior is capable of transferring impact energy over long distances (Asphaug *et al.*, 1996). These observations are consistent with their interiors — at least to the depth reached by cratering — being structured and made of materials that are connected and can fail brittlely. Of course, Vesta, and possibly Lutetia, are large enough to be primordial differentiated objects that have not been fully damaged and are surely competent (e.g., Pätzold *et al.*, 2011; Russell *et al.*, 2012; Park *et al.*, 2014).

However, collisional-evolution models strongly suggest that smaller asteroids, like Eros and Ida, should be rubble piles (Michel *et al.*, 2001; Durda *et al.*, 2007). The low observed porosity and global lineament patterns observed for some asteroids might be indicators of rubble piles with good internal connectivity. Numerical simulations of impacts into loosely bound aggregates show that well-connected aggregates are probably necessary to generate the stresses that produce lineament patterns like those observed on Eros (Crawford and Barnouin-Jha, 2003). Alternatively, Asphaug (2009) proposed that the surface morphology and density of Eros could be explained by a cohesive sand pile, although the apparent relationship of many of the lineaments to large craters (in the same way lineaments are related to large craters on Vesta and Lutetia) casts doubt on a sand-pile model. Furthermore, surface roughness assessments indicate that some bedrock could be protruding through regolith on slopes (Cheng *et al.*, 2001, 2002), which suggests that these asteroids have competent components that may even retain some memory of their relationships on their parent bodies from which they were liberated by catastrophic collisions (see the chapter by Michel *et al.* in this volume).

Mathilde is an exception to what we observe for many of the other asteroids. Unlike Eros and Ida, as well as many of the larger bodies, this C-type asteroid has a limited number of lineaments identified (perhaps due to poor imaging resolution) and high porosity (~50%) (Yeomans *et al.*, 1997). Mathilde also possesses an inordinate number of large craters relative to other asteroids (e.g., Cheng and Barnouin, 1999; Chapman *et al.*, 1999). It is well known that high porosity limits the extent to which impact-derived shocks can travel through an asteroid (Love *et al.*, 1993; Cheng and Barnouin, 1999; Housen and Holsapple, 2003; Schultz *et al.*, 2007; Jutzi *et al.*, 2010b). This can limit the extent of lineament formation (Jutzi *et al.*, 2010b), and permit the formation of many large craters without disrupting Mathilde. This difference might be a reflection of the physical differences between ordinary and carbonaceous chondrites (Britt *et al.*, 2002).

## 5. CONCLUSIONS

Our knowledge of cratering of asteroids increased greatly after 1991, when the Galileo spacecraft imaged the asteroid Gaspra during a close flyby. Continuing opportunistic flybys

as well as dedicated missions to asteroids have now revealed numerous asteroids, all of whose surfaces are cratered to varying degrees. Future missions already launched or under development [such as Hayabusa-2 and the Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx)], and higher-resolution radar delay-Doppler mapping, promise to provide a continuing source of cratering data.

Given the lack of endogenic geological activity on most asteroids, it is no surprise that the dominant evolutionary process influencing the surface of asteroids is impacts by other asteroids and comets. These result in cratered surfaces, although larger impacts penetrate the interiors of asteroids, giving rise to a variety of linear features, ridges, and trenches, also expressed on the observed surfaces. Large impacts can also trigger mass wasting and, in other ways, degrade and eventually erase preexisting craters and landforms. Asteroids imaged at submeter resolutions (Itokawa, Eros) present boulder-strewn surfaces with fewer obvious craters as the inherent rubble-pile constituents and more effective crater-destruction processes tend to dominate over formation and retention of craters.

Size-frequency distributions of craters tend to vary not only from asteroid to asteroid, but also on different geological units on the same asteroid. Nevertheless, crater SFDs tend to initially reflect a single MPF (that of the collisionally relaxed SFD for the main-belt asteroid population; see the chapter by Bottke *et al.* in this volume), subsequently modified by formation of secondary craters in some cases and by crater-degradation processes. The degree to which these crater SFDs are undersaturated or instead approach or reach saturation enables us to not only date relative age differences on an individual asteroid, like Lutetia and Vesta, but also to approximately provide absolute ages for surfaces of different asteroids. Such absolute ages depend heavily on model parameters, including models for the rate of decline of the impact flux from the earliest times, assumed crater-scaling laws, and assumed target properties (strength, density, porosity). Given the uncertainties involved in cratering ages, it is important to compare with other methods whenever possible.

On Vesta, crater-retention ages of major units range from ~1 Ga for terrain associated with the Rheasilvia basin to perhaps as much as ~4.4 Ga for the most heavily cratered terrains, although the older estimate is highly uncertain. There have been arguments from studies of the dynamics of the Vesta asteroid family (see the chapter by Nesvorný *et al.* in this volume) that Rheasilvia, presumably the scar from the impact that created the family, has an age of ~1 Ga (Marzari *et al.*, 1996; Milani *et al.*, 2014), although other analyses pose a lower limit of ~0.5 Ga (see the chapter by Nesvorný *et al.* in this volume). The case of Vesta is particularly important because we have samples of this asteroid in our meteorite collections: the howardite, eucrite, and diogenite (HED) meteorites. Meteorites can retain a record of their parent body's collisional history in their isotopic signatures (e.g., Bogard, 2011). Particularly useful for this purpose is the K-Ar system,

which can be reset during collisions. The HED meteorites show a characteristic K-Ar age spectrum indicating numerous resetting events older than  $\sim 3.5$  Ga (Bogard, 2011; Marchi et al., 2013). Most HEDs are thought to originate from the formation of the Rheasilvia basin on Vesta, although older basins may also contribute. Interestingly, a recent high-spatial-resolution analysis of feldspar grains in Kapoeta, a howardite, yielded ages ranging from 0.8 to 1.2 Ga (Lindsay et al., 2015), compatible with Rheasilvia's cratering age.

We find ages for Gaspra and Ida of  $\sim 1.8$  Ga and  $\sim 3.5$  Ga, respectively (the age estimate for Ida would be a lower limit if Ida's surface were saturated with craters). Since Gaspra is probably a member of the Flora family [here we assume it is of rocky composition, and not metallic as suggested by Chapman (1996)] and Ida is quite certainly a member of the Koronis family, it is interesting to compare our results with dynamical ages for those families,  $\sim 1$  Ga and  $\sim 2.5$  Ga, respectively (Dykhuis et al., 2014; see the chapter by Nesvorný et al. in this volume); these are reasonably consistent, given the approximate nature of both cratering and dynamical ages. We have no independent check on our estimate of  $\sim 1.5$  Ga for the crater retention age on Eros, since Eros cannot be linked to a specific family. Age estimates for other nonfamily asteroids (Lutetia, Steins, Toutatis), based on the same methodology, are presented in the chapter by Barucci et al. in this volume. Because of great uncertainty about the applicable crater-scaling law for Mathilde and the strength of that C-type asteroid, we do not propose a cratering age for it.

We have described depth-diameter measurements for craters on several asteroids. The great diversity of crater morphologies exhibited on asteroids imaged up close (e.g., the bimodal craters formed on steep slopes on Lutetia and Vesta) suggest that more complete analyses than have been done to date of the statistics of craters of different morphologies (e.g., across the range of degradational states) may illuminate issues of crater formation, degradation, and obliteration, which are the dominant processes shaping asteroid surfaces. In a similar way, studies of impact-induced lineaments, such as ridges and trenches, can help to reveal aspects of the bulk structure of asteroids by providing constraints on how shock waves travel through asteroids.

As Dawn approached (1) Ceres in early 2015, there were ideas that this dwarf planet might exhibit large craters, like those on Vesta and Lutetia, or might not, because of its different composition, which may affect the formation, preservation, and/or survivability of craters. For example, Tyre on Europa and palimpsests on Callisto show little relief. Approach images of Ceres suggest a complex cratering history.

Impact cratering on asteroids appears to be a very complex process for which many facets are not yet fully understood despite the significant progress made over the last decade. As we have indicated, craters and impact-induced surface features potentially hold a great wealth of information about the past evolution and internal structures of asteroids. Future missions will certainly improve our understanding of these processes and undoubtedly provide new challenges.

---

The geophysical study of asteroids has moved from the realm of speculation and constraint to a more data rich environment where observations can be directly used to understand and probe the physical nature of these bodies. While many broad questions were posed in the *Asteroids III* chapter on asteroid interiors, in the current setting we are now able to probe more deeply into these questions, taking advantage of many different observations of asteroids across their entire size scale. The current chapter will take a very broad survey of what constraints currently exist in this area, what progress has been made in understanding these bodies analytically and through simulations, and what current theories can inform and guide future observations and tests of our understanding. The following topics are covered in this chapter: the strength of asteroid materials as inferred from meteors and meteorites, the density and porosity of asteroids as inferred from remote observations, global constraints on asteroid strength and morphology based on ground- and spacebased observations, analytical theories of asteroid strength and evolution, and the current state of numerical simulation techniques of asteroid interiors and morphology.

## 1. INTRODUCTION

The past decade has seen an astonishing array of advances across a wide spectrum of important inputs to the problem and mystery of asteroid interiors. These include the development of a large database concerning asteroid component strengths, as evidenced by meteors and meteorites (section 2); the compilation of extensive densities and inferred porosities for asteroids based on groundbased observations (section 3); the development of new computational techniques for the simulation of how asteroid rubble piles deform and fission or shed mass when subject to extreme rotation rates (section 4); and the development of crucial insights into the unique geophysics of specific asteroidal bodies (section 6). This chapter will review these different areas of advancements in an attempt to unify these disparate topics and show where future progress can be made in this field.

Knowledge about asteroid interiors is a crucial aspect for understanding these bodies, as it provides clues about their evolutionary history, in turn providing strong constraints on the history of the solar system. Unlike asteroid surfaces, it is impossible to peer directly within or easily take a sample

measurement from within a body. Thus the study of asteroid interiors must rely on a combination of measurement and theory to develop constraints on the interior environment. Given these restrictions, previous investigations have studied observable characteristics that may be related to the nature of their interiors. This being said, there are measurement techniques that can probe the interior properties of bodies, in particular through seismic and radar sounding measurements. These are discussed in section 5 and represent a potential source for future advancements in this field.

The most accessible features of an asteroid that are related to their interior structure are the mass, density, shape, and spin. These are strongly constrained by the interior structure, and by the strength and mechanical properties of that structure. By focusing on these specific observables, we can start to answer basic questions about these bodies: How strong are they? What is the nature of that strength? Are the interiors rubble piles full of voids at various size scales, or are they solid coherent structures? How do these properties depend on composition, shape, spin, size, or location?

Important steps in answering the above questions have occurred since the publication of the *Asteroids III* volume

(e.g., Asphaug *et al.*, 2002; Britt *et al.*, 2002). These advances are related to the accumulation of fundamental data on these bodies through meteor falls and groundbased observations, analytical studies of the shapes of rubble piles, and ever more precise numerical simulations that probe the mechanics of rubble-pile interactions. We do note that our discussion will be more focused on the smaller asteroid bodies and rubble-pile structures, as this is where much of the progress has occurred in the last decade. This is not to discount the important results from the European Space Agency (ESA) Rosetta mission to asteroid (21) Lutetia or the NASA Dawn mission to asteroid (4) Vesta; however, we refer the interested reader to the chapters in this volume by Russell *et al.* and Barucci *et al.* for a detailed discussion of those scientific results.

The topic of asteroid interiors has been dealt with previously in the *Asteroids III* chapter by Asphaug *et al.* (2002). That chapter serves as a fundamental starting point for the current survey, and we assume that the interested reader is familiar with that work. The current chapter takes a different approach from that earlier work, reflecting the current thinking about what aspects of observations can be directly applied to understanding asteroid interiors. Another important resource from the *Asteroids III* book is the chapter on gravitational aggregates by Richardson *et al.* (2002). The current chapter extends that descriptive chapter in the direction of geophysics, striving to link the possible granular nature of asteroids with fundamental physical processes that occur for aggregates. The goal of that chapter was to distinguish the different ways in which a shattered body could exist, from a random assemblage to a coherent collection of components shattered in place from an initial monolithic body. The current chapter does not deal much with this distinction, although its implications do arise when discussing observations of macroporosity. What is new in the current chapter, with regard to gravitational aggregates, is the realization that such assemblages may have a small level of cohesion, which changes the dynamical evolution of these bodies in a significant and observable way. Additionally, not considered in that chapter was the size distribution of the particles of these aggregates, which has now been theorized to be a crucial aspect of their geophysics (Sánchez and Scheeres, 2014). Observations have not conclusively identified which of the many types of gravitational aggregates discussed in Richardson *et al.* (2002) might in fact exist in nature; however, many different observations (as discussed in this chapter) seem to fit best with their definition of “rubble pile,” stated verbatim as: “*This structure is literally a pile of rubble, with the organization that you might expect from a bunch of rocks dumped from a truck. A body that has been completely shattered and reassembled may fit into this category.*”

The outline of the chapter is as follows. In section 2 we focus on what we know about the fundamental strength and mechanical properties of the constituent pieces of asteroids as represented in the meteorite collection and meteor observations. From this study we find that there remain interesting and significant disconnects between the measured strength of meteorites and the inferred strength that they have based

on the altitude at which they fail, which is expected to be related to their possible rubble-pile structure. This data provides insights into bodies up to several meters in size, but not beyond this limit.

In section 3 we use groundbased observations, and some spacecraft observations, to develop a wide range of constraints on how the constituent components of asteroids are assembled by computing their density and porosity. The implications are that some asteroids are highly porous bodies, in general, supporting the idea that these can be rubble piles. From this data there is also a clear progression of larger bodies having lower porosities, indicating the importance of gravitational compression. From this data we gain insight into the structure of bodies at the larger scale, ranging up to several hundreds of kilometers in size.

Section 4 applies and interprets the size-spin data for insight and motivation into an understanding of asteroid morphology and strength. From this data we can place constraints on the properties of the asteroid population and expose areas of uncertainty and ambiguity. Linking these observations with modeling and theories of asteroid strength has provided new insights and constraints on the global strength of asteroids, and provided clues as to their internal morphology. Theory and data from this section also help address the gap between the insights from meteorites on smaller bodies and from the groundbased studies of larger bodies.

Section 5 discusses the insights that can be inferred on asteroid interiors using the visible geology of asteroid surfaces, constraints on the transmission of seismic energy, and by an improved understanding of the rate of dissipation that may occur in asteroids. These methods indicate a potential pathway for better probing and determining the unique geophysical environment within small rubble-pile bodies.

Finally, section 6 focuses on a number of specific asteroids that have been observed with some level of precision since *Asteroids III*, with the exception of (4) Vesta. These include the targets of spacecraft missions, (433) Eros and (25143) Itokawa; the unique case of 2008 TC<sub>3</sub>, which was analyzed both with groundbased observations and on the ground with meteorite falls; and a number of ground observed asteroids including (216) Kleopatra, (29075) 1950 DA, (66391) 1999 KW<sub>4</sub>; and two active asteroids, P/2013 P5 and P/2013 R3. Many of these bodies are discussed in detail elsewhere in this book, but our discussions are focused specifically on what these bodies tell us about asteroid interiors and strength. Finally, overall conclusions are drawn and future areas where additional research and observations are needed are highlighted.

## 2. MATERIAL CONSTRAINTS

Meteorites and meteors are samples of materials from small bodies in near-Earth space, albeit transported from all regions of the solar system (see the chapter by Binzel *et al.* in this volume). Note that a meteorite and a meteor can be just different manifestations of the same object; a meteor is the visual and sonic phenomena of the small body transit-

ing Earth's atmosphere, while a meteorite is the surviving material that can be collected on the surface of Earth. As small bodies encounter Earth, their interaction with Earth's atmosphere, their mass loss on entry, the characteristics of their fall, and analysis of recovered fragments all provide clues about the structure, cohesion, and mineralogical homogeneity of the parent small bodies. This subsection is focused on summarizing and collecting in one place information on the strength of these bodies, both as individual components and as agglomerations when they first enter the atmosphere. For more information, see also the chapters by Borovička et al. and Jenniskens in this volume.

## 2.1. Meteorite Strength

An individual recovered meteorite is a direct sample of the material properties and strength of the components of small bodies. However, the samples that survive the stress of deceleration and atmospheric entry are necessarily biased toward the strongest and most coherent materials in the parent object. Weak and volatile-rich material tends to be destroyed on entry. Shown in Table 1 are the compressive strengths of a number of meteorites along with common materials for comparison [taken from Popova et al. (2011); see also Kimberley and Ramesh (2011) for additional data].

Natural materials can be very strong, such as individual crystals of quartz (1100 MPa). Single mineral strengths derive from the inherent strength of the crystal structure. Rocks are collections of minerals and their strength derives from a mixture of their mineral crystal strengths, their formation conditions, and the nature of the bonding between minerals. Igneous rocks like granite, for example (100–140 MPa), are composed of a substantial amount of quartz, but as a whole the bonding between their minerals makes the rock much less

strong than the individual minerals. Unreinforced concrete at 20 MPa compressive strength is a good comparison standard.

Like rocks, there are substantial variations in the inherent strength of meteorites. Most ordinary chondrites (the most abundant type of meteorite fall) are much stronger than concrete. Volatile-rich carbonaceous chondrites are much weaker, and in some cases, e.g., the Tagish Lake meteorite (meteorites are named for the localities where they are recovered and in this chapter they will be often referred to by their meteorite name), their measured strengths are on the order of weakly consolidated soils (dirt clods).

Why are ordinary chondrites so strong? In general, they are conglomerates of chondrules (millimeter-sized spheres of minerals formed in the solar nebula), chondrule fragments, dusty matrix, and iron-nickel metal that have been welded together by varying levels of grain-boundary melting. In addition to welding in the silicates, the metal in ordinary chondrites provides a natural reinforcing mesh that is often interconnected in some ordinary chondrites that have been subjected to higher temperatures and thus have undergone some degree of remelting and metamorphic processing referred to as having higher metamorphic grades. As a result, high-metamorphic-grade ordinary chondrites can have many of the strength properties and reactions to stress of steel-reinforced concrete. However, there are some very weak ordinary chondrites. The Holbrook meteorite (Table 1) is a high-metamorphic-grade ordinary chondrite but is very weak and friable. Weston is also a high-grade chondrite but the individual chondrules are so poorly cemented that it falls apart with handling. The best analogy for this sample is a loosely glued collection of millimeter-sized spheres. However, the individual chondrules that are weakly held in Weston are individually quite strong.

The major exception to the story of relatively weak ordinary chondrite bolides is the large and well-studied Chelyabinsk

TABLE 1. Meteorite and material strength.

Material	Meteorite Type	Compressive Strength (MPa)	Tensile Strength (MPa)
Concrete — Unreinforced	Typical sidewalk	20	
Quartz	Single crystal	1100	55
Granite		100–140	
Medium dirt clod		0.2–0.4	
Holbrook, Arizona	L6 (OC)	6.2	
La Lande, New Mexico	L5 (OC)	373.4	
Tsarev	L5 (OC)	160–420	16–62
Covert	H5 (OC)	75.3

Krymka	LL3 (OC)	160	22
Seminole	H4 (OC)	173	22.5
Plutusk	H5 (OC)	21.3	31
Hoba	Iron — ataxite	700	
Sikhote-Alin	Iron — octahedrite	410	44
Tagish Lake	C2 (CC)	0.25–1.2	
Murchison bolides	CM (CC)	~50	0.1–1

OC = ordinary chondrite; CC = carbonaceous chondrite. Data from Popova et al. (2011).

bolide and meteorite (*Borovička et al.*, 2013). While its first breakup was at high altitude (~45 km and 0.7 MPa), it underwent a series of fragmentation events. This included 11 fragmentations between 39 and 29 km under atmospheric dynamic pressure loads of 1–5 MPa and several boulders breaking off at 26–24 km under loads of 10–13 MPa. Interestingly, the main body remained relatively intact down to 22 km until its massive disaggregation at 18 MPa. This is probably due to the heterogeneities and highly shocked nature of the Chelyabinsk meteorite and the presence of extensive melt veins that welded portions of the meteorite.

Volatile-rich materials like the Tagish Lake meteorite are much different than the ordinary chondrite bolides. In this case the strength of the individual cobbles is roughly what is seen in the atmospheric breakup phenomena and this is the only case where the maximum compressive strength inferred in the atmosphere is greater than the compressive strength of the measured meteorite. This may be due to the presence of ice surviving in Tagish Lake. Recovered samples often expressed significant amounts of water when brought above freezing temperatures (*Brown et al.*, 2002), and samples of Tagish Lake that have been kept at freezing temperatures show lower porosity than samples that have been allowed to warm (*Ralchenko et al.*, 2014). It may be that ice-filled pore space within the meteorite provided extra strength for the bolide during atmospheric entry.

The meteorites listed in Table 1 are samples of hand- and cobble-sized survivors of atmospheric entry, which are the strongest and most coherent materials of the original small body. The vast majority of bolides do not survive entry as anything other than widely dispersed ablation dust. Typically the minority of small bodies that do survive entry lose approximately >95% of their preatmospheric mass (*Popova et al.*, 2011). Only a handful of bolides have been tracked to delivering material to the surface with that material recovered. Shown in Table 2 are bolides with recovered meteorites (*Popova et al.*, 2011).

TABLE 2. Select bolides with recovered meteorites (*Popova et al.*, 2011; *Borovička et al.*, 2013).

Meteorite (type)	Compressive Strength (MPa)		
	Range for Met. Type	First Breakup	Max.
Pribram (H5)	77–247	0.9	
Lost City (H5)	77–247	0.7	2.8
Innisfree (L5)	20–450	0.1	3
Chelyabinsk (LL5)	0.7	18	
Tagish Lake (C2)	0.25–1.2	0.3	2.2

Jesenice (L6)	63–98	0.3	3.9
Grimsby (H4–6)	77–327	0.03	3.6

## 2.2. Bolides and Boulders

A bolide is roughly defined as a large, bright meteor that is typically brighter than the full Moon during its brief peak brightness. The physical phenomena are the result of a small body entering the atmosphere at hypersonic speeds [in the case of near-Earth asteroids (NEAs), velocities are in the range of ~12–20 km s<sup>-1</sup>) and rapidly shedding their orbital kinetic energy into visible and thermal energy from friction with the atmosphere. As the body comes apart the initially compact mass fragments, exposing a larger surface area to rapid deceleration. This is seen as bright flashes within the bolide as smaller fragments rapidly heat, ablate, and decelerate. This typically occurs at altitudes ranging over 70–23 km and the small body's response to the atmospheric ram pressure can be used to estimate the body's coherent strength under compression (*Popova et al.*, 2011). These bolides are typically recorded on specialized optical tracking networks, but for the brightest objects security cameras and even dashcams are a valuable source of data (*Brown et al.*, 2002). Table 2 shows strength data from bolides with recovered meteorites. This permits a direct comparison of the strength of the surviving fragments with the strength estimated during the breakup of the small body on atmospheric entry.

Several points are readily apparent from Table 2. While most recovered meteorites are very strong, the initial breakup of the entering small body occurs at very low compressive stress. Initial breakup altitudes can be very high, as much as 70 km in some cases for the weakest bodies in Table 2, and the maximum compressive stress in Table 2 may occur at what are also substantial altitudes typically in the range of 35–20 km. For the initial breakup, these altitudes represent relatively low stresses, creating failures within weakly bound materials.

A question that has yet to be fully addressed is whether these stresses are consistent with some small asteroids being rubble piles, potentially held together by weak cohesive forces (see section 4.5). Examples of low-coherent-strength objects from Table 2 would include the Grimsby and Park Forest meteorites. However, while the first breakup provides insight into the strength of the entering body, the bolide phenomenon continues as the individual large pieces of the body break up under rising compressive stresses. Essentially these are the cobbles and boulders within the body shattering under rising stresses, and represent the state of fracturing and cohesion within individual components of the small body. For example, Park Forest started to fail under low compressive stress of 0.03 MPa, but the last major breakup was at more than 2 orders of magnitude greater stress. One possible explanation would be that the weak breakup occurred for a boulder within the rubble pile that failed along zones of preexisting weakness. While the basic material of ordinary chondrites is very strong, these objects are often pervasively fractured from a long impact and shock history and would be much weaker along their existing fractures. Indeed, that is the primary reason for multiple observations that large bodies are globally much weaker than smaller ones. However,

not all entering bolides fail under the stress of atmospheric entry. There are a number of examples of coherent “boulders” impacting the ground with little or no apparent fragmentation during entry. A recent example was the meter-sized boulder Carancas (H4–5) that created a 13-m-wide crater near Lake Titicaca in 2007 (*Borovička and Spurný*, 2008).

### 2.3. Meteorite Showers

While coherent boulders occasionally do survive atmospheric entry, a much more typical case is the meteorite shower. These are small bodies that break up in the atmosphere similarly to the observed bolides. Table 3 includes a list of selected large meteorite falls (meteorites that were observed to fall from space) and finds (meteorites that were found some time after they fell). The discussion of atmospheric breakup and observed bolides has focused on stony meteorites, since so far no iron meteorite falls have been instrumentally recorded. On the other hand, irons are much stronger under compression and tension than stones and recovered irons are typically much larger than stones. Most of the recovered mass of meteorites are irons and the 15 largest meteorites are all irons. There are strong positive selection effects in finding irons since they are clearly unusual in the terrestrial environment. That said, note that of the largest irons, only two are single bodies. The largest meteorite in total mass is Campo del Cielo, which fell in at least 30 fragments. Most of the fragments are buried so the mass and fragment count is a rough estimate. The largest single body to reach the ground is either Hoba, which was found in a single mass, or Sikhote-Alin, which fragmented on impact (producing a 60-m-diameter crater and more than 9000 fragments).

For stony meteors, almost all the large mass meteorites are showers. Some of the more famous showers are listed in Table 3. With stones, the entry phenomena make it more likely that they will shatter in the atmosphere, producing a literal shower of rocky fragments. These fragments tend to

be largely homogeneous. Investigations of several showers have, with one notable exception, not found significant mineralogical variation within the shower (*Consolmagno et al.*, 2008). The major exception is the Almahata Sitta fall, which was primarily ureilite material with a significant component of ordinary chondrite (see the chapter by Jenniskens in this volume). Heterogeneity within meteorites is not unknown and it is not uncommon to find xenoliths (different meteorite types, literally “foreign rock”) incorporated into meteorite breccias (*Brearley and Jones*, 1998); however, the level of heterogeneity is typically pretty small. Xenoliths are usually confined to single or a few clasts within a much larger homogeneous matrix. The shower data suggests that an Almahata Sitta level of heterogeneity is rare. For discussion about Kaidun, see the chapter by Borovička et al. in this volume.

### 2.4. Summative Discussion

The data presented here on meteorites, bolides, and showers provides some basic insights on the structure of meteorite parent bodies up to several meters in size. For stony bodies of even a few meters in diameter, rubble piles seem to be the norm. The relatively low stresses on breakup seen in most of the bolides and the prevalence of showers for large stones point to a rubble-pile structure being very common. The individual components of these aggregates can be very strong, ranging up to an order of magnitude stronger than concrete, but the overall body is very weak. Volatile-rich bodies are both individually and collectively very weak.

Mineralogical homogeneity seems to be the general rule in small bodies. While there are significant exceptions and xenoliths are not uncommon, the shower data point to largely homogenous small bodies. Finally, for small bodies, irons are easily the strongest and most-coherent materials. Their large compressive and tensile strengths and apparent relatively low fracturing result in irons being by far the largest meteorites that survive atmospheric entry. However, they are relatively rare in the fall population, and the selection effects of their large strength suggest they are overrepresented in the fall population relative to their share of the NEA population.

## 3. ASTEROID BULK PROPERTIES

The next section probes the interiors of asteroids through a different approach, based on determining their bulk densities and bulk porosities. This takes us beyond the strength of the individual components of asteroidal bodies, either determined by measurements on meteorite falls or through inferred strengths in the upper atmosphere. The bulk densities are found by comparing mass estimates to volume or size estimates for these bodies. Bulk porosities are estimated by comparing the bulk densities to the asteroid spectral type, to determine likely grain densities and hence bulk porosities

The fundamental data compiled here concerning asteroid densities and macroporosities are presented in Figs. 1 and 2. Details on how the data were compiled are given in *Carry* (2012), and are not repeated here. While the previous section

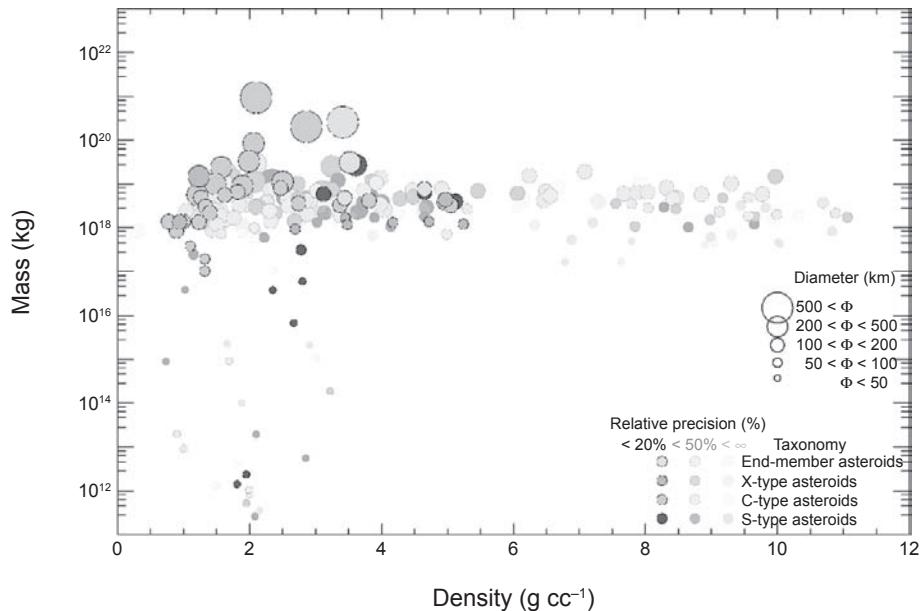

TABLE 3. Selected large meteorites and showers (*Grady*, 2000).

Meteorite	Date (dd/mm/yyyy)	Mass (kg)	No. Fragments
Campo del Cielo (IAB Iron)	Find	100,000	30
Sikhote-Alin (IIAB Iron)	12/02/1947	70,000	9000

Homestead (L5)	12/02/1875	230	
Holbrook (L/LL6)	09/06/1866	218	14,000
Forest City (H5)	02/05/1890	122	2000

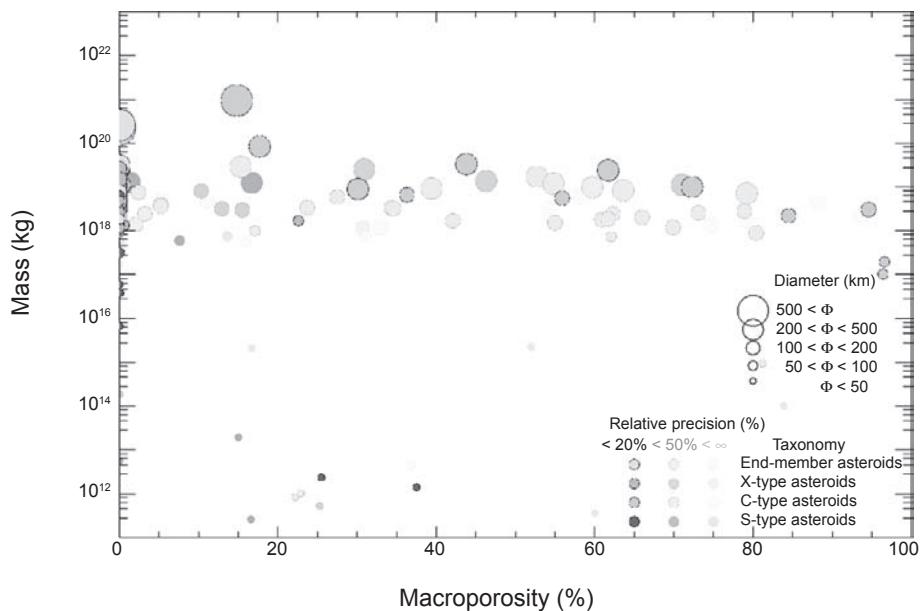

was focused on meter-sized bodies, the focus in this section is necessarily on the other end of the scale, with most of the reliable data on densities and porosity existing for larger bodies, up to hundreds of kilometers. Only in a few situations are there good data on smaller bodies.

The first evidence on asteroid interiors was derived from meteorites, with identification of differentiated and nondif-

ferentiated internal structures (see section 2). Dynamical families, originating from catastrophic disruptive collisions, provide another way to study asteroid interiors. Clumps of asteroids identified dynamically (e.g., *Bendjoya and Zappalà*, 2002) also share common surface properties, which are in turn used to discriminate genuine family members from the background population (*Parker et al.*, 2008; *Carruba*

**Fig. 1.** See Plate 24 for color version. Density vs. mass. Asteroids are divided into four taxonomic groups (from *DeMeo et al.*, 2009): S-complex in red, C-complex in gray, X-complex in green, and end members in yellow. The size of the symbols indicates the asteroid diameter, below 50 km, between 50 and 100 km, 100 and 200 km, 200 and 500 km, and above 500 km. The three different levels of contrast correspond to three cuts of relative accuracy: <20%, <50%, and regardless of precision (< $\infty$ ).

**Fig. 2.** See Plate 25 for color version. Macroporosity vs. mass. See Fig. 1 for the explanation of symbols.

*et al.*, 2013). Such similarities are suggestive of a homogeneous interior for the parent bodies of these families (see the chapter by Michel *et al.* in this volume).

### 3.1. Density

Density is perhaps the most fundamental property for discriminating the composition and internal structure of asteroids (Britt *et al.*, 2002). It is also extremely difficult to measure, and the number of precisely measured asteroid densities is still very limited. This is because both mass and volume are required to determine the density of an asteroid.

Estimating any mass at all is a challenge, owing to the relatively low mass of asteroids as compared to other planetary objects. The exception is for binary asteroids, for which the total mass can be easily estimate (see the chapter by Margot *et al.* in this volume). The number of mass determinations thus limits the number of density estimates. The precision of these estimates is, however, limited by the uncertainty on asteroid diameters (Carry, 2012).

Any determination of the mass relies on measurements of the gravitational interaction between the target asteroids and other objects. The most accurate estimates (at a few percent accuracy) are derived from radio science experiments during spacecraft encounters [orbit or flyby (e.g., Yeomans *et al.*, 2000; Abe *et al.*, 2006; Pätzold *et al.*, 2011)] and studies of binary asteroids (see the chapter by Margot *et al.*). The vast majority of asteroids, however, have never been visited by spacecraft nor possess satellites [only a handful of large asteroids possess satellites, albeit the fraction is higher at smaller size; about 15% of near-Earth asteroids have satellites (Margot *et al.*, 2002)]. It is nevertheless possible to determine their mass from the gravitational pull they exert on other planetary objects: asteroids, planets and their satellites, and interplanetary spacecrafs (see, e.g., Hilton, 2002; Fienga *et al.*, 2008; Kuchynka and Folkner, 2013; Goffin, 2014).

Methods based on long-range influence rely heavily on the modeling of all relevant gravitational effects and interactions in the solar system (e.g., asteroid ephemerides, planets, general relativity) and are therefore more prone to systematic errors, and current precision is still limited to date [often above 50%, see the dispersion of estimates, together with the discussion on the accuracy and biases affecting mass estimates, in Carry (2012)]. Current samples of asteroid masses are therefore strongly biased. First, the best determinations are for binaries, but there may be differences between binary and single asteroid internal structures and thus extrapolating the density determined from binary asteroids to the whole population may introduce biases. Second, only large asteroids are massive enough to perturb the orbits of other objects. Thus this sample is mainly limited to asteroids larger than 100 km, while there is evidence for a size-dependence of the density owing to a different level of macroporosity [see Fig. 2 below and Fig. 9 in Carry (2012)].

The situation for diameter estimates is less dramatic. There are many techniques to measure the apparent size or surface area of an asteroid, and diameter estimates are available for

tens of thousands of objects (e.g., Masiero *et al.*, 2011). Although diameter estimates are less prone to systematics than mass estimates [values generally agree to within measurement uncertainties (see Carry, 2012)], their contribution to the density uncertainty overwhelms that of mass. Diameter determinations have to be as accurate as 2–3% to allow density estimates to be more precise than 20%, a level over which density estimates hardly provide constraints. While simple modeling can have systematics above this level, realistic descriptions of asteroids, including knowledge of spin and three-dimensional shape, can provide this level of accuracy (see the chapter by Durech *et al.* in this volume).

Despite these limitations, the field of asteroid density has seen a revolution since the time of *Asteroids III* (Britt *et al.*, 2002). There has been a tenfold improvement in sample numbers (from 20 to 320), spanning many different taxonomic classes (and hence composition), diameters, and heliocentric distance (Carry, 2012). The upcoming decade will certainly provide many more determinations with a high level of accuracy. First, the stellar catalog at the microarcsecond level provided by the ESA Gaia mission should improve the precision on asteroid astrometry by an order of magnitude. Mass determinations from orbital perturbations should therefore become more precise. The observation of asteroids by Gaia will also allow the determination of the mass of about 150 asteroids with a relative precision better than 50%. It is even expected that 50 of these determinations will be more precise than 10% (Mouret *et al.*, 2007). The number of known binaries is also constantly increasing, adding to the number of high accuracy density estimates (see the chapter by Margot *et al.*).

### 3.2. Macroporosity

A density estimate by itself can restrict the list of possible components of an asteroid's composition. For example, a low-density asteroid such as (617) Patroclus [ $\rho \approx 1 \text{ g cm}^{-3}$  (Marchis *et al.*, 2006; Mueller *et al.*, 2010)] cannot host large fractions of dense material or even silicates. The internal structure can be constrained using a comparison of the asteroid bulk density ( $\rho_A$ ) with the grain density of its most likely constituents ( $\rho_C$ ), as determined from study of the surface composition (see the chapter by Reddy *et al.* in this volume).

If  $\rho_A \ll \rho_C$ , the asteroid is underdense. This points toward large-scale voids or the presence of low-density material (i.e., volatiles) in its interior. While this is a typical case for comets, many asteroids are also seen to have porous internal structure. The porosity  $p$ , i.e., the fraction of volume occupied by empty space ( $p = 1 - \rho_A/\rho_C$ ), provides a measure of these structures. Because meteorites have microporosity (empty spaces at the grain-size scale, noted  $p_m$ ), the macroporosity  $P$  has been defined as the fraction of volume occupied by large voids, i.e.,  $P = p - p_m$ . The question of the distribution of these volatiles or voids inside the asteroid remains open (Britt *et al.*, 2002). Following the terminology of Richardson *et al.* (2002), we can ask whether they are the results of cracks within a shattered monolith,

or interstices of a rubble pile formed through gravitational reagglomeration after a disruptive collision.

If  $\rho_A \gg \rho_C$ , the asteroid is overdense, and some high-density material must be present in its interior. This could be due to gravitational self-compression, differentiation (e.g., Russell *et al.*, 2012), or the result of the collision between two bodies of different densities. Most asteroids with a mass above  $10^{19}$  kg are overdense, while the majority of asteroids below that threshold present some level of macroporosity. This is consistent with large bodies having enough internal energy from accretion and radioactive decay to differentiate.

If  $\rho_A \approx \rho_C$ , no clear conclusions can be made. However, given the comparable spectral properties observed among members of dynamical families, it may be reasonable to assume that the body is homogeneous.

### 3.3. What Can Be Concluded

Based on the data presented in Table 4 and Figs. 1 and 2, and more fully discussed in Carry (2012), there are a number of overall conclusions that can be drawn from these compilations, listed below.

- Asteroids in the S-complex are on average more dense than those in the C-complex.
- Asteroids in the C-complex seem to have larger macroporosity than those in the S-complex, hinting at a looser structure.
- The density of asteroids from both the S-complex and the C-complex seems to increase with the mass, apparently resulting from a decreasing macroporosity.
- In both the C and S-complex, NEAs (with masses from  $10^{11}$  to  $10^{16}$  kg) seem to have a lower density than main-belt asteroids, following the trend between mass and density observed for large asteroids.
- At comparable sizes, B-types appear significantly denser ( $\rho \sim 2.4$  g cm $^{-3}$ ) than the other types of the C-complex that gather around  $\rho \sim 1.4$  g cm $^{-3}$ .

- While asteroids in both C- and S-complexes have narrow density ranges (with a few exceptions), asteroids in the X-complex covers a larger range, from the most dense Xc-types with  $\rho \sim 4.9$  g cm $^{-3}$  to X-types with  $\rho \sim 1.8$  g cm $^{-3}$ .
- Dwarf-planets (with masses above  $10^{20}$  kg) apparently have little macroporosity, contrary to small bodies whose masses are inferior to  $\approx 10^{20}$  kg (Consolmagno *et al.*, 2008).
- With the exception of NEAs, the dispersion in density and macroporosity is huge.

### 3.4. Future Prospects

As discussed above, the accuracy and reliability of density estimates have seen dramatic improvement since the time of *Asteroids III*. Even though many estimates still suffer from mild inaccuracy, the techniques are constantly being refined, and the next decade will provide more, increasingly reliable density measurements. A major issue still to be resolved is, how certain are the link between asteroids and meteorites? Based on their spectral properties, asteroids are classed within taxonomies (e.g., Tholen and Barucci, 1989; Tedesco *et al.*, 1989; Bus and Binzel, 2002). The latest to date by DeMeo *et al.* (2009) defines 26 classes, but analog minerals and meteorites have been identified for only 50% of them (see the chapters in this volume by DeMeo *et al.* and Reddy *et al.*). In other words, we have no reference density for half the taxonomic classes among asteroids. Discovering this meteorite-asteroid link is crucial for future interpretations of asteroid interiors.

## 4. ASTEROID STRENGTH AND FAILURE LIMITS

In addition to the constraints on asteroid density and porosity that can be determined from the population of ob-

TABLE 4. Average density, porosity, and macroporosity for the 12 (out of 26) taxonomic classes where density determinations more accurate than 20% are available ( $N$  determinations).

Class	Met.	$N$	Density (g cm $^{-3}$ )	Porosity (%)	Macroporosity (%)

served asteroids, there are also significant constraints that can be gleaned from the combined data on asteroid spin rates, spin states, morphology, and sizes, filling the gap between meter-sized meteors (section 2) and kilometer-sized asteroids (section 3). The significant data for these inferences are summarized in Fig. 3, which shows asteroid diameters and spin rates taken from the database described by Warner *et al.* (2009). Also indicated on this figure are those asteroids that are tumbling or are binary asteroids, and a number of spin-limit curves as a function of different cohesive strength theories (all to be discussed later). Over the last few decades these observations have accumulated to the point where useful inferences on asteroid morphology can be made. In Fig. 3 we only show those bodies that have a quality measure of 2<sup>-</sup> or higher, meaning that these observations are deemed reliable. It is interesting to note that there are a number of unconfirmed observations of spin periods (i.e., of quality measured less than 2<sup>-</sup> and thus not shown in the figure) that could be significant if shown to be true. These are discussed later, in the hopes of motivating additional observations.

This data has motivated several different theories for the strength and morphology of asteroids. Significant among

these is a better understanding that the spin limits do not require the rubble-pile hypothesis for almost all asteroids, the cohesion hypothesis in rubble-pile bodies, and the existence of tidal dissipations within such bodies. In the following subsections we discuss these issues in more detail, trying to integrate the physical and mathematical theories used to explain certain aspects of this data alongside a discussion of the data itself.

The precursor to these studies was given almost 20 years ago by Harris (1996), in which he noted that no asteroid had a spin period shorter than about 2.2 h and that the spin periods of objects in a given size range abruptly truncate at that value. He noted that this limit is essentially the spin rate  $\omega_s = \sqrt{4\pi G\rho/3}$ , where  $G$  is the gravitational constant and  $\rho \sim 2.2$  is the bulk density, at which internal tensile stresses would be present within a spherical, constant density object (the actual spin rate for a body also depends strongly on its elongation). This spin rate also corresponds to local circular speed at the surface of the body, at which centrifugal forces equal the gravitational attraction of the body. From that connection he concluded that all or most asteroids must have a rubble-pile structure, as defined earlier, although that is not

**Fig. 3.** See Plate 26 for color version. Asteroid size vs. spin period, with binaries and tumblers called out specifically. All others are assumed to be single, uniform rotators. Only bodies with periods deemed to be reliable (see Warner *et al.*, 2009) are shown. The plot shows distinct structures. No object larger than a kilometer in diameter spins faster than an ~2.4-h period, now known as the gravity spin barrier and that is understood to not be an indicator of cohesionless material by itself. Instead it is simply that at these size scales the gravity effects dominate any strength effect. A number of smaller bodies spin faster; those must experience tensile stress and must have some cohesive strength to hold together. Typically, the observed maximum spins are larger for smaller sizes. Also plotted are spin limits as a function of diameter for levels of asteroid strength. Data shown is as of August 2014.

the current interpretation. In addition, he also predicted that asteroids could spin faster than this limit if they had some strength, although no such asteroids were known at that time. He suggested there would be two regimes for spin, a gravity-dominated regime for larger asteroids and a strength-dominated regime for smaller asteroids. He suggested that in the strength regime their spin could increase inversely proportional to the diameter of the object. Since that paper, these ideas have been essentially verified and expanded, but with clarifications and new interpretations. A number of “fast spinners” have been found with shorter periods; however, they are all less than 1 km in diameter. And there have been detailed modeling studies deriving the relation between asteroid shape, maximum spin, and internal properties.

#### 4.1. Analytical and Numerical Models of Rubble Piles

We first provide a brief review of current and past methods used to model asteroids, their interiors, and their morphologies. Studies of relations between shape, density, and spin of isolated self-gravitational bodies dates back several centuries, but mainly in application to fluid bodies. In those cases, the nature of the bodies was assumed to be fluid, the spin was known, and the goal was to determine the permissible shape. In 1687, Isaac Newton determined that the shape of a fluid Earth with gravitational and rotational forces is a slightly oblate spheroid. In 1742, Colin Maclaurin extended the work to discover the existence of equilibrium oblate spheroidal shapes with large ellipticity for rotating bodies with self-gravity, now called the “Maclaurin spheroids.” Jacobi (1834) discovered the “Jacobi ellipsoids”: equilibrium ellipsoidal shapes with three unequal axes. Roche (1850) added tidal forces during an orbit around a parent body and determined that there is a limit to the orbit radius, the famous Roche limit, inside of which there are no equilibrium solutions. Poincaré (1885) discovered other pear-shaped, non-ellipsoidal possibilities for equilibrium. Chandrasekhar (1969) gives a complete exposition of these classical works. A number of authors have used those fluid limits to infer limits on the mass density or density distribution of solar system bodies, although the mass density dependence can be swamped by other factors, the most important of which is the nonfluid composition. A separate approach to analyzing the internal stress properties of a nonfluid gravitating ellipsoid was given by Chree (1895), using linear elastic response from an initial stress-free state to model the mechanics of a self-gravitating body. This approach has motivated some modern study as well, discussed later.

Just as for a fluid, an ideal rubble-pile body can be assumed to have no tensile strength. But that does not mean that it behaves as a fluid. Consider an idealized rubble-pile body consisting of dry sand. Sand is an assemblage of relatively rigid, angular, submillimeter-sized grains that must interact during deformations. In a shearing deformation, the grains must move up and over adjacent grains. That motion is suppressed if the sand is subjected to a compressive pressure such as from gravity. That simple physical idea is the basis for the standard continuum soil mechanics models of

failure, the Mohr-Coulomb and the Drucker-Prager criteria. In those models, the shearing strength is strongly increased by a compressive pressure in a relation that is assumed to be linear. The coefficient of that linear form is called the “angle of friction,” although its presence is due to the interlocking of grains, not surface friction. These criterion have similar results, although Mohr-Coulomb is considered to be more accurate while Drucker-Prager is easier to handle analytically. It is the basis for the important difference between the behavior of water and the behavior of sand. The shearing resistance of water is independent of the confining pressure so that the angle of friction is zero. From this example it is clear that a material with no tensile strength can certainly have other strengths, including shear strength.

For that reason, the classical fluid theories relating shape and spin do not apply to rubble-pile, asteroid objects. Holsapple (2001, 2004) presented a comprehensive study of the relations between shape, spin, and internal properties for rubble-pile objects as a direct generalization of the historical fluid theories, and includes them as special cases. He assumed constant mass density, a general ellipsoidal shape, and in Holsapple (2001) a Mohr-Coulomb and in Holsapple (2004) a Drucker-Prager failure model. He was able to derive specific algebraic relations for the maximum spin allowable as a function of internal density, ellipsoidal shape, and angle of friction. Sharma *et al.* (2009) and Sharma (2013) analyze the problem following a somewhat different methodology and find similar results. Other studies on the stability of a continuum model of asteroids have also been made more in line with the classical approach developed by Chree (1895). In particular, Dobrovolskis (1982) studied internal stresses in Phobos; Washabaugh and Scheeres (2002) study the energetics of nonfluid, self-gravitating ellipsoids using a linear elastic model with a Young’s modulus and Poisson ratio; and Kadish *et al.* (2005, 2008) studied stresses in bodies grown by accretion.

In the analytical realm Scheeres has also pursued the understanding of how a collection of self-gravitating rigid bodies evolves when subject to increasing spin rates. These studies have mainly focused on the dynamical stability of fissioned bodies (Scheeres, 2002a, 2009b), conditions for when bodies will transition from resting to orbiting configurations (Scheeres, 2002b, 2009a), and identification of different possible resting states that bodies may have when in contact (Scheeres, 2002b, 2012). These analyses are, by default, somewhat simple, although there are a few general results that can be discerned.

Over this same time period a number of researchers have pursued the modeling of cohesionless asteroid rubble piles using numerical methods, primarily with discrete element method (DEM)-based approaches. There have been two major modeling directions that have been used, the so-called hard-sphere DEM (HSDEM) and soft-sphere DEM (SSDEM) models. An HSDEM code models all particle interactions as impulsive, and thus does not directly determine or track forces. This is a computational simplification that allows for relatively rapid combined dynamical and interaction

computations, but makes it difficult to track or determine interior stress states or conditions. An SSDEM code allows for particle deformation (using an analytical model), and thus directly computes contact forces between the grains. This provides a more natural and realistic way for computing rubble piles in a condensed phase, as the grains are then allowed to come to complete rest with each other (which is impossible in an HSDEM as it only models two-body interactions), form force chains, and enable the internal stress state of the modeled body to be computed. The chapter by Murdoch et al. in this volume provides a more detailed discussion of HSDEM and SSDEM codes as applied to asteroids.

Some representative initial studies in this area for modeling asteroids were done by Richardson's group using an HSDEM code (Richardson et al., 1998, 2005; Walsh and Richardson, 2006). They studied the ability of a collection of same-sized grains with a given level of spin to form a stable configuration, with the use of classical Jacobi or Maclaurin ellipsoids used as a measure of stability, and explored how such bodies would deform and fission following a planetary flyby or when subject to a rapid rotation rate. The mechanical properties of the grains are not directly controlled in these studies; in particular, the friction angle is simulated by having the grains either fall into a crystalline-packed matrix or through the use of a bimodal grain size distribution to promote a loss of friction (Walsh et al., 2012).

Sánchez and Scheeres introduced a self-gravitating SSDEM model for describing the global behavior of rubble-pile bodies (Sánchez and Scheeres, 2011, 2012), in part to overcome such limitations. These models used grains with a size dispersion to avoid crystallization. The friction angle of the rubble pile is controlled by surface friction and interlocking. With this approach it becomes possible to track the internal stress and failure conditions using a granular mechanics code. Relevant results are given below.

An additional approach to the modeling of asteroid rubble piles was introduced in Hirabayashi and Scheeres (2014) and applied in Hirabayashi (2014) and Hirabayashi and Scheeres (2015). In this approach a detailed asteroid shape model can be used and the interior stress states computed by using commercial finite-element-analysis methods. This approach has the significant capability of being able to develop detailed models for the failure of asteroids when subject to gravitational and inertial forces. The use of a general approach enables the detailed analysis of plastic deformation modes and inclusion of detailed continuum model parameters such as Poisson ratio, cohesion, and angle of friction.

#### 4.2. Rubble-Pile Shapes

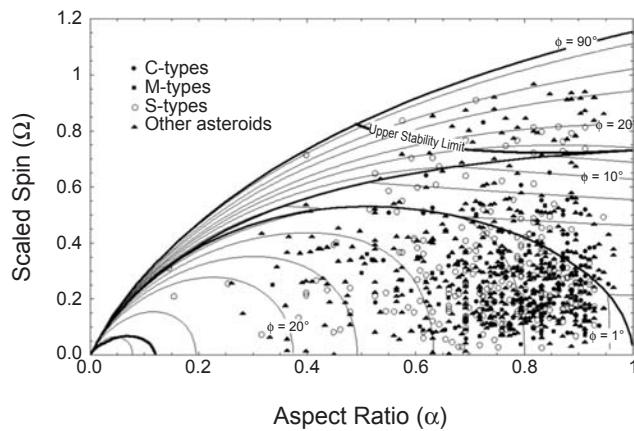

Using the methods outlined above, the most fundamental question to be asked is what the expected shape of a rubble pile should be. Some insight can be gained by observing the surface slopes of asteroids, as these can indicate if there are regions that are clearly beyond the angle of repose for geological granular material; however, this cannot always be clearly linked to the internal processes. A number of different

asteroid slopes have been computed in the past for specific shapes, and a recent analysis by Richardson and Bowling (2014) shows that most asteroids with known shapes have the majority of their surfaces beneath a typical angle of repose for granular material of  $\sim 35^\circ$ . While there are some specific bodies that have significant regions of their surface that are clearly beyond these angles, such as (6489) Golevka (Hudson et al., 2000) and (4179) Toutatis (Hudson et al., 2003), such situations have not been commonly found in the estimated asteroid shapes described to date.

There have been some attempts at approaching the stability of rubble-pile asteroids through analysis of their shapes alone. Harris et al. (2009) and Minton (2008) approached the problem by analyzing the expected shapes of an asteroid where the surface slopes are constrained to be less than or equal to a certain limit. These analyses were used to explore the likely surface environment of rotationally symmetric, spheroidal asteroids commonly found to be the primaries of binary systems. The poster child of such asteroid shapes is (66391) 1999 KW<sub>4</sub>-Alpha, which exhibits many peculiar features that are indicative of this body to be at or near its failure limit. More recently, Scheeres (2015) has studied these bodies using an approach that is fundamentally motivated by the surface slopes and combines some of the methodology from Harris et al. (2009) along with orbital dynamics considerations.

Such analyses are limited, however, in that they do not consider the totality of the mechanical principles that must be accommodated in order to say with certainty whether a given shape is stable or not. Indeed, it is possible for a given shape to have low slopes across its surface (even zero slope, and much less than the angle of repose), yet be structurally unstable as viewed from a mechanics point of view, which also considers its internal stress field and common failure theories. The necessary approach for that sort of analysis requires the development of a stress field within the body that accounts for all internal forces and that vanishes at the surface. The development of such stress fields is not in general unique. However, if one assumes linear elasticity, an ideal ellipsoidal shape, and a stress-free initial state, then a unique stress field can be derived. Given such a stress field, it is then possible to evaluate it against a failure theory, with the most commonly used ones being the Mohr-Coulomb or Drucker-Prager theory. For a cohesionless body these are simply specified as a function of their interior stress field for a given internal friction angle. Furthermore, there is only one stress state that is in equilibrium and also at the failure limit at each interior point. That occurs at a higher spin than for the elastic solutions, and provides the maximum possible spins among all possible stress fields.

In a series of papers, Holsapple (2001, 2004) applied this basic approach and evaluated the limit spins as a function of the ellipsoidal shape of a large range of asteroids modeled as ellipsoids of axes  $a \geq b \geq c$ . A representative result is given in Fig. 4, which depicts the maximum equilibrium spin as a function of the aspect ratio  $b/a$ , for a prolate object ( $a > b = c$ ), along with data for a number of asteroids. The limit

**Fig. 4.** Maximum equilibrium spin limits ( $\Omega$ ) for a prolate rubble pile body as a function of its aspect ratio defined as its polar extent over its total length, ( $\alpha = c/a$ ). The spin limit is normalized to be independent of density and depends upon the angle of friction, ( $\phi$ ), and for each angle of friction there is an upper spin limit and a lower spin limit. At the upper limit equilibrium cannot be achieved for a larger spin and at the lower limit equilibrium cannot be achieved for a smaller spin. Under the dictates of the theory all the asteroid objects plotted, even if not exactly ellipsoidal, must have some nonzero angle of friction arising from a particulate structure. See Holsapple (2001) for a more complete discussion of this figure.

spin is found to depend explicitly on the angle of friction, as is shown in the curves, which for most soils is on the order of  $35^\circ$ . (A fluid body with spin cannot be exactly prolate, but instead must have a Jacobi shape. Therefore it does not appear on this figure.)

Spherical asteroids are represented at the right abscissa of Fig. 4. As an example computation, assume a  $35^\circ$  angle of friction and a mass density of  $2.5 \text{ g cm}^{-3}$ . From this analysis the body cannot have a period shorter than 2.5 h before it begins to deform. However, the period at which a loose surface particle would spin off that spherical object is  $p_s = 2\pi = (\omega_s 3600) = 2.08 \text{ h}$ , the case noted by Harris (note that the surface speed for escape from a spherical asteroid is a factor of  $\sqrt{2}$  faster than the spin-off speed, so a particle would not escape after spin-off unless the spin period was shorter than 1.5 hr). Between these limits loose particles spun off could remain around the asteroid for some period of time. A similar elongated ellipsoidal object with an aspect ratio of 0.5 has a deformation spin period limit of 4.2 h and the particle spin-off limit of 2.9 h.

These theoretical results add detail to the basic idea that rubble-pile asteroids cannot spin faster than some well-defined limit, with specific results about the dependence of that limit spin on the actual shape, density, and internal strength of an object. For the idealized ellipsoidal case, elongation lowers the spin limit, but not as much as the linear decrease as suggested in Harris (1996).

On a case-by-case basis these analyses can be compared to calculations with numerical codes. A particle-based analysis

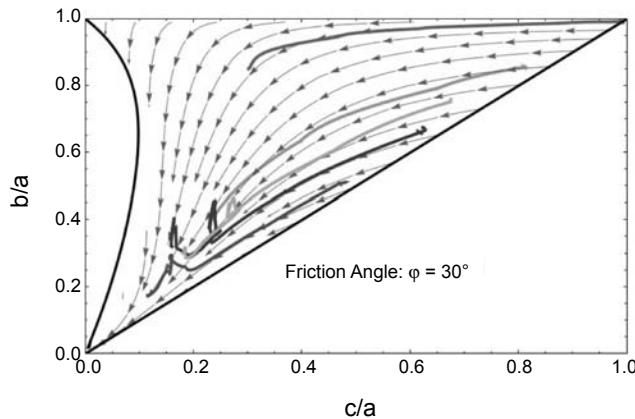

of equilibrium shape was presented by Richardson *et al.* (2005) using an HSDEM code with 1000 total particles. They considered a spinup of an initial shape and the subsequent reformation to an equilibrium shape. Those reformed equilibrium shapes were roughly consistent with the Holsapple continuum limits discussed above, but for an angle of friction of  $\sim 40^\circ$ . Subsequent analysis by Walsh *et al.* (2012) indicated that the effective friction angle of their stacked hard-spheres was on the order of  $40^\circ$ , leading to consistency with this result. It is also relevant to note that Washabaugh and Scheeres (2002) showed that the total energy of ellipsoidal shapes at a given level of angular momentum was minimized in a broad region in the vicinity of the Jacobi and Maclaurin ellipsoids. While not providing specific failure conditions, their analysis did include the effect of Poisson's ratio in their stress field, accounting for a non-incompressible condition that has been associated with granular materials. In another study, Tanga *et al.* (2009) demonstrate the ability of rubble piles modeled with HSDEM to evolve toward the fluid equilibrium shapes of Jacobi and Maclaurin ellipsoids when subject to intermittent "shaking" due to relatively small impacts.

#### 4.3. Deformation of Rubble Piles

A natural follow-on question regards the expected shape deviation of a rubble-pile body when subject to a changing angular momentum. For asteroids such changes in angular momentum are known to occur for smaller bodies due to the Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) effect (see the chapter by Vokrouhlický *et al.* in this volume) and for larger bodies due to impacts. The outcomes of such evolutionary questions can only be addressed through theory and simulation; however, such studies are important as they provide predictions for what may occur in actual asteroid systems.

This question of the fate of an object as its spin limit is slowly subjected to additional angular momentum was analyzed using a continuum model in Holsapple (2010). Such an object must globally change shape once it reaches the limiting failure condition outlined above in order to remain stable. Holsapple assumed that the body transitions through a sequence of evolving ellipsoidal shapes. The dynamical theory leads to an ordinary differential equation for the axis ratios of the ellipsoid (Holsapple, 2010, equation (45)), which can be numerically integrated. A typical result is presented in Fig. 5, which plots the axis ratios along level sets of solutions to the differential equations.

For an object starting in the upper right corner of this figure, which represents a slightly oblate initial shape, the body will flatten, becoming more oblate. It can ideally approach a very flat shape with thickness only a fraction of its diameter before then deforming to a prolate shape. For a body initially at a shape near the center of this plot, it will become more prolate, eventually approaching a very long shape, with  $a/c$  of 5.1 or more. As it deforms, although its angular momentum increases, in most cases its spin decreases because its moment of inertia increases. The implication of this is important for

**Fig. 5.** Figure showing the deformation path of the semi-major axis ratios of an ellipsoid as its angular momentum is increased. An object with the angle of friction of  $30^\circ$  can be at its limit spin at any point along one of the curves in this figure. If the angular momentum is slowly increased, e.g., by YORP, the object deforms and traces a path in the direction indicated along the curves shown. The overlaid lines show results of numerical simulations using a SSDEM model. From Sánchez and Scheeres (2012). These curves terminate when the body fissions, which is not modeled in the analytical theory.

interpreting the spin limit in Fig. 3. It predicts that bodies that lie at the minimum spin period line may not necessarily be at the limit of their angular momentum, but may be starting to go through a deformation that may actually decrease their spin rate as their angular momentum increases.

These deformational dynamics have also been seen in numerical simulations. Walsh *et al.* (2008) analyzed the effect of spinup on initially spheroidal rubble piles modeled with an HSDEM code. They found that as spin increased, components of the body would migrate to the equator, both causing a bulge to form and leading to loss of components into orbit about the body. These studies indicated a link between the expected shape deformation from YORP spinup and with these bodies being linked to binary formation. Sánchez and Scheeres (2012) also analyzed such spinup deformations using an SSDEM code. Their numerically computed deformations are plotted in Fig. 5 and are seen to closely follow the analytical curves derived by Holsapple (2010). However, we note that these simulations are only started in ellipsoidal shapes and are not constrained to be ellipsoidal (unlike the Holsapple computations). Thus as the angular momentum becomes large enough, the collections of grains are seen to undergo deformation beyond the classical ellipsoid shape. This is seen as the sequence of ideal ellipsoid deformations end once they become unstable and sensitive to collapse, which occurs at extreme elongations. The manner in which such systems fail range from surface shedding to fission, and is largely driven by the morphology of the mass distribution. Specifically, in the Sánchez and Scheeres (2012) simulations, initially ellipsoidal bodies are found to separate due to fission while initially spherical bodies are seen to shed material from

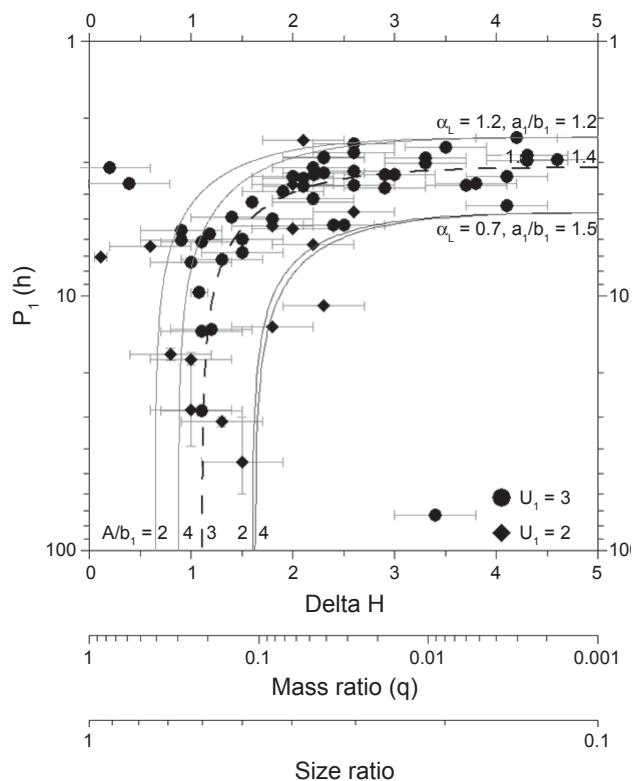

their surface. Another possible outcome of deformation is a change in the body's YORP coefficient, which can cause a body's spin evolution to change sign, as initially noted in Scheeres *et al.* (2007) and recently studied in detail in Statler (2009) and Cotto-Figueroa *et al.* (2015).

Strongly oblate shapes have been found in several asteroids, some of which are fast rotating, such as (66391) 1999 KW<sub>4</sub>, (341843) 2008 EV<sub>5</sub>, (367943) Duende (formerly 2012 DA<sub>14</sub>), (101955) Bennu (formerly 1999 RQ<sub>36</sub>), (65803) Didymos, (2867) Šteins, and others. The equators of these objects generally protrude outside the equivalent oblate ellipsoidal shape, and therefore loose particles at their equator can spin off (Scheeres, 2015). Such shed particles are found to eventually escape (Jacobson and Scheeres, 2011a), although if sufficient numbers are shed in a short period, they may also form into a secondary (Walsh *et al.*, 2008, 2012). Analytical studies of such spunup shapes have been published by Harris *et al.* (2009), Minton (2008), and most recently Scheeres (2015). These studies seek to tie surface deformation to the overall shape of the body, with a particular focus on the oblate, fast-spinning shapes that have been associated with primaries of binary asteroids.

#### 4.4. Evidence for Fission

One predicted outcome for rapidly spinning bodies is that they can undergo a shape bifurcation and separation into multiple components. This outcome is to be compared to the loss of material directly from the surface — a distinction that has been studied to some extent in Walsh *et al.* (2008), Hirabayashi and Scheeres (2014), and Hirabayashi (2014). Analytical methods applied to simplified studies have been able to model such fission mechanics. In Scheeres (2009a) it was shown that the first components to fission in a non-uniform body will be those whose mass centers are the furthest from each other. For simple models of ellipsoids resting on each other, this corresponds to the distinct bodies fissioning first. Under this assumption, it is possible to show that the dynamical evolution of a fissioned body can be directly related to the relative mass fraction between the components (Scheeres, 2007, 2009b). Specifically, if the mass ratio between the bodies is less than  $\sim 0.2$ , the resulting system has positive total energy and can escape [albeit not immediately (Jacobson and Scheeres, 2011a)], while for mass ratios larger than this the bodies are gravitationally bound and cannot escape without exogenous forcing.

This theory was specifically supported with the observations from Pravec *et al.* (2010) on asteroid pairs, which are asteroids that have had an extremely close passage to each other at an extremely slow speed ( $<1 \text{ m s}^{-1}$ ) at some point in the past (Vokrouhlický and Nesvorný, 2008). In the Pravec survey the relative sizes of asteroid pairs were determined and the spin period of the primary measured (see Fig. 6). This survey showed the predicted relation between mass ratio and formation of asteroid pairs, as there is a cut-off in asteroid pairs for mass ratios larger than  $\sim 0.2$ . As a secondary confirmation, the analysis also showed that the spin rates of

**Fig. 6.** Asteroid pairs showing the mass ratio and spin period of the primary with data through September 2014 (Pravec, 2014). There are a few significant outliers that do not fit with the theory, although the majority of added pairs is consistent with the initial interpretation in Pravec *et al.* (2010), where the parameters and detailed models used are described.

primaries decrease as the mass ratio limit is approached, which is the predicted mechanism for ejection, where energy for escape is taken from the spin rate of the primary. Additional observations of asteroid pairs have largely been consistent, although there are a few bodies that do not follow this rule and thus may be asteroid pairs formed by another mechanism (cf. Vokrouhlický and Nesvorný, 2008). There have also been spectroscopic studies of these asteroid pairs by Polishook *et al.* (2014), which have also been interpreted to support the fission hypothesis. This is significant as it has direct bearing on the manner in which rubble-pile bodies fail, even though there is not much detail. The implications of such fissioning have been investigated in Jacobson and Scheeres (2011a), which is described more fully in the chapter by Walsh and Jacobson in this volume.

#### 4.5. Spin Limits for Cohesive Objects

Since *Asteroids III*, a significant number of small asteroids spinning above the limits derived for a cohesionless rubble pile have been discovered. Those objects, whose existence was predicted in Harris (1996), must have sufficient internal strength to withstand their internal tensile stresses. The ques-

tion these bodies raise is what physics provide the source of that strength, what magnitude of strength is needed, and whether these can still be thought of as rubble-pile bodies.

That question was first addressed in Holsapple (2007), where the rubble-pile analysis outlined above was expanded to include strength models with cohesive strength, and it was found that the limit spins could be substantially faster if the internal material was capable of withstanding some level of tensile stress. However, that is true only for smaller asteroids, as can be seen in Fig. 3, as all the strength-limit curves fall back to the nominal spin limit for increasing size (which is the reason why the gravity spin limit does not necessarily imply cohesionless rubble piles). Holsapple derived specific limit curves for two strength cases. First, for a constant strength it is found that the maximum spin rate decreases linearly as the asteroid diameter increases, as noted in Harris (1996). Second, it was assumed that the strength of meter- to kilometer-sized objects will decrease with increasing size, to the  $-1/2$  power, and in this way accounting for increasing planes of weakness in a larger body. Then the limits of spin vs. size decrease with the power of  $-5/4$ . The resulting curve is the upper, bounding curve plotted in Fig. 3. This curve furnishes an upper bound to all the present data and is for a material that has a tensile strength of only 100 kPa in a 10-cm specimen, and then decreasing as  $1/\sqrt{r}$  with size  $r$ . That value is more than an order of magnitude less than measured for typical meteorites (see section 2). Therefore, whether these data are really constrained by a strength limit or not remains an open question, as the limit may only indicate a lack of mechanism to further increase spin rates. A related question is also whether this represents the strength of individual components.

Sánchez and Scheeres (2014) have investigated the question of what minimum level of strength could exist between rubble-pile components. It is an important distinction that they are not considering the strength of all components, but are probing for the presence of possible cohesive strength between rubble-pile components. Their theory notes that van der Waals attractions between the finest material present in the rubble pile (in sufficient quantities to form an underlying matrix of material) should hold larger components in place, in the same way that cement holds rocks within a matrix. Using data from the Apollo lunar experiments and samples, and information on size distributions inferred from observations and samples from Itokawa, they predict the possible strength of this regolith to be on the order of 100 Pa, with their preferred value stated as 25 Pa (it should be noted that this value depends on an assumed density, angle of friction, and other shape parameters). This model probes the lower end of the strength envelope to determine whether there is any evidence for such cohesive strength in rubble-pile asteroids.

Sánchez and Scheeres (2014) point to a few aspects of the asteroid size, spin, and morphology database represented in Fig. 3, in addition to some specific asteroids, as evidence for their theory. First they note that cohesive strength between rubble-pile components greater than  $\sim 100$  Pa should

lead to a more filled-in population below the strength line in the intermediate size range of 0.1–1 km. However, only when total effective strength (which is actually a function of density and shape assumptions as well) falls below the 100-Pa limit is the visual gap less significant. Another prediction from this theory is that binaries should not form when less than a certain size, as the spin rate required for fission to overcome cohesion would cause the resulting fragments to separate at speeds in excess of their mutual gravitational escape speed. They use this to explain the sharp drop-off in binaries below a few hundred meters, which has been shown to be statistically significant (see the chapter by Margot et al. in this volume). Finally, the presence of small and rapidly spinning tumbling asteroids at the strength limit is also consistent with the failure of rubble-pile asteroids with cohesion, as such a failure will generally induce tumbling in the separated bodies, which will also immediately escape from each other (Scheeres et al., 2010). There are also a few specific bodies that provide additional support for this weak level of strength being present in a rubble-pile body. These are P/2013 R3, (29075) 1950 DA, and 2008 TC<sub>3</sub>, which are discussed in the final section.

Before continuing it is important to note that the apparent gap between strengths greater than 100 Pa and the observed bodies in the 0.1–1-km range has been challenged by a number of observations that show the existence of objects that fill in the region beneath the upper bound. These are noted in Holsapple (2007) and reported in Masiero et al. (2009), Chang et al. (2014), and Urakawa et al. (2014). These observations have not been deemed sufficiently reliable in the lightcurve database (Warner et al., 2009) to include in the confirmed cases. It is important that these objects be viewed in future apparitions to confirm them. Confirmation of these bodies' size and spin rates would have a significant impact on our understanding of the possible strength of asteroids.

## 5. PROBING ASTEROID INTERIORS

Although the previous models and interpretations take the interior properties of asteroids into account, they do not directly sense or constrain the interior properties or geophysics. This is because they still rely on external measures of the asteroid stability state, such as its shape, size, and spin. This section discusses approaches that are currently being developed to probe the interior properties of an asteroid, taking advantage of fundamental geophysical properties and observable effects. There are three main recent advances in this area, the first of which is the classical interpretation of surface geological structures to make inferences on the interior of an asteroid. Second is the analysis of the interior seismic properties of rubble-pile bodies. Third is the analysis of tidal dissipation effects within small rubble-pile bodies. A fourth advance that can be mentioned in passing is the use of radar to probe the interior of a rubble-pile body. However, there have not been definitive analyses of this approach for asteroidal bodies, although such analyses will be performed for the first time at a comet by the Rosetta spacecraft.

### 5.1. Geological Interpretation

The classical approach to interpreting the interior structure of an asteroid was pioneered at the asteroid (433) Eros, although it has also been applied to interpret the interior of Phobos (see the chapter by Marchi et al. in this volume). The underlying theory is outlined in Prockter et al. (2002) and interprets surface features as expressions of subsurface strength. The key focus was on the lineaments and global structures such as Rahe Dorsum on Eros. Buczkowski et al. (2008) studied the lineaments across Eros to determine whether there was clear evidence for internal strength or structures. While certain correlations seem to exist, along with evidence for some subsurface structure, it is also difficult to independently confirm what these structures may be, whether they arise from the mechanical properties of the regolith itself, or how they could be uniquely estimated (Robinson et al., 2002). The approach has also had limited use at (25143) Itokawa, where there are no specific global geographic features that could be used to make interior interpretations other than the component shapes themselves. On the other hand, such an approach can be very valuable at a larger body such as (4) Vesta, which has many global features that could be used as constraints on the interior of the body (reviewed in the chapter by Russell et al. in this volume).

### 5.2. Seismic Effects

The importance of seismic effects was underlined by the Near Earth Asteroid Rendezvous (NEAR) observations of Eros. While craters were present on that body, they became more sparse at smaller sizes, with the surface dominated by a thick layer of regolith (Chapman et al., 2002). This was explained using a statistical and global analysis of crater erasure due to seismic shaking as a result of impacts on Eros (Richardson et al., 2004). In a subsequent analysis, Thomas and Robinson (2005) were able to positively correlate the erasure of small craters with a single large impact, thus linking the transmission of seismic energy from an impact to the surface motion of regolith and not due to regolith created in the impact itself. The chapter by Marchi et al. in this volume reviews this material in more detail.

Motivated by, and contemporaneous with, this physical correlation there were many different studies of the effects of impacts on the redistribution of regolith. These include the use of particle hydrodynamic codes for simulating impacts (Nolan et al., 2001), coupled models of seismic transmission and granular motion (Richardson et al., 2004; Richardson and Bowling, 2014), and the application of Earth geophysical models of seismic-energy transmission to rubble-pile bodies (Martin et al., 2008; Blitz, 2009).

A culmination of these analyses is the realization that the mechanical properties of a rubble-pile body can be linked with the observed crater distributions and levels of erasure. Asphaug (2008) proposes a methodology to directly estimate the attenuation of seismic energy within a rubble pile using the observed largest crater on that body. This basic idea has

also migrated beyond the use of naturally occurring impacts to include the application of controlled and induced cratering blasts or impacts on the surface of a rubble-pile asteroid. By controlling the energy and deposition of the blast, it is possible to infer the seismic transmission of energy at distal points of a rubble-pile body by comparing before and after images of the surface. This can be enhanced by the deployment of instrumented devices across the surface, where they can record the sensed seismic energy or, in the extreme case if they are lofted from the surface, determine the strength of the seismic wave by tracking the length of their ballistic phase. Such ideas were proposed in Scheeres *et al.* (2003) and have subsequently appeared as a concept in a number of space science missions, with the combination of calibrated blasts and sensing measuring devices proposed in the Discovery mission Binary Asteroid In-Situ Explorer (BASiX) (Robert *et al.*, 2010). Similar concepts have also been subsequently proposed in the mission concepts of MarcoPolo-R (Michel *et al.*, 2014) and Asteroid Impact and Deflection Assessment (AIDA) (Galvez *et al.*, 2013). This approach to seismic inference will be realized with the currently planned Hayabusa-2 mission to primitive asteroid 1999 JU<sub>3</sub>. This mission concept calls for using an explosive device to accelerate an impactor into the surface of the body, creating a crater and seismic energy source that can then be tracked by observing modifications of the surface (Tsuda *et al.*, 2013).

### 5.3. Tidal Dissipation

Another measure that can be used to peer into the interior of a rubble-pile body is related to energy dissipation due to tidal deformations. There are two main ways in which rubble-pile bodies can dissipate excess kinetic energy via this method. One occurs if the body is in a non-uniform rotation state, as this induces traveling waves of alternating accelerations, which can cause stress and strains that dissipate energy. This effect has been linked to the fact that the vast majority of asteroids are in or near a rotation state about their maximum moment of inertia (Burns and Safronov, 1973). Harris (1994) showed that the vast majority of known tumbling asteroids had an overall slow rotation rate, meaning that the time for them to relax to uniform rotation could be long, although these estimates depend on assuming that the geophysical properties of larger planetary bodies and satellites are similar to rubble-pile bodies.

To better constrain and understand how the observed tumblers should be interpreted in terms of their internal geophysics of tidal dissipation, there have been several analytical and numerical studies of how asteroids could enter complex rotation states and what the frequency of them entering such states should be. This would allow for the comparison of the population with different dissipation rates. The trend of tumbling with greater spin period implicitly indicates that asteroids are dissipative bodies. The degree of dissipation is not fully understood, and depends on the assumed parameters of rigidity,  $\mu$ , which measures the stiffness of the body; the quality factor,  $Q$ , which is inversely proportional to the rate

of energy dissipation due to non-uniform deformations; and the rate at which tumblers are created. We note that tumblers can be created in several ways: catastrophic disruptions (Asphaug and Scheeres, 1999; Scheeres *et al.*, 2000b), planetary flybys (Scheeres *et al.*, 2000b, 2005; Pravec *et al.*, 2014), YORP-induced fission (Sánchez and Scheeres, 2014), and, potentially, YORP spindown effects either in isolation (Vokrouhlický *et al.*, 2007) or in combination with impacts (Marzari *et al.*, 2011; Henych and Pravec, 2013).

On the other hand, the application of standard planetary theory geophysics to rubble-pile asteroids made in earlier studies may not be appropriate. This has motivated researchers to develop improved mathematical models and to carry out geophysical analyses that are relevant for this environment. Efroimsky and Williams (2009) considered the effect of frequency dependent terms in tidal dissipation, while Sharma *et al.* (2005) and Breiter *et al.* (2009) have developed novel mathematical expressions for tidal dissipation. Perhaps most fundamental, however, is the study by Goldreich and Sari (2009), which shows that rubble-pile bodies are expected to behave distinctively relative to the classical planetary satellite theory. In their analysis they show that the functional relationship between the quality factor,  $Q$ , and the Love number of an object,  $k$  (related to the rigidity of the body and how the shape responds to tidal stress), should follow a variation where  $Q/k \propto r$ , the radius of the body, which is distinctly different than the classical relationship. Specifically, they show that the effective dimensionless rigidity of a rubble pile is smaller than that of a monolithic body of the same size, with the reduction arising from the concentration of stresses due to the presence of voids. Using this result they show that it is likely that a rubble-pile secondary in a binary asteroid system should circularize, which cannot be necessarily concluded if the secondary is monolithic and follows the classical planetary relation. The implications of their analysis for the relaxation time for tumbling asteroids has not been made as of yet.

The Goldreich and Sari analysis has been applied to develop a more detailed model for the expected evolution of binary asteroid systems. In Jacobson and Scheeres (2011b) they analyze the joint evolutionary dynamics of tidal dissipation and the binary YORP (BYORP) effect (see the chapter by Vokrouhlický *et al.* in this volume) in light of the Goldreich and Sari theory for tidal dissipation. They find that there should exist a so-called BYORP and tide equilibrium where a contractive BYORP effect acting on the synchronous secondary is balanced by an expansive tidal effect due to dissipation in the rapidly rotating primary. The existence of this equilibrium is significant for a number of reasons, described elsewhere in this volume in the chapters by Walsh and Jacobson and Vokrouhlický *et al.* In the context of this chapter the significance is that this provides a direct way in which to constrain and indirectly measure the rigidity of the primary in a rubble-pile binary asteroid. Once a binary asteroid is known or suspected to lie in such an equilibrium, it also provides a way to evaluate the functional relationship between a body's size and its quality factor and tidal

Love number. The existence of this equilibrium has been recently validated for binary asteroid 1996 FG<sub>3</sub> (Scheirich et al., 2015). From that study there is an inferred value of rigidity times quality factor of  $\mu Q \sim 2.7 \times 10^9$  Pa, which is orders of magnitude less than that expected for a monolithic body and for what has been bounded in the past for binary asteroids (Margot et al., 2002). This result is significant, as it is the first “measured” value of this parameter for a rubble-pile body, albeit there are a number of significant sources of uncertainty that are discussed in that paper.

A significant next step in analysis will be to start to blend these results to better understand the dissipation rate within rubble-pile bodies. This will require additional theoretical, observational, and ultimately numerical computations to fully understand. It also provides motivation for a space science mission to a binary asteroid in a BYORP-tide equilibrium, since obtaining a precise estimate of the rigidity requires that the secondary body be fully mapped.

## 6. SPECIFIC ASTEROID OBSERVATIONS

In addition to the insights obtained by analyzing the asteroid population database, there have been significant insights from analyzing specific asteroids. There have been a number of dramatic and unprecedented observations of single bodies that provide deep insight into the morphology and, in some cases, the mechanical properties of these asteroids. In the following we discuss some of the more significant of these bodies. As some of these bodies are discussed in more detail elsewhere, in some cases we only draw on a few aspects of the analysis and indicate the appropriate chapter for more details. Instead of grouping these bodies by how they were observed, which could be done, we just list them in order of their alphabetical names and designations.

### 6.1. (433) Eros

At the time the *Asteroids III* book was being completed, significant, but incomplete, data on asteroid (433) Eros taken by the NEAR-Shoemaker spacecraft was already included. The definitive analysis of the gravity field of this asteroid had not been published, however, and is what we focus on here. Initial data indicated that the asteroid’s gravity field was homogeneous at the few-kilometers scale (Asphaug et al., 2002). Subsequent analysis of the gravity field was made and reported in two papers (Miller et al., 2002; Konopliv et al., 2002). Both papers included a comparison between the measured gravity field and a homogenous gravity field computed from the shape with a constant density assumption. Density variations can be detected through the comparisons of measured and computed gravity field coefficients (cf. Scheeres et al., 2000a; Takahashi and Scheeres, 2014). Gravity field comparisons in both papers showed differences at the relative level of less than  $10^{-3}$  through the 6th degree-and-order gravity terms. At higher degree and order the uncertainty in the gravity-field coefficients was greater than this relative level, meaning that at these higher levels the differences were

indistinguishable from noise. This provides a strong constraint on the density homogeneity within this asteroid. We also note that the bulk density of this body was determined to be  $2.67 \pm 0.03$  g cm<sup>-3</sup> (Miller et al., 2002), indicating a relatively low level of macroporosity of approximately 20% assuming the S-type asteroid had a grain density of ordinary chondrites (Yeomans et al., 2000). The Miller et al. (2002) paper also made an accurate rotation-state estimate for the body, and was unable to observe any complex rotation except that driven by solar torques. This indicates that the body had fully relaxed to principle-axis rotation.

### 6.2. (25143) Itokawa

The asteroid (25143) Itokawa was visited by the Hayabusa spacecraft in 2005 (see the chapter by Yoshikawa et al. in this volume). The greatest achievement of that mission was the collection of a small but valuable sample of regolith from the surface. However, several important observations and measurements of the asteroid were also taken during the few months that the spacecraft was in close proximity to that body. There were several important determinations with regard to the geophysics of this asteroid. These include the total bulk density of the body, measured to be  $1.9 \pm 0.13$  g cm<sup>-3</sup>, corresponding to a macroporosity of 41% for this S-type asteroid (Fujiwara et al., 2006). As the spacecraft never spent significant time in ballistic motion close to the asteroid, the gravity field determination was not able to progress beyond the total mass. Subsequent to the mission it has been speculated that the density distribution within the body is heterogeneous. This idea was first proposed in Scheeres and Gaskell (2008) to explain the apparent disconnect between the predicted YORP torque (which was computed to be negative based on several different computations) and the lack of a detected change in its spin. This theory predicted that either the head or neck region of the body should have a greater density. Lowry et al. (2014) were able to detect a measurable acceleration in the spin rate of Itokawa. Based on the theory outlined in Scheeres and Gaskell (2008) and Breiter et al. (2009) it was determined that the density disparity between the head and body would need to be 2.85 and 1.75 g cm<sup>-3</sup>, respectively, for this effect alone to account for the disparity. Such a drastic disparity between densities, 62%, is not out of the question given that the secondary and primary of (66391) 1999 KW<sub>4</sub> have a large density disparity, although for that body it is only 42% for the nominal values (see below). However, as discussed in the chapter by Vokrouhlický et al. in this volume, there are other effects besides a density disparity that could have caused the acceleration of Itokawa, making the result somewhat uncertain.

Beyond the mass, bulk density, macroporosity, and possible density heterogeneity, important information was obtained regarding the size distribution of rocks, boulders, and grains on Itokawa. Based on images taken while in close proximity to the body, the size distribution of boulders and rocks across its surface was measured and found to follow a size distribution with an exponent of  $-3.1 \pm 0.1$  down to

5 m (*Michikami et al.*, 2008). A more recent paper revisits the Itokawa data and focuses on the difference between the head and body of this asteroid, as well as discussing several possible hypotheses for its formation (*Mazrouei et al.*, 2013). They find a somewhat steeper size distribution down to 6 m, albeit changing depending on where on the body one looks. Ultimately their general conclusions on the distribution of larger blocks are consistent with *Michikami et al.* (2008). Using the returned samples, a size-distribution analysis was also made by *Tsuchiyama et al.* (2011). Across the grain sizes ranging from 0.5 to 100  $\mu\text{m}$  they found a size distribution with an exponent between  $-2.8$  and  $-2$  (steeper at the smaller sizes). While these two size distributions (from the observations and the samples) cannot be easily combined, they do present some insight into the size distribution of grains and boulders within a rubble-pile asteroid. *Tsuchiyama et al.* present the hypothesis that the size distribution may break to a shallower level at millimeter- to centimeter-sized grains, which may explain why they were viewed as the dominant grain size on the body [at least in the Muses-Sea region (*Yano et al.*, 2006)]. These measurements of size distribution are important as they speak directly to the presumed size distributions that all rubble-pile bodies may have. Also, the recent theory on cohesive strength in rubble piles (*Sánchez and Scheeres*, 2014) depends explicitly on the presence of fine regolith grains for its physical realization.

### 6.3. (216) Kleopatra

The asteroid (216) Kleopatra is a strangely shaped main-belt asteroid with a total length on the order of 250 km and with a very narrow “neck” (*Ostro et al.*, 2000). This asteroid has already been distinguished by its rapid rotation and odd shape. *Descamps et al.* (2011) reported the discovery of two satellites about this asteroid, enabling a precise mass of the asteroid to be determined. However, while their observations were also consistent with the *Ostro et al.* (2000) radar-based shape, they reported finding a significantly larger size for this body, approximately 25% larger in mean diameter than the *Ostro et al.* radar shape. A different set of observations by *Marchis et al.* (2012) reported an even larger size, raising the interesting situation of knowing the mass and shape of the body but not its size and hence density. The rapid rotation of this object and its shape mean that the stability of this body is highly sensitive to its bulk density and size. *Hirabayashi and Scheeres* (2014) took advantage of this size ambiguity to probe the stability of this body across a range of sizes, from the *Ostro et al.* (2000) size to the *Marchis et al.* (2012) size. Based on an averaged stress analysis, essentially applying the averaging method of Holsapple to a non-ideal shape, they were able to determine that the *Descamps et al.* (2011) size requires the lowest angle of friction to keep the body stable. This analysis has also been confirmed using a finite-element plastic-deformation analysis that shows that the smaller *Ostro et al.* (2000) size will tend to collapse, the larger *Marchis et al.* (2012) size will tend to separate, and the *Descamps et al.* (2011) size seems to be the most

stable again, and is only susceptible to surface failures that could be related to inaccuracies in the detailed shape of the body (*Hirabayashi*, 2014). This analysis is listed here as it represents a unique use of continuum and failure theory to help resolve an inconsistency in measurements.

### 6.4. (29075) 1950 DA

The asteroid (29075) 1950 DA is well known as one of the most hazardous bodies for Earth in the solar system, due to its relatively high impact probability of 1 in 4000 (albeit in the year 2880) and its relatively large size, on the order of 1 km (see the chapter by Harris et al. in this volume). In *Rozitis et al.* (2014) the body’s density is determined by using the measured Yarkovsky acceleration of the body and analyzing the thermal inertia. This allowed them to infer that the body was a rubble pile, that the rotation of the body was retrograde, and that the corresponding shape model for this rotation pole could be used (*Busch et al.*, 2007). Based on these measurements, *Rozitis et al.* (2014) determined that the body was spinning beyond the failure limit at which both loose material would be shed from its surface and it would undergo global deformation. Due to this they concluded that the body required cohesion to stay intact, and applied basic techniques (*Holsapple*, 2001) to determine the level of cohesive strength needed. Based on a Drucker-Prager failure model they were able to identify a minimum necessary strength of approximately 65 Pa for the body to hold together, which they note is comparable to the level of strength for rubble-pile bodies hypothesized in *Sánchez and Scheeres* (2014). A detailed finite-element analysis was performed by *Hirabayashi and Scheeres* (2015) that confirmed this strength as a lower bound and found that for uniform strength, the center of the body should fail prior to the surface. They note that should this occur, it could result in a less-dense core, which could be detected with an orbiting spacecraft.

### 6.5. (66391) 1999 KW<sub>4</sub>

The binary asteroid (66391) 1999 KW<sub>4</sub> was observed with range-Doppler radar at a number of epochs, enabling a detailed model of the shapes of each of its components and their relative orbital and rotational dynamics (*Ostro et al.*, 2006; *Scheeres et al.*, 2006). These papers provided the first, and to date most accurate, insight into the morphology of a binary asteroid system, and it is of interest to briefly review the results here. First, it is important to note that in the nominal model the primary rotates just shy of where loose material should be shed from its surface, implying that its interior may also be close to a failure limit. At the lower end of density for the primary the surface may require cohesive strength to stay together. Thus this body exhibits and showcases the traits of the rapidly rotating oblate bodies discussed earlier in this chapter and has been used as the motivating example of this class of body (*Harris et al.*, 2009; *Scheeres*, 2015).

The primary has an obliquity of about 3° with respect to the orbit plane of the binary and the secondary has relative

librations of several degrees. Thus the system is not in a fully relaxed state. Based on the shape of the secondary we note that the predicted BYORP coefficient is positive, meaning that this system could be undergoing expansion (the system is currently being monitored for BYORP expansion, as described in the chapter by Vokrouhlický et al. in this volume). As this system has not settled into a fully relaxed state it introduces the interesting possibility that it could be tracked over longer time periods to possibly determine or detect effects associated with either tidal relaxation or with BYORP expansion.

There is a large density disparity between the primary and secondary body. The primary density is determined to be  $1.97 \pm 0.24 \text{ g cm}^{-3}$  and the secondary to be  $2.81^{+0.82}_{-0.63} \text{ g cm}^{-3}$ , a relative factor of 42%. Possible reasons for such a disparity are discussed in Scheeres et al. (2006), and involve the compaction of the secondary by continuous shaking and the expansion of the primary due to the extremely rapid rotation rate.

## 6.6. 2008 TC<sub>3</sub>

Now we consider asteroid 2008 TC<sub>3</sub>, which became the Almahata Sitta meteorite (Jenniskens et al., 2009). This asteroid was observed prior to entering Earth's atmosphere during the brief period after its discovery. Lightcurve observations of this body showed that it was spinning with a period of 100 s and also was in a tumbling rotation state (Scheirich et al., 2010). It can be found on Fig. 3, where it is the smallest known tumbler and only requires approximately 100 Pa of cohesive strength to withstand disruption. Based on analysis of the meteorite fall, this body consisted of several different mineralogical types that constituted separate components in the parent asteroid (see the chapter by Jenniskens in this volume), with one possible interpretation being that it could be described as a rubble pile (Jenniskens et al., 2009). Analysis of the preentry observations and the meteorite falls also indicate that the body had significant macroporosity (Kohout et al., 2011). The meteor was observed to break up high in the atmosphere, indicating a weak body (Borovička and Charvat, 2009; Popova et al., 2011). Furthermore, Borovička and Charvat (2009) note the presence of an abundance of micrometer- and larger-sized dust associated with the meteor, consistent with this dust composing a “substantial part” of the total mass of the object. These disparate observations related to this asteroid were linked together in the recent theory proposed in Sánchez and Scheeres (2014), and described earlier in section 4.5, although there remain questions about that interpretation (see discussion in the chapter by Borovička et al. in this volume).

## 6.7. P/2013 P5

Body P/2013 P<sub>5</sub> was initially catalogued as a comet, yet now seems to more properly identified as an asteroid (see the chapter by Jewitt et al. in this volume; Jewitt et al., 2013; Hainaut et al., 2014). This body has exhibited periodic shedding over a number of different observational epochs. Material

shed from its surface has been seen to consist of fine grains down to 10 μm in size at least. A clear explanation for its periodic shedding has not been found, although some initial analysis of this phenomenon has occurred (Scheeres, 2015).

## 6.8. P/2013 R3

Finally, we mention another active asteroid, P/2013 R<sub>3</sub> (Jewitt et al., 2014). This body was seen to fail in an entirely different morphological fashion, splitting repeatedly into smaller components that escaped from each other. Hirabayashi et al. (2014) analyzed the main components of this body and estimated the initial spin rate of the protobody by mapping estimates of size and speed backward to the inferred epoch of disruption. Based on this analysis they predicted a range of possible strengths for the progenitor rubble-pile body prior to breakup, from 40 to 200 Pa, with the range of values accounting for uncertainties in size, density, and relative speed.

## 7. CONCLUSIONS

In this chapter we bring together disparate material on the strength, mechanics, and morphology of asteroids based on meteors and meteorites, groundbased observations, spacebased observations, analysis, and numerical simulation. While there has been significant progress on all fronts since *Asteroids III*, many new issues and questions have been exposed as well. A main issue that arises is the wide variation in strength determinations of asteroids and their constituents. While direct comparisons of meteor strengths as parameterized by dynamic pressure and strength parameterized by spin rate cannot be naively made, there must be some underlying connection between these. Elucidation of this should be a priority, as it would enable a clear application of meteor data to the interpretation of strength of rubble-pile bodies. Another area that is ripe for progress is an improved theory of tidal dissipation within rubble-pile bodies, coupled with new ways in which the fundamental parameters of rubble piles can be estimated. This involves a better understanding of how asteroids are made to tumble, modified theories for tidal dissipation of rubble-pile bodies, and estimation of improved values for rigidity, tidal Love number, and quality factors of rubble piles. Finally, the continued advancement in analytical and numerical simulation tools will be essential for continued progress in this difficult and fundamental issue of asteroid mechanics.

---

The regolith-covered surfaces of asteroids preserve records of geophysical processes that have occurred both at their surfaces and sometimes also in their interiors. As a result of the unique microgravity environment that these bodies possess, a complex and varied geophysics has given birth to fascinating features that we are just now beginning to understand. The processes that formed such features were first hypothesized through detailed spacecraft observations and have been further studied using theoretical, numerical, and experimental methods that often combine several scientific disciplines. These multiple approaches are now merging toward a further understanding of the geophysical states of the surfaces of asteroids. In this chapter we provide a concise summary of what the scientific community has learned so far about the surfaces of these small planetary bodies and the processes that have shaped them. We also discuss the state of the art in terms of experimental techniques and numerical simulations that are currently being used to investigate regolith processes occurring on small-body surfaces and that are contributing to the interpretation of observations and the design of future space missions.

## 1. INTRODUCTION

Before the first spacecraft encounters with asteroids, many scientists assumed that the smallest asteroids were all monolithic rocks with a bare surface, although there had been a few articles suggesting possible alternative surface properties and internal structures (e.g., *Dollfus et al.*, 1977; *Housen et al.*, 1979; *Michel et al.*, 2001; *Harris*, 2006). Given the low gravitational acceleration on the surface of an asteroid, it was thought that regolith formation would not be possible; even if small fragments of rock were created during the impact process, nothing would be retained on the surface (e.g., *Chapman*, 1976). However, the NASA Galileo, Near Earth Asteroid Rendezvous (NEAR)-Shoemaker (hereafter simply NEAR), and Japan Aerospace Exploration Agency (JAXA) Hayabusa space missions revealed a substantial regolith covering (951) Gaspra, (243) Ida, (433) Eros (*Sullivan et al.*, 2002; *Robinson et al.*, 2002), and (25143) Itokawa (*Fujiwara et al.*, 2006). In addition to finding each of these bodies to be regolith-covered, there is strong evidence that this regolith has very complex and active dynamics. In fact, it was due to the NEAR observations of Eros that the local gravity was first

understood to be of importance to asteroid surface processes (*Robinson et al.*, 2002). The importance of gravity for regolith dynamics was emphasized even further when the first images were received from the Hayabusa probe.

Over the course of these space missions and others, a wide range of geological features have been observed on the surfaces of asteroids and other small bodies, such as the nucleus of Comet 103P/Hartley 2 (*Thomas et al.*, 2013). However, we do not have direct access to the properties of the granular material that led to these features. Although constitutive equations exist for granular interactions on Earth, the inferred scaling to the gravitational and environmental conditions on other planetary bodies such as asteroids is currently untested. Understanding the dynamics of granular materials in the small-body gravitational environment is vital for the interpretation of their surface geology and is also critical for the design and/or operation of any device planned to interact with their regolith-covered surfaces.

Regolith was originally defined as “a layer of fragmented debris of relatively low cohesion which overlies a more coherent substratum” (*Shoemaker et al.*, 1968), although this definition runs into difficulties when there is no clear interface

separating the fragmented debris and the coherent substrate (*Robinson et al.*, 2002). Here we will use the term regolith to describe, in general terms, the “loose unconsolidated material that comprises the upper portions of the asteroid” (as defined in *Robinson et al.*, 2002). However, we note that self-gravitating aggregates like Itokawa, often referred to as “rubble piles” (*Richardson et al.*, 2002), are composed of rubble — boulders on the order of tens of meters and less — held together by gravity and cohesive forces instead of being a monolithic body (*Fujiwara et al.*, 2006). As such they are essentially made of regolith throughout. Therefore, although not discussed in this chapter, understanding how granular materials behave in these extremely low-gravity environments can also improve our understanding of the interiors of these bodies.

This chapter will start by presenting our current knowledge of the surfaces of asteroids (433) Eros, (25143) Itokawa, (21) Lutetia, and (4) Vesta. After a short introduction to granular materials, we will then introduce the unique asteroid environment and suggest how this may influence the regolith dynamics. Next, we discuss in detail the underlying physical mechanisms behind the geological processes observed to occur on the surfaces of asteroids. Finally, a discussion of the experimental techniques that can be used to simulate the asteroid environment and the recent advances in modeling regolith dynamics is provided.

## 2. IN SITU OBSERVATIONS OF ASTEROID SURFACES

In this section we will briefly discuss the *in situ* observations of four asteroids: (433) Eros, (25143) Itokawa, (21) Lutetia, and (4) Vesta. For more detailed reviews about these bodies the readers are referred to *Cheng* (2002) and the chapters in this volume by *Yoshikawa et al.*, *Barucci et al.*, and *Russell et al.* Additionally, detailed reviews of the geology of other asteroids such as (951) Gaspra, (243) Ida, and (253) Mathilde are available elsewhere (e.g., *Carr et al.*, 1994; *Sullivan et al.*, 1996; *Thomas et al.*, 1999).

### 2.1. Asteroid (433) Eros

(433) Eros (hereafter simply Eros; Fig. 1, Table 1), the second largest near-Earth asteroid (NEA), shows a subdued,

gently undulating and complex regolith-covered surface, characterized by abundant, but not uniformly distributed, ejecta blocks and conspicuously degraded craters (*Veverka et al.*, 2000, 2001a; *Cheng et al.*, 1997). The effective topography on Eros has a range of about 2 km and the slopes, calculated relative to the local gravity vector, vary over the surface of the asteroid [for an explanation of how elevation is defined on irregular bodies, see section 5 of *Cheng et al.* (2002a)] with an average slope of ~8° to 10° (*Zuber et al.*, 2000; *Thomas et al.*, 2002).

**2.1.1. Evidence of regolith motion on Eros.** In general, Eros is very bland in terms of color and albedo variations. However, visible variations, such as several bright features typically with sharp boundaries, can be seen in regions that have steep slopes (see Fig. 2) (*Veverka et al.*, 2000; *Robinson et al.*, 2001; *Cheng*, 2002; *Mantz et al.*, 2004; *Murchie et al.*, 2002). As all the NEAR data indicate global compositional homogeneity, the brighter surfaces imply freshly exposed material that has not yet been subjected to space weathering (*Chapman*, 2004; see also the chapter by *Brunetto et al.* in this volume). In contrast, dark soils are typically located at the bases of bright streaks and display both diffuse and sharp boundaries (*Thomas et al.*, 2002; *Riner et al.*, 2008). These observations, and morphological data, indicate that the bright streaks are the results of preferential downslope movement or a landslide of mature regolith, revealing immature material beneath (e.g., *Robinson et al.*, 2002; *Thomas et al.*, 2002; *Riner et al.*, 2008; *Murchie et al.*, 2002).

Indeed, on closer inspection, accumulations of granular material that have been gravitationally transported away from topographic highs can be seen on Eros (Fig. 20 (*Thomas et al.*, 2002; *Veverka et al.*, 2001b; *Robinson et al.*, 2002)). These granular deposits appear to result from low-momentum downslope movements and some observations suggest that mobilized regolith may even be halted by frictional or other effects before reaching the foot of the slope (*Mantz et al.*, 2004; *Thomas et al.*, 2002). Downslope motion has also been observed on slopes that are well below the expected angle of repose for granular materials. Whether this indicates the necessity for a triggering mechanism or not is a subject currently under debate (*Cheng*, 2002; *Holsapple*, 2013).

**2.1.2. Craters and crater morphology on Eros.** Further evidence for regolith motion is that, despite the large number of craters on the surface of Eros, there is a deficiency of small

TABLE 1. Characteristics of the asteroids discussed in detail in this chapter.

Asteroid	Space Mission	Mean Diameter (km)	Bulk Density (g cm <sup>-3</sup> )	Rotation Period (h)	Surface Acceleration (cm s <sup>-2</sup> )	Escape Speed (m s <sup>-1</sup> )

(<2-km-diameter) craters (Veverka et al., 2000, 2001b). As there are sufficient projectiles in near-Earth space to produce small craters, there must therefore be a process that either covers or erodes small craters on Eros (Veverka et al., 2001b). It has been suggested that impact-induced seismic shaking (see section 5), which causes the regolith to move, may erase small crater features and thus explain their paucity compared to predictions of dynamical models of projectile populations (e.g., Richardson et al., 2004; Michel et al., 2009). However, alternative degradation mechanisms have also been suggested, including microcratering and thermal creep (Cheng, 2002). For a detailed discussion of cratering on asteroids, see the chapter by Marchi et al. in this volume.

Additional evidence of resurfacing and modification is visible in the interiors and the subdued rims of several craters (Robinson et al., 2002; Zuber et al., 2000). The depth-to-diameter ratio of craters on Eros is, on average, ~0.13, but the freshest and youngest craters approach lunar values of ~0.2 (Robinson et al., 2002). Many of the topographic lows are filled with deposits of fine granular material (Fig. 2) (e.g., Veverka et al., 2001a). These features, referred to as “ponds,” are characterized by smooth, level surfaces that are sharply delineated (Robinson et al., 2001; Cheng et al., 2002b). They are found preferentially at low latitudes and in the bottom of small (<1 km) craters or other topographic lows (Robinson et al., 2001; Cheng et al., 2002b); however, this may be due to observational biases (Roberts et al., 2014b). The bottoms of the ponds are often offset in a direction toward the downslope of the crater (Veverka et al., 2001b), and recent results have found that the pond floors are not as flat as originally believed (Roberts et al., 2014a).

**2.1.3. Linear features on Eros.** On the surface of Eros several lineations can be observed, including chains of craters,

**Fig. 2.** Evidence of regolith transport on Eros. (a) Bright, freshly exposed material on a large crater wall, as the darker material moves downslope (PIA03134). (b) An example of a dust pond (2001\_028\_5\_eros.png from <http://ser.sese.asu.edu/near.html>).

sinuous and linear elongated depressions, and topographic ridges (Veverka et al., 2000). Such lineations are similar to those observed on the martian satellite Phobos (Thomas et al., 1979). Prockter et al. (2002) explain that, on Eros, these linear features, or grooves, exist on a global scale (prominent wide troughs and ridges several kilometers in length), a regional scale (chains of craters and straight-edged grooves several hundreds of meters long), and also on very local scales (closely spaced ridge and trough terrains tens of meters in scale). The large variations in directions, patterns, and relative ages of the lineations indicate that they were formed during many different and unrelated events (see section 5, the chapter by Marchi et al. in this volume, and also Veverka et al., 2000; Prockter et al., 2002; Thomas et al., 2002; Robinson et al., 2002). For a full map and analyses of the linear features on Eros, see Buczkowski et al. (2008).

**2.1.4. Depth and character of Eros’ regolith.** Eros has a widespread unconsolidated regolith of depths that are typically several tens of meters in thickness, but not uniform over the surface (Cheng, 2002; Barnouin-Jha et al., 2001; Veverka et al., 2001a; Robinson et al., 2002). The heterogeneity of the regolith depth distribution is probably caused partially by the asymmetric nature of crater ejecta blankets [a consequence of the asteroid’s rotation; see section 5 and Geissler et al. (1996)] and is further accentuated by the irregular spacing of craters and the subsequent downslope motion and regolith transport that, as discussed above, appears to occur commonly on the surface of Eros (Robinson et al., 2002).

The surface of Eros is extremely rough and the surface roughness is approximately self-affine from scales of a few meters to hundred of meters (Cheng, 2002). The regolith particles range in size from the fine (much less than centimeter-sized) dust particles found in the ponds to the numerous ( $>10^4$ ) large ( $>10$  m) ejecta blocks of boulders at the extreme large end of the particle size distribution (Thomas et al., 2002). The morphology of these blocks ranges from angular to fractured

to disaggregated (Robinson *et al.*, 2002), and their size distribution is described adequately by a power law with a slope of about  $-3$  on a cumulative plot (Fig. 3). For more information about the nature of these boulders, see the chapter by Marchi *et al.* in this volume.

## 2.2. Asteroid (25143) Itokawa

Compared to Eros, the NEA (25143) Itokawa (hereafter simply Itokawa; Fig. 1, Table 1) was found, astonishingly, to have entirely different structural and surface properties despite their similar taxonomic class. The reason for these different properties is not clearly understood, but perhaps this shouldn't have been surprising; because of their size (mass) difference, if gravity is the discriminator, then Itokawa is expected to be as different from Eros, geologically, as Eros is from the Moon (Asphaug, 2009).

One of the most remarkable features of Itokawa is the global shape, which seems to consist of two parts: a small "head" and a large "body" separated by a constricted "neck" region [Fig. 1 (Fujiwara *et al.*, 2006; Demura *et al.*, 2006)]. It is highly likely that Itokawa is a rubble-pile asteroid rather than a monolithic body (Fujiwara *et al.*, 2006). The low bulk density of Itokawa (Table 1) provides further evidence for the rubble-pile interior structure, with estimates suggesting that Itokawa's macroporosity may be as high as  $\sim 41\%$  (Fujiwara

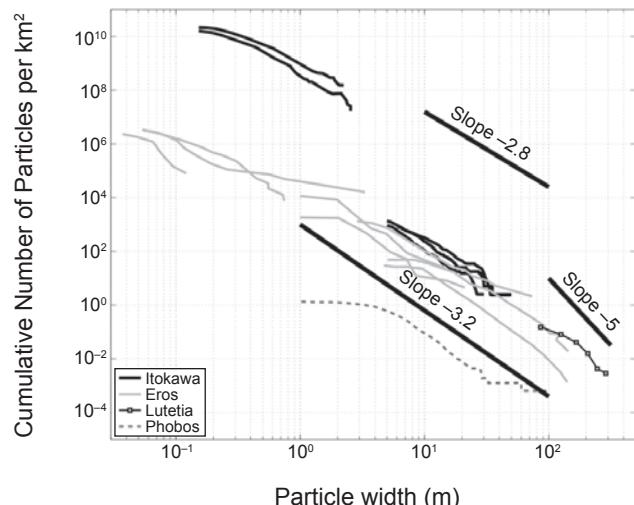

*et al.*, 2006). However, these density measurements do not rule out the presence of a core on the order of 100 m in size.

**2.2.1. Depth, character and migration of Itokawa's regolith.** Two different types of terrain — rough and smooth — are observed on Itokawa (Saito *et al.*, 2006). The rough deposits consist of numerous boulders (Fujiwara *et al.*, 2006) and typically exhibit variations in elevation that range from 2 to 4 m over small lateral distances (Barnouin-Jha *et al.*, 2008). The very highest and roughest parts of the asteroid are covered in large gravel and boulders and are completely devoid of all particles smaller than 1 cm in size (Barnouin-Jha *et al.*, 2008). The smooth terrains — Muses Sea and Sagamihara — coincide with the low-gravitational potentials and are generally homogeneous, featureless, and relatively flat (slopes  $<8^\circ$ ). This is consistent with a loose granular layer that has been allowed to seek out its minimum energy configuration after the formation of the asteroid (Miyamoto *et al.*, 2007; Fujiwara *et al.*, 2006; Yano *et al.*, 2006; Riner *et al.*, 2008). This idea is further reinforced by the close-up images and measurements taken during the touchdown of the Hayabusa spacecraft; these indicate that small regolith particles are being transported into the Muses Sea region and are gradually covering up the boulder-rich surface (Miyamoto *et al.*, 2007; Barnouin-Jha *et al.*, 2008). The regolith depth in the smooth regions on Itokawa is estimated to be approximately 2.5 m (Barnouin-Jha *et al.*, 2008; Cheng *et al.*, 2007).

In general, Itokawa's regolith appears to be dominated by grains  $>1$  mm in size (Miyamoto *et al.*, 2007). That said, the regolith particles that were returned to Earth are fine-grained [size range between 3 and 180  $\mu\text{m}$ , but most  $<10 \mu\text{m}$  (Nakamura *et al.*, 2011)]. The apparent absence, or at least the small quantity, of fines on the surface of Itokawa may be explained by processes such as electrostatic levitation combined with solar radiation pressure (Lee, 1996; Scheeres, 2005); segregation of the fines toward the interior of the body (Asphaug, 2007; Miyamoto *et al.*, 2007); or simple higher-ejection velocities following impacts, making reaccumulation difficult (Nakamura *et al.*, 1994). Some of these processes will be discussed later in sections 4 and 5.

The size distribution of boulders on Itokawa's surface is estimated to be a power law with a slope of  $-2.8$  to  $-3.0$  on a cumulative plot (Fig. 3). It is possible, however, that the observed distributions on Itokawa may be related to the preferential displacement of some block sizes relative to others, and the settling locations of differing-sized blocks. The abundance of meter-sized boulders [particularly on the western side (Fujiwara *et al.*, 2006)], and the fact that decameter-sized boulders exist [the length of the largest boulder is approximately one-tenth of the length of Itokawa itself (Saito *et al.*, 2006)], indicate that they may have been produced during a catastrophic disruption event, consistent with the rubble-pile structure (Fujiwara *et al.*, 2006; Michel *et al.*, 2001).

**2.2.2. Further evidence for an active regolith on Itokawa.** At the boundary of the Muses Sea region with the rough terrain, boulders are typically piled on top of each other without being buried by fines. The larger-sized gravels tend

**Fig. 3.** Measured cumulative size distribution as a function of particle size on the surfaces of asteroids and Phobos. Data combined from several papers. Itokawa: Miyamoto *et al.* (2007), Saito *et al.* (2006), Michikami *et al.* (2008), Mazrouei *et al.* (2012); Eros: Thomas *et al.* (2001); Lutetia: Küppers *et al.* (2012); Phobos (a martian satellite with a mean diameter of  $\sim 22$  km): Thomas *et al.* (2002). For the papers in which the cumulative number of particles was given, this has been approximately converted to cumulative number per square kilometer using the information provided in the respective papers. A shallower slope may indicate that boulders have experienced less processing, including breaking, sorting, and transporting (Thomas *et al.*, 2002).

to overlie the smaller particles and are aligned with directions coincident with the local gravity slope (*Miyamoto et al.*, 2007). This type of organization of gravels is referred to as imbrications, in this case with the longest axes of the gravel being preferentially orientated transverse to the granular flow. The positions and orientations of all the particles indicate that they are stable against local gravity and that the migrations were gravity-induced (*Miyamoto et al.*, 2007).

Evidence of landslide-like deposits can be seen in Fig. 4. There are large boulders that have blocked the migration of smaller particles, resulting in piles of smaller particles on the uphill sides of the boulders (*Miyamoto et al.*, 2007). Unlike the surface of Eros, Itokawa is very heterogeneous in color and albedo, with brighter surfaces being found in three main areas: areas with steeper slopes; areas of local high terrain; and apparently eroded areas, e.g., crater rims (*Saito et al.*, 2006). *Saito et al.* (2006) suggest that this dichotomy is due to dark surfaces being removed, leaving the fresh regolith newly exposed at the surface, as observed on Eros.

All these observations provide a strong indication that regolith on the surface of Itokawa has been relocated since the initial accumulation or deposition.

**2.2.3. Craters and crater morphology on Itokawa.** Itokawa has very few craters in general (the total number of craters on Itokawa is <100 over the entire surface, including indefinite candidates) and absolutely no distinct craters <1 m in diameter (*Saito et al.*, 2006; *Fujiwara et al.*, 2006). Those craters that do exist on the rough and transitional terrains, and that retain their regolith, are filled with finer particles, similar to the “ponds” seen on Eros. The best example of a crater on the surface of Eros — Komaba — is located near the edge of the highlands. It has a small depth-to-diameter ratio

(0.09) consistent with crater formation in a coarse granular target, a flat floor, and is surrounded by brighter rims (*Saito et al.*, 2006; *Barnouin-Jha et al.*, 2008). In addition, there appears, unusually, to be no apparent correlation between the locations of boulders and craters (*Michikami et al.*, 2008). These observations are further evidence of regolith motion and suggest that a mechanism is filling in and erasing the craters on the surface of Itokawa. Such a mechanism may well be seismic shaking, as proposed to explain the paucity of small craters on Eros (see section 5). Alternatively, it is also possible that Itokawa could have been generated relatively recently in the main belt before being moved to its current orbit (*Saito et al.*, 2006).

**2.2.4. Linear features on Itokawa.** Unlike Eros, there are no global lineaments on Itokawa (*Fujiwara et al.*, 2006). However, on the body of Itokawa, subtle local linear features can be observed. These features, caused by the alignment of boulders (*Cheng et al.*, 2007), are not as tall as other structures such as large boulders. Nonetheless, they are an important contributor to the topography of Itokawa due to their large lateral extent (*Barnouin-Jha et al.*, 2008).

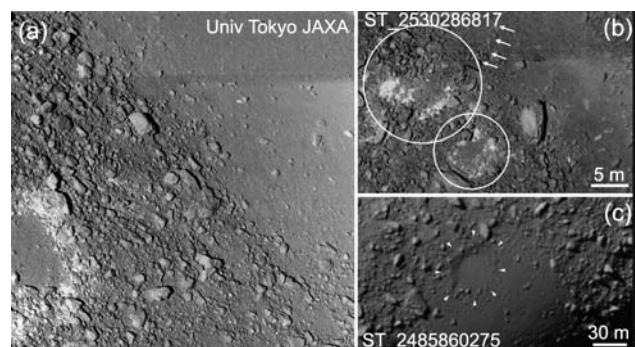

### 2.3. Asteroid (21) Lutetia

The main-belt asteroid (21) Lutetia (hereafter simply Lutetia; Fig. 1, Table 1) has a highly complex surface geology with significant interactions between ancient and more recent structures (*Sierks et al.*, 2011; *Thomas et al.*, 2012).

**2.3.1. Craters and crater morphology on Lutetia.** The higher gravity and escape velocity on Lutetia have provided an environment for continuous ejecta patterns with obvious relations to the impact from which they formed (*Massironi et al.*, 2012). The typical depth-to-diameter ratio of craters on Lutetia is 0.12, but values have been observed ranging from 0.05 to 0.3 (*Vincent et al.*, 2012). The distribution of depth-to-diameter ratios varies depending on the region of Lutetia’s surface, indicating that not only are there variations of physical properties across the surface, but there are also differences in the surface evolutionary processes (*Vincent et al.*, 2012).

*Thomas et al.* (2012) divide the craters on Lutetia into four different categories: standard craters, buried or partially filled craters, distorted or cut craters that have been disturbed by lineament formation, and morphologically nonstandard impact structures. By the latter they refer to craters that are not typically bowl-shaped and/or do not have a round rim, and the strange form is not obviously linked to linear features. Such unusually shaped craters (for examples, see *Thomas et al.*, 2012) could be the result of oblique impacts (*Thomas et al.*, 2012; *Herrick and Hessen*, 2006; *Krohn et al.*, 2014), but other mechanisms have also been proposed (*Vincent et al.*, 2012).

Similarly to the surface of Eros, Lutetia’s surface exhibits a paucity of small (<1 km) craters. This could perhaps be explained by seismic shaking; however, there is also a depletion in craters of sizes up to 8 km, which is more difficult to attribute to seismic shaking. The craters that have been deformed by linear features are additional evidence that the

**Fig. 4.** Evidence of regolith transport on Itokawa. **(a)** High-resolution image of the boundary area between Muses Sea and the rough terrains. Piles of gravel can be seen on the uphill sides of boulders. Such a characteristic is similar to terrestrial landslides. **(b)** Image of the “neck” area of Itokawa (13 cm/pixel) showing piles of angular boulders at the lower part of the image. Crater-like depressions are shown by the circles and the arrows indicate the debris, which appears to have drained from the rim of the upper crater toward the smooth terrain. **(c)** A circular depression that appears to be filled with finer particles.

surface has been modified since the crater formation (*Sierks et al.*, 2011).

**2.3.2. Depth and character of Lutetia's regolith.** The surface of Lutetia is covered by an extensive regolith, similar to that of the Moon (*Coradini et al.*, 2011). Nonetheless, Lutetia's surface is very heterogeneous. Images taken during the close approach of the European Space Agency's (ESA) Rosetta spacecraft allowed Lutetia's surface to be separated into several distinct regions [for a detailed map of the Lutetia regions, see *Sierks et al.* (2011) and *Massironi et al.* (2012)]. Some regions are very old and heavily cratered with significant deformation by linear features, while others exhibit sharp morphological boundaries. The Baetica (north pole) region contains a cluster of craters, created from a series of superposed impacts (*Massironi et al.*, 2012); this is one of the most prominent features imaged on Lutetia's surface. The extremely low crater density and lack of linear features in this region can perhaps be attributed to the covering of smooth regolith material, probably the ejecta blanket from the crater cluster (*Sierks et al.*, 2011; *Vincent et al.*, 2012).

Lutetia's regolith is estimated to be up to ~600 m in depth (*Vincent et al.*, 2012). This estimate is based on the thickness of the ejecta blanket of the largest crater assuming a uniform gravity field, and may therefore be improved with a more detailed study of regional ejecta geophysics, taking into account the complex gravitational field of Lutetia. Surface slopes can exceed 30° in some places but are generally less than this (*Sierks et al.*, 2011; *Thomas et al.*, 2012). The size distribution of blocks on Lutetia is reported to be a steep power law of -5 (Fig. 3) (*Küppers et al.*, 2012). It is noted, however, that the method used by Küppers et al. for binning the boulders is different to the method used by other research groups.

**2.3.3. Evidence for an active regolith on Lutetia.** Diverse evidence for regolith motion was observed inside the large crater cluster in the Baetica region. The observations include albedo variations with bright regions on the steep slopes indicative of relatively recent landslides (as observed inside craters on Eros and on Itokawa), deposits of smooth and fine particles with boulders, and apparent landslide deposits (*Sierks et al.*, 2011). In addition, observations show craters that have poorly defined rims as a consequence of multiple landslides (e.g., Fig. 5 of *Thomas et al.*, 2012). Rocky outcrops are also visible at what appears to be the source of the landslides (*Thomas et al.*, 2012).

**2.3.4. Linear features on Lutetia.** Lutetia displays a huge number of lineaments (e.g., Fig. 5) that can be found over the entire imaged surface, with the exception of two young regions (*Thomas et al.*, 2012). The orientation of these linear features, which are similar in appearance to those on Eros discussed in section 2.1, has been linked to three impact craters (*Besse et al.*, 2014). The linear structures have been classified into several types by *Thomas et al.* (2012): irregular troughs, large faults and tectonic troughs, organized linear reflectance variations and narrow faults, rows of coalesced pits (known as pit-chains), intracrater trenches, intracrater layers and ejecta layers, and finally scarps and ridges. The

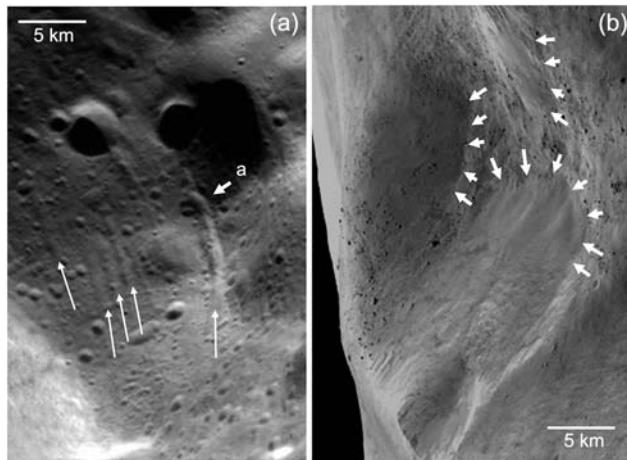

most striking linear feature on Lutetia's surface is the very long (~10 km) and wide (~1.2 km maximum width) groove in the Noricum region (*Thomas et al.*, 2012). This groove is situated on a local topographic high and is approximately 100 m in depth (*Sierks et al.*, 2011). For a complete discussion of the lineaments on Lutetia, including multiple examples, see *Thomas et al.* (2012).

## 2.4. Asteroid (4) Vesta

(4) Vesta (hereafter simply Vesta; Fig. 1, Table 1) is the second most massive main-belt asteroid and is one of the fastest rotators of the large asteroids. Vesta's surface has a complex topography at all spatial scales (*Jaumann et al.*, 2012). One of the most dramatic discoveries on the surface of Vesta is an 18-km-high mountain in the center of a huge (460-km-wide) crater named the Rheasilvia basin. This peak is the second highest in the solar system after Olympus Mons on Mars.

**2.4.1. Depth and character of Vesta's regolith.** The thickness of Vesta's regolith is estimated to be approximately 800 m (*Jaumann et al.*, 2012). The surface slopes on Vesta can exceed 40° and there are a considerable number of steep slopes that may be indicative of intact bedrock beneath or the presence of cohesive forces in the regolith. Dark materials, of likely exogenic origin (carbon-rich low-speed impactors), are distributed unevenly across Vesta's surface [(Fig. 6a (*Jaumann et al.*, 2014))].

**2.4.2. Craters and crater morphology on Vesta.** Craters on Vesta display a wide range of degradation states, from fresh craters with unmodified rims to impact crater ruins showing almost no visible rims (*Jaumann et al.*, 2012).

**Fig. 5.** Closeup images of Lutetia. **(a)** Curvilinear features. Some linear features cut crater rims (arrow labeled "a"), implying that these features post-date the craters (ID 224598, ESA 2010 MPS for OSIRIS Team MPS/UPD/LAM/IAA/RSSD/INTA/UPM/DASP/IDA). **(b)** The central crater cluster in Baetica showing landslides (arrows) and numerous boulders (ID 216820, ESA 2010 MPS for OSIRIS Team MPS/UPD/LAM/IAA/RSSD/INTA/UPM/DASP/IDA).

Depth-to-diameter ratios are similar to Lutetia, varying from 0.05 to 0.4 with a mean of 0.17 (Jaumann et al., 2012; Vincent et al., 2012, 2013). The northern hemisphere is observed to be heavily cratered, whereas the southern hemisphere shows comparatively fewer craters, most probably due to the relatively recent basin-forming impacts near the south pole (Vincent et al., 2013). Shallower craters are found in the oldest regions on the surface of Vesta, as would be expected due to progressive crater degradation. The deep, loose regolith in the younger southern hemisphere may also aid the formation of deeper craters (Vincent et al., 2013).

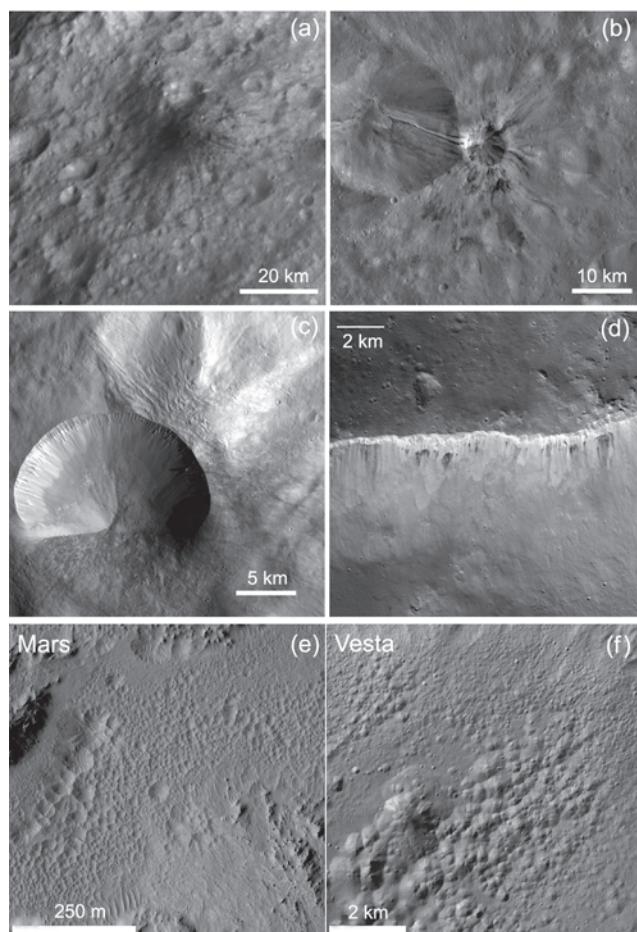

Topography plays a much more important role in crater formation and evolution on small bodies and moons than on terrestrial planets. For example, Vesta's ratio of observed relief to size [15% (Williams et al., 2013)] is significantly greater than for terrestrial planets [1% (Jaumann et al., 2012)]. Strongly asymmetric craters have been seen on the many steep surfaces of Vesta (Fig. 6c). During impacts on

steep slopes, ejecta is prevented from being deposited in the uphill direction and slumping material superimposes the deposit of ejecta on the downhill side (Krohn et al., 2014). This leads to craters with a smoothed downslope rim that is often covered by the asymmetric ejecta (Jaumann et al., 2012). Resurfacing due to impacts, gravitational modifications, and seismic shaking are important geophysical processes that not only add to the complexity of Vesta's surface evolution, but also substantially alter Vesta's morphology (Jaumann et al., 2012). Young bright and dark-rayed craters and their ejecta field are superposed across the surface of Vesta (Fig. 6b) (Williams et al., 2014; Yingst et al., 2014). Pond-like deposits are also seen on the surface of Vesta. Similarly to those on Eros, they tend to have a downslope asymmetry within craters on slopes, and show no evidence for regolith flows into the craters and depressions (Jaumann et al., 2012; Cheng et al., 2002b). However, given the more important gravity on Vesta (compared to Eros) and the larger size of such pond-like features, their formation may simply be due to standard crater slumping, rather than a process by which external material is transported into the crater.

**2.4.3. Evidence for an active regolith on Vesta.** As on the surfaces of the other asteroids discussed so far, extensive evidence of regolith mobility has been observed on Vesta; slumps of material, scarps beginning at the top of a slope, and dark and bright material emanating from the rims or walls of impact craters or running downslope into the crater bowl (Fig. 6d) (Jaumann et al., 2012; Williams et al., 2013; Yingst et al., 2014). Lobate, flow-like features are generally observed in close proximity to impact craters or in steep slopes (Williams et al., 2013). These features are interpreted as gravity-driven mass flow deposits, impact ejecta deposits, or, for a small number of features, impact melt deposits (Jaumann et al., 2012; Williams et al., 2013).

On Vesta, the seismic shaking created by the giant basin-forming impacts probably contributed to smoothing and erasure of small features well beyond the extent of the ejecta blankets (Vincent et al., 2013). Mixing of regolith materials (e.g., the dark exogenic materials with impact ejecta) is evident on Vesta's surface (Jaumann et al., 2014; Pieters et al., 2012). There is also a dearth of large-scale volcanic features on the surface of Vesta, compared to what was expected (e.g., Wilson and Keil, 1996; McSween et al., 2011). Jaumann et al. (2012) suggest that the lack of such features may be due to extensive cratering, regolith formation, and resurfacing that has removed the evidence of large-scale volcanism that ceased early in Vesta's history (Williams et al., 2013; Jaumann et al., 2012). This will be discussed further in section 5.

**2.4.4. Linear features on Vesta.** Large equatorial and northern troughs appear on Vesta's surface (Fig. 1). The equatorial troughs are wide, flat-floored, and bounded by steep scarps along ~240° of longitude, while in the remaining longitude muted troughs, grooves, and pit crater chains are evident (Jaumann et al., 2012). The northern troughs display gentler slopes, rounded edges, and considerable infilling. This, combined with the heavy cratering, suggests that they

**Fig. 6.** Surface processes on Vesta. (a) Dark hill (PIA14689, modified). (b) Fresh crater (center) with bright and dark rays (PIA15045, modified). (c) Crater on a slope with a sharp crest uphill and slumping material covering the lower rim (PIA15495). (d) Dark and bright material at the rim of Marcia crater (NASA/JPL-Caltech/UCLA/MPS/DLR/IDA/LPI/ASU). (e) Pitted terrains on Mars (PIA16185, modified). (f) Pitted terrains on Vesta (PIA16185, modified).

are much older than the equatorial troughs (*Jaumann et al.*, 2012). The center positions of these circular troughs correspond to the center of Vesta's two southern basins, indicating that the formation of the troughs and the basins are very likely related (see Fig. 2 of *Jaumann et al.*, 2012).

### 3. AN INTRODUCTION TO GRANULAR MATTER

Granular materials are unlike solids in that they can conform to the shape of the vessel containing them, thereby exhibiting fluid-like characteristics. On the other hand, they cannot be considered a fluid, as they can be heaped (*Gudhe et al.*, 1994). The study of granular dynamics is incredibly complex and constitutes an entire field of research by itself. In fact, P. G. De Gennes, a French physicist and Nobel Prize laureate, said that, “*For physicists, granular matter is a new type of condensed matter; as fundamental as liquid, or solid; and showing in fact two states: one liquid-like, one solid-like. But, there is yet no consensus on the description of these two states. Granular matter, in 1998, is at the level of solid state physics in 1930*” (*de Gennes*, 1999). This is not to say that granular matter has not been studied; ancient Egyptians did indeed know how to work with it, at least at an empirical level (*Fall et al.*, 2014); Ernst Chladni (*Chladni*, 1787) and Michael Faraday (*Faraday*, 1831) studied the interaction of grains and fluids; and researchers in the field of geosciences have also long dealt with its complexities on the surface of Earth.

On Earth, we can observe granular materials involved in dramatic avalanches and rockslides, as well as active sand dunes moving across deserts. Industries also handle several different types of granular materials. Some examples are tablets or powders in the pharmaceutical trades as well as agricultural products such as wheat, oats, rice, and other cereals and sands in the construction industry. Theoretical models of granular dynamics are also widely employed to understand traffic flow and even crowd dynamics.

#### 3.1. What is Granular Material?

The term granular material is most often used to describe a material containing a large number of particles that interact with each other through dissipative contact forces (*Richard et al.*, 2005; *Jaeger et al.*, 1996). In these aggregates, although each individual grain can be adequately described by Newtonian physics, a collection of grains offers complex behavior that is often extremely sensitive to external conditions (such as external forcing). Granular material is a material for which the relevant energy scale is the potential energy rather than the thermal energy; i.e., particles in granular material are massive enough for their potential energy to be orders of magnitude larger than their thermal energy (*Schroter et al.*, 2005). For example, a typical grain of sand of mass  $m$ , raised by its own diameter  $d$ , in Earth's gravity,  $g$ , will have potential energy,  $mgd$ , that is at least  $10^{12}$  times the thermal energy  $k_B T$  at room temperature on Earth (*Jaeger et al.*, 1996).

The size of the constituent particles is closely linked to the type of interactions between the particles that will dominate the behavior of the aggregate. On Earth the approximate size at which dissipative contact interactions dominate is 100  $\mu\text{m}$ ; at grain sizes  $<100 \mu\text{m}$ , humidity and van der Waals forces will influence the particle interactions. Additionally, if present, interstitial fluid will also influence the dynamics of the grains depending on the density of the fluid and the grain size (*Burtally et al.*, 2002; *Biswas et al.*, 2003). We will discuss in section 4 how the importance of some of these forces changes in the low-gravity environment of an asteroid.

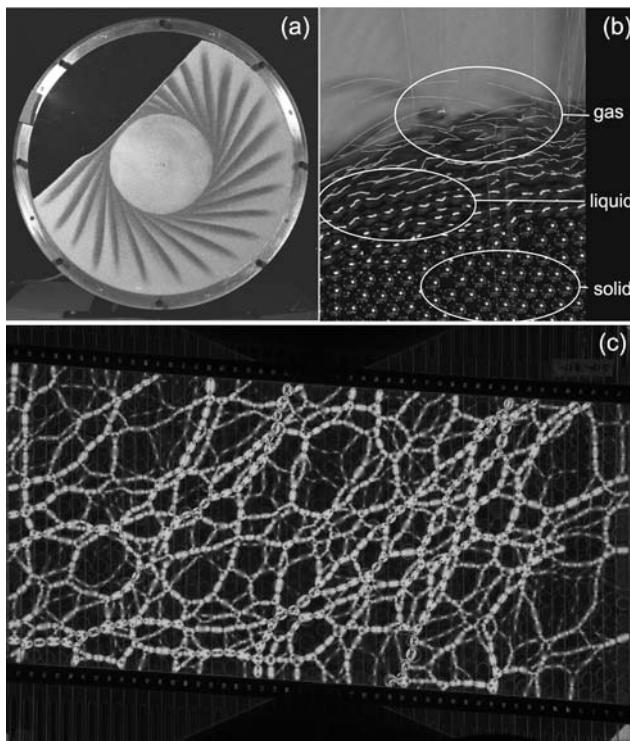

#### 3.2. Basic Characteristics of Granular Material

Granular materials exhibit several characteristics that make them interesting but equally very difficult to model and understand. From the definitions presented above, some characteristics can be extracted, while others come from observation: (1) the grains that form a granular material are solid; (2) grain-grain interactions are highly dissipative; (3) potential energy, more than temperature, of the system is the relevant parameter; (4) granular materials are thixotropic, meaning they exhibit solid-, liquid-, and gas-like behavior; and (5) friction, globally understood to be a combination of surface-surface friction and geometrical interlocking that prevents motion, makes aggregates able to sustain shear stress and contribute to the dissipative nature of grain-grain interactions.

From these basic characteristics, some phenomena result. For example, Fig. 7b shows the solid-, liquid-, and gas-flow regimes obtained in an avalanche-like situation. In a solid-like state, such as a heap or pile, the material is said to be “quasistatic” as the individual particles are in a stable mechanical equilibrium with their local neighbors. In the liquid-like and gas-like states, the material is said to “flow.” Dense flows (liquid-like state) are dominated by many-body interactions and occur when particles have long-lived contacts with many neighbors. In rapid or dilute flows (the gas-like state) there are no enduring contacts and the collision time is much smaller than the time between collisions [*Andreotti et al.* (2013) provide a thorough exposition of these topics].

Flowing granular materials can segregate according to particle properties (size, density, shape, and more), making granular media highly heterogeneous (Fig. 7a). The phenomenon of segregation is a continued source of frustration for industries (*McCarthy*, 2009); however, segregation may help us to explain several geological features observed on the surface of asteroids and discussed at the beginning of this chapter.

The final, but very important, property of granular materials is the nonlinear transmission of force between particles via force chains. A force acting on a granular material is distributed through a complex force distribution network that depends on the positioning and packing of the individual particles. This grain network resists reorganization when stressed and imposes a granular drag force when a solid object is pushed through the material (*Costantino et al.*,

**Fig. 7.** (a) Segregation of particles in a tumbler. The large sugar crystals (white) and small iron particles (black) segregate in the tumbler as described in Gray and Chugunov (2006). Credit: N. Gray, University of Manchester. (b) Solid, liquid or gas? An illustration of the solid- (bottom), liquid- (middle), and gas- (top) flow regimes obtained by pouring steel beads on a pile. Credit: O. Pouliquen and Y. Forterre. (c) Force chains in a granular material. Photoelastic image of a system that has been jammed by applying simple shear strain from an initially force-free state. The apparatus used here applies shear from the boundaries and also from the base, which consists of individual slats that deform affinely with the boundary. Credit: J. Ren and R. P. Behringer, Duke University.

2008). Figure 7c shows the force chains inside a granular material. The presence of force chains can induce complex stresses at the sides of grain silos (Schwartz et al., 2012), preventing explosions at the bottom and instead leading to ruptures at the sides (Janssen, 1895; Jaeger et al., 1996). This can be linked to the nonlocal effects granular materials exhibit (Nichol et al., 2010) and may even cause asteroids to experience long-range consequences of small events such as meteoroid impacts (Murdoch et al., 2013b).

### 3.3. Theoretical Framework

As shown above, granular matter can present solid-, liquid-, and gas-like behaviors, all at the same time. Although a complete theory to describe each behavior simultaneously has yet to be proposed (e.g., Jop et al., 2006; GDR-MiDi, 2004), different regimes (or states) can be modeled within certain frameworks. Depending on which of these theo-

retical frameworks is best suited to the regime at hand, the properties of the grains will be described by different sets of parameters, e.g., friction, elastic moduli, viscosity, and restitution coefficients among others.

The elasticity-perfect plasticity models can be used for the static case (e.g., Holsapple, 2004; Holsapple and Michel, 2006). These models belong to the field of continuum mechanics and, as the name would suggest, they treat a granular media as continuous. This can be done under one assumption: the size of the grains that form the media (or soil) are very small compared with the typical length scale or size of the sample. The dynamics of the media is modeled through yield criteria such as Mohr-Coulomb or Drucker-Prager, in which the main parameters are angle of friction and cohesive strength. The pressure and shear stress (both derived from the principal stresses of the stress tensor) define the stress state of the media and are average quantities that in reality result from the contacts between particles and the interactions between their surfaces.

Fluid mechanics equations are used for dense flows, or for when grains begin to flow like a liquid (e.g., Haff, 1983; Forterre and Pouliquen, 2008). Within this framework, the dynamics of the medium is described through a continuity equation, derived from the conservation of mass principle; a momentum equation, derived from the conservation of momentum principle (in the case of granular materials, a description of viscosity must be included); an energy equation, derived from the conservation of energy principle; and an equation of state relating the three conservation equations.

Kinetic theory (e.g., Jenkins and Zhang, 2002; Brilliantov and Pöschel, 2010), used for dilute, highly dynamical (gas-like) systems, makes the assumption that the particles only have binary collisions. Of course, in a real system this is not the case, as multi-particle collisions may also occur; however, they are determined to be too rare to be taken into account. The validity of the assumption is related to the density of the granular system (must be safely below the jamming density) and the duration of the collisions (must be short in order to avoid the occurrence of three or more particles in simultaneous contact). Thus, the particles of this system are idealized as hard spheres (instantaneous collisions). In this particular regime, the concept of granular temperature can be defined. A “granular temperature” can be defined in multiple ways, but essentially it is some measure of the average of energy fluctuations exhibited by a collection of grains. An example of one such definition, for a collection of  $N$  grains of average velocity  $\bar{v}$  and average spin  $\bar{\omega}$ , with each grain having a mass  $m_i$ , velocity  $v_i$ , moment of inertia  $I_i$ , and spin  $\omega_i$ , the granular temperature may be defined as

$$T_g = \frac{1}{2Nk_B} \sum_{i=1}^N \left( m_i |\mathbf{v}_i - \bar{\mathbf{v}}|^2 + I_i |\boldsymbol{\omega}_i - \bar{\boldsymbol{\omega}}|^2 \right) \quad (1)$$

This quantity does not include, but is analogous to, the thermodynamic temperature (Walton and Braun, 1986). One important difference between a granular gas and a molecular gas is the inelastic nature of the collisions of the former, which

leads to clumping and effectively serves to distinguish the behavior of granular material.

#### 4. THE ASTEROID SURFACE ENVIRONMENT

By now it should be clear that asteroid surfaces are formed by regolith of various shapes, sizes, materials, and, therefore, material properties. In a granular aggregate, these material properties are intrinsically related to the size and shape of the grains, their atomic and electronic structure, and the gravitational field to which they are subjected, to mention the most important factors. These properties will also play a role in how asteroid surfaces, and asteroids as a whole, react to external agents such as gravitational fields of other planetary bodies, solar radiation pressure [the Yarkovsky and Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) effects, particle transport, and levitation] or impacts. In what follows, we will explore these aspects of the surfaces of asteroids. Note that SI units should be assumed in all expressions in this section.

##### 4.1. Surface Characterization

**4.1.1. Materials.** Different mineral compounds form the regolith that is present in asteroid surfaces; they provide their spectral, thermal, and some mechanical characteristics. The first two are obvious as they have to do with the absorption, transmission, and reemission of energy (*Masiero et al.*, 2009); the third comes from how regolith is formed, as that would be a reflection of the hardness of the material, the crystalline structure, and forces between the surfaces of grains in contact (adhesion, cohesion, and friction).

At the moment, what is known about the materials that make up asteroids comes from the meteorites that have crashed on Earth, from spectral observations, and, more recently, from the samples returned from asteroid Itokawa by the Hayabusa mission. Through the research carried out on the available samples, it has been found that asteroids are formed mainly by pyroxene, olivine, plagioclase, and iron compounds. These materials have crystalline structures, and their detailed study belongs to the field of solid-state physics or condensed-matter physics.

**4.1.2. Observed regolith characteristics.** Section 2 has already summarized the main observations and interpretations made about the slopes and grain size distributions on asteroid surfaces.

**4.1.3. Surface gravity.** Up to this point, in the description and characterization of the surface regolith of asteroids, there are no big differences from what can be found on Earth. However, it is here where the similarities end, as one of the most important factors affecting the dynamics of the regolith on asteroids is the ambient gravity, i.e., the sum of the local gravitational field and centrifugal forces due to the rotation of the asteroid. The calculated surface gravity of asteroids such as Itokawa and 1999 KW<sub>4</sub> can be found in the chapters by Yoshikawa et al. and Scheeres et al. in this volume, *Scheeres et al.* (2010), and *Hartzell and Scheeres* (2013).

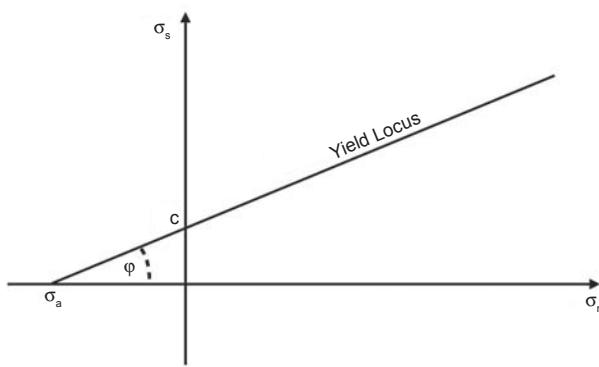

These surface gravity calculations show some important features that are not common in our terrestrial experience: (1) gravity is 10<sup>3</sup>–10<sup>6</sup> times smaller than Earth's gravitational field, g; (2) the gravitational field is not always perpendicular to the terrain; and (3) relatively small displacements on the surface of a small body could mean big changes in the gravitational field. Among the main implications are that escape speeds are in the order of centimeters per second, micrometeoroid impacts could transfer enough energy to generate surface or even global changes, and stepping or landing on one of these aggregates could generate an ejecta field that could damage the instruments of a spacecraft or generate a local avalanche.

**4.1.4. Friction.** Intuitively, the idea of friction is that of a force that resists the relative motion of two bodies that are in contact. This resistance may appear in various ways; the work carried out by *Bowden and Leben* (1939), *Bowden and Tabor* (1939), and *Bowden et al.* (1943) and later summarized by *Rao et al.* (2008) suggested that asperities or projections on the surfaces of the bodies adhere to form junctions. Therefore work must be done to deform and break these junctions, and this is accompanied by wear or erosion of material in the interfacial region. Additional work is associated with the deformation of the material in a larger region near the interface (plowing).

The first attempt to formulate a macroscopic friction coefficient is attributed to *Coulomb* (1776), who equated it to the tangent of the angle of repose, by defining it to be the ratio of shear and normal stresses on an inclined pile of sand. The seminal work of *Bagnold* (1954, 1966) found that the frictional force varied as the square of the shear rate for grain-inertial flow in the regime of rapid shear. On the other hand, *GDR-MiDi* (2004) made it clear that the rheological properties of granular flows (friction, viscosity) depend on the shear rate, i.e., on the dynamics, thus putting the work of Bagnold and collaborators into context.

*Mehta* (2007) recognizes that the proper microscopic formulation of intergrain friction remains an outstanding theoretical problem. In a granular material, it is not only the grain-grain surface friction that will determine the resistance of a grain to movement, or the resistance of the aggregate to be sheared and deform, but also the grains' shapes, geometrical interlocking, packing, and size distribution; all these factors are usually pulled together in a single term: the angle of (internal) friction that appears in the Mohr-Coulomb or Drucker-Prager yield criteria.

Within the Mohr-Coulomb yield criterion, the angle of internal friction is defined as the arctangent of the ratio of shear to normal compressive stress at the stability limit (see Fig. 8). The Mohr-Coulomb criterion prescribes that shearing along any plane in a granular material cannot occur unless the shear stress ( $\sigma_s$ ) on that plane reaches a value proportional to the normal (compressive) stress on that plane:  $\sigma_s = \mu\sigma_n$ . The proportionality constant  $\mu$ , the friction coefficient, is written as the tangent of the friction angle  $\phi$ :  $\mu = \tan(\phi)$ . Thus, the friction angle is a material property. The Drucker-Prager criterion is based on similar physical ideas, but uses a linear

**Fig. 8.** Mohr-Coulomb yield criterion: normal stress ( $\sigma_n$ ), shear stress ( $\sigma_s$ ), cohesive strength (c), tensile strength ( $\sigma_a$ ), and friction angle ( $\varphi$ ).

dependence of an average shear stress, as measured by the  $J_2$  stress invariant, on the pressure (Holsapple, 2013; Chen and Han, 1988). Theoretically, if a material is cohesionless, the angle of repose corresponds to the angle of internal friction. On the other hand, for a cohesive aggregate, the angle of repose has to be such that is related to the cohesive strength of the material [see Nedderman (2005) for an indepth explanation].

Cohesive forces (electrostatic and van der Waals are among the best known interactions) are kept in a different term and, within either criteria, do not affect the angle of friction, but only the angle of repose. Figure 8 shows the relation between the normal stress ( $\sigma_n$ ), shear stress ( $\sigma_s$ ), cohesive strength (c), tensile strength ( $\sigma_a$ ), and friction angle ( $\varphi$ ). If cohesive strength is defined as the shear stress at zero normal stress, then tensile strength is the normal stress at zero shear stress.

On Earth, a well-known experimental fact is that angles of internal friction of cohesionless granular materials vary from  $25^\circ$  for smooth spherical particles to  $45^\circ$  for rough angular particles (Carryg, 1970; Pohlman et al., 2006; Kleinhans et al., 2011). Calculations made on asteroids Eros and Ida and martian satellites Phobos and Deimos show that only Ida has more than 2% (by area) of gravitational slopes above typical repose angles ( $35^\circ$ ). At this point it is worth explaining that the static angle of repose is the maximum slope that can be supported before the formation of an avalanche, and a dynamic angle of repose is the slope that results after this avalanche has taken place. The maximum angle of stability, critical angle, and static angle of repose are the same; angle of repose and dynamic angle of repose are also the same. The static angle of repose may be related to cohesive forces, including van der Waals forces, electrostatic forces, and capillary forces in the case of microscopic fluid pockets between the particles. Using a parabolic flight experiment, Kleinhans et al. (2011) concluded that for decreasing gravity, the static angle of repose increased while the dynamic angle of repose decreased for all tested materials.

**4.1.5. Electrostatic forces and cohesion.** As mentioned before, any kind of cohesive force between the grains of

an aggregate is going to increase the value of its angle of repose. This includes van der Waals, capillary, electrostatic, and magnetic forces. The effects of these cohesive forces can be clearly seen in powders on Earth (flour, toner, pollen, and chalk are common examples). How they appear and when they are apparent in the behavior of granular aggregates will be discussed in the next sections.

## 4.2. Cohesive and Adhesive Forces

Cohesive and adhesive forces have the same origin, the only difference being that the term cohesive applies to the attractive force between molecules of the same material and the term adhesive applies to molecules of different materials. For example, liquid water molecules attract one another and form water droplets with surface tension (this is cohesion); water molecules and silica molecules also attract one another and water can make a glass wet (this is adhesion). These attractive forces are electromagnetic in nature and are appreciable when the electronic clouds of the atoms that form the surfaces of two bodies are within a few angstroms. The term van der Waals forces is used here very loosely and refers to the totality of nonspecific attractive or repulsive intermolecular forces other than those responsible for ionic and covalent molecular bonds (McNaught and Wilkinson, 1997). These interactions are often modeled by the Lennard-Jones potential (Jones, 1924)

$$V_{LJ} = 4\epsilon \left[ \left( \frac{\gamma}{r} \right)^{12} - \left( \frac{\gamma}{r} \right)^6 \right] \quad (2)$$

where  $\epsilon$  is the depth of the potential well,  $\gamma$  is the finite distance at which the interparticle potential is zero, and  $r$  is the distance between the two particles (neutral atoms or molecules). Although other, more accurate forms of the potential exist, this one is usually used in computer simulations due to its simplicity. The  $r^{-12}$  term describes the Pauli exclusion principle due to overlapping electron orbitals and the  $r^{-6}$  term describes the long-range attraction (van der Waals force, or dispersion force).

Johnson et al. (1971), Heim et al. (1999), and Hughes et al. (2008) theoretically and experimentally studied the characteristics of the van der Waals force in granular materials. The cohesion between two spherical particles (radii  $r_1$  and  $r_2$ ) can be approximately described by (Castellanos, 2005; Perko et al., 2001; Rognon et al., 2008)

$$F_c = \frac{A}{48(t+d)^2} \frac{r_1 r_2}{r_1 + r_2} \quad (3)$$

where  $A$  is the Hamaker constant for the grains ( $4.3 \times 10^{-20}$  J for lunar soil),  $t$  is the minimum distance between the particle surfaces due to adsorbed molecules, and  $d$  is the width of any additional separation between the particles beyond that caused by the presence of the adsorbed molecules. In the extreme environment of space, the minimum distance between the materials can be much closer than possible on

Earth, where atmospheric gases, water vapor, and relatively low temperatures allow for significant contamination of surfaces ( $d = 0$ ). These much cleaner surfaces and closer contacts allow for increased cohesion (Perko *et al.*, 2001; Scheeres *et al.*, 2010).

Perko *et al.* (2001) define a cleanliness factor  $S$  as  $\Omega/t$ , where  $\Omega$  is the diameter of an oxygen ion ( $O^{2-}$ ) and  $t$  is defined as above. This being so, the cohesive force between a grain (radius,  $r$ ) and a flat surface (or a much larger grain) is

$$F_c = \frac{AS^2}{48\Omega^2} r \quad (4)$$

### 4.3. Electrostatic Forces

Electrostatic forces have been hypothesized to play an important role on the surfaces of asteroids, and have been specifically invoked as one means by which small dust grains can be transported across a body's surface. The first evidence of electrostatic lofting was the lunar horizon glow observed by the Surveyor spacecraft (Rennison and Criswell, 1974) at the terminator region. A second discovery contributing to this hypothesis was the existence of ponds on Eros and other asteroids, even though it has been found that their apparent distribution could have an observational bias. Finally, there is also the fact that the Hayabusa mission was able to bring back samples of grains from asteroid Itokawa despite the malfunctioning of the sampling mechanism (Yano *et al.*, 2006). It has been proposed that the electrostatic interaction between charged particles and a possibly charged sampler horn helped collect the sample (Tsuchiyama *et al.*, 2011). Whether or not dust levitation occurs on asteroids is still an open question, although it is undoubttable that surface grains on these bodies are subject to electrostatic forces. Unfortunately, as of yet, this is still not fully understood.

The electrostatic force felt by a particle on the surface of an asteroid is related to its location on the surface. The charge density at any point on the surface is the result of the difference between the number of electrons that are deposited on it by the solar wind and those that leave the surface due to photoemission. These two vary with the location of the surface and with time as the asteroid rotates and solar wind influences different areas of the surface. Photoemission and solar wind interaction depend on the solar incidence angle and a variety of plasma-related phenomena that vary with solar longitude, respectively. The resulting charge on the surface of the asteroid then influences the charging of the particle in question and influences the plasma environment (photoelectron and plasma sheaths) that will be experienced by the particle if it is lofted above the asteroid's surface (Scheeres *et al.*, 2010).

If grains are idealized as spherical, and we make the same assumptions as Colwell *et al.* (2005) about the plasma sheet, it is then possible to demonstrate that for a particle of radius  $r$  (surface area,  $\Lambda = 4\pi r^2$ ), the electrostatic force that would provide lofting is:

$$F_{es} = \epsilon_0 E^2 \Lambda \approx 4\pi\epsilon_0 E^2 r^2 \Rightarrow F_{es} \approx 9 \times 10^{-9} r^2 \quad (5)$$

where  $\epsilon_0$  is the permittivity of vacuum and  $E$  is the electric field.

Recent theoretical analysis and experiments have shown that cohesion will play a role in dust levitation (Hartzell and Scheeres, 2011; Hartzell *et al.*, 2013), and that cohesion will dictate the electric field required for lofting for particles smaller than 1 mm on Itokawa (100  $\mu m$  on Eros and 10  $\mu m$  on the Moon). Furthermore, these experiments have also shown that a balance between cohesive, gravitational, and electrostatic forces is needed to ensure levitation.

### 4.4. Link Between Surface Environment and Geophysical Features

In the previous sections we have tried to account for and describe the origin of the main forces that could affect grains on the surface of an airless planetary body. However, an even more interesting aspect is the interplay of these forces, as this determines the dynamics of the grains and the landscape of the surface as a whole. With this in mind, and following the notation used by Scheeres *et al.* (2010), we define something called a bond number as

$$B = \frac{F_c}{W} \quad (6)$$

where  $F_c$  is the cohesive force acting on a grain and  $W$  is its weight. For an ambient gravitational acceleration of  $g_A$  the ambient weight of a grain is defined as  $W = mg_A$ , where  $m$  is the particle's mass.

On small planetary bodies, self-gravity between individual grains is much more important than on Earth and should be taken into account in calculations. For two equal-sized particles of radius  $r$  and density  $\rho_g = 3500 \text{ kg m}^{-3}$  (larger than the asteroid's bulk density), the bond number is

$$B_{self} = G \frac{4\pi\rho_g}{3g_A} r \approx 1 \times 10^{-6} \frac{r}{g_A} \quad (7)$$

For the electrostatic force due to photoelectric emission alone, using equation (5)

$$B_{es} = 6 \times 10^{-13} \frac{1}{g_A r} \quad (8)$$

We note that triboelectric charging and other (not yet understood) mechanisms in the terminator regions could increase the electrostatic force to  $F_{es} \approx 0.1 r^2$ . This would, therefore, increase the electrostatic bond number to

$$B_{es} \approx 7 \times 10^{-6} \frac{1}{g_A r} \quad (9)$$

For cohesive forces and for material parameters of lunar regolith

$$B_c = 2.5 \times 10^{-6} \frac{S^2}{g_A r^2} \quad (10)$$

where S is the cleanliness factor defined earlier.

On small planetary bodies, for sufficiently small grain sizes, these bond numbers can easily attain values greater than 1, meaning that the grain's own weight can be overcome. Strong cohesive forces give rise to highly porous structures first called "fairy castles" by *Hapke and van Hoen* (1963). Back then they attributed the existence of such structures to adhesive and long-range electrostatic forces that act between grains during deposition and influence their trajectories. After that, the work of *Matson and Nash* (1983), *Kreslavsky and Shkuratov* (2003), and *Cassidy and Johnson* (2005) shed more light on how these structures affect photometric anomalies of the Moon. Anomalous halos around small bright impact craters have been associated with changes in porosity probably related to some geologically recent damage of the equilibrium regolith structure.

Additionally, the scaling of cohesive forces with ambient gravity means that centimeter-sized grains in a microgravity environment may behave as micrometer-sized grains in Earth's gravity. Keeping this in mind, *Mériaux and Triaudafillou* (2008) and *Durda et al.* (2013) have begun research to understand the dynamics of cohesive powders under vacuum as a proxy to regolith-covered granular surfaces on asteroids. Simulations carried out by *Sánchez and Scheeres* (2014) and *Hirabayashi* (2014) have shown that modest values of cohesive strength (25–150 Pa) and a heterogeneous structure can drastically modify the maximum spin rates, disruption patterns, and the existence (or lack) of surface flow. The results obtained by *Rozitis et al.* (2014), *Hirabayashi et al.* (2014), and *Scheeres* (2014) about 1950 DA and P/2013 R3 also seem to agree with the models, showing that values of cohesive strength under 100 Pa and angles of friction similar to those found on granular aggregates on Earth (35°–45°) are enough to explain the elevated spin rates of these asteroids.

## 5. GEOPHYSICAL PROCESSES ACTING ON ASTEROIDS

As we have already discussed, asteroids observed by spacecraft preserve records of geophysical processes that have operated at their surfaces and sometimes in their interiors. Here, these processes are classified into the following three categories: (1) exogenic phenomena, which are outer geophysical processes including impact cratering and slope failures/collapses; (2) endogenic phenomena, which are inner geophysical processes including ridges, faulting, and possible volatile and volcanic activities; and (3) other origins, including tidal and YORP effects. Note that some processes dominantly acting on one asteroid might not necessarily act on other asteroids because the physical, especially mechanical, environments of asteroids vary significantly (for example,

Vesta is considered to have been volcanically active because its mass is significantly large, 10 orders of magnitude larger than that of Itokawa, which is simply a pile of rubble).

### 5.1. Exogenic Phenomena

Because of the lack of an atmosphere, an asteroid is directly exposed to solar wind, cosmic and solar rays, and influxes of meteoroids of varying sizes. An impact can largely modify the shape of an asteroid and even its arrangement (such as impact-induced breakup of an asteroid). This will not be discussed here; rather, we focus on surface processes resulting from impacts.

On small bodies, regolith is traditionally believed to result from repetitive impacts that excavate the surface and distribute ejecta materials. However, speeds of ejecta are typically greater than several tens of centimeters per second (*Housen et al.*, 1979; *Housen and Holsapple*, 2011), which corresponds to the gravitational escape speed of kilometer-sized asteroids. Impact debris reaccumulation therefore may not be solely responsible for the ubiquitous presence of regolith on small asteroids. Other regolith-formation processes have been proposed, including during contact-binary forming collisions of asteroids, by tidal forces, as well as due to the retention of regolith from a parent body (*Barnouin-Jha et al.*, 2008; *Scheeres et al.*, 2007). Using laboratory experiments and numerical simulations, *Delbo et al.* (2014) have shown that thermal fragmentation induced by diurnal temperature variations breaks up rocks larger than a few centimeters more quickly than comminution by micrometeoroid impacts. The latter was demonstrated by adapting the lunar impact-induced comminution rates of *Hoerz et al.* (1975) to asteroids. Because thermal fragmentation is independent of asteroid size, this process can also contribute to regolith production on larger asteroids. Production of fresh regolith originating in thermal fatigue fragmentation may therefore be an important process for the rejuvenation of the surfaces of NEAs (*Delbo et al.*, 2014).

Once formed, resultant deposits of loose debris will be affected by the gravity in a longer timescale, where repeated disturbances cause overall slow motion in the downhill direction. The disturbances may be caused by processes such as small impacts and severe thermal cycling, while many of the surface processes are in some aspects similar to those terrestrial phenomena resulting from expansion and contraction processes, heating and cooling, wetting and drying, and freezing and thawing. We note here that there are many important temperature-related processes occurring on asteroid surfaces and these are discussed in the chapter by Delbo et al. in this volume.

**5.1.1. Impact ejecta mantling.** An impact will excavate the surface and create impact ejecta, which usually results in a deposit of debris surrounding the impact crater except for the cases in which the target has too little gravity to retain ejecta or too much porosity to produce it. The ejecta deposits normally affect at least the area within 5 crater radii by blanketing the original surface (*Melosh*, 1989). In

the case of gravity-dominated cratering, the thickness of the deposit,  $H_b$ , is given by

$$H_b = 0.14R_c^{0.74} \left[ \frac{r_c}{R_c} \right]^{-3} \quad (11)$$

where  $r_c$  is the distance from the crater center and  $R_c$  is the crater radius (McGetchin *et al.*, 1973). As suggested in this equation, the ejecta deposit is thickest at the crater rim and thins with increasing distance away from the crater. Impact-ejecta mantling may account for the absence of discernible surface features near craters on bodies such as Lutetia.

When the ejecta deposit is continuous and clearly recognized to be the result of the cratering event, it is called an ejecta blanket. However, such a blanket is not recognized on the surface of a small asteroid. Considering the low gravity, as well as the often irregular shapes, the above equation might not be directly applicable for small asteroids. In fact, other than the local gravity, spin parameters, especially the rotational period, can significantly affect the situation and cause very asymmetric ejecta blankets as observed on Eros. For example, a three-dimensional smoothed-particle hydrodynamics (SPH) simulation of a hemispheric-scale impact onto Vesta, which spins every 5.3 h, shows that variably shaped, multiply folded deposits can be formed (Jutzi and Asphaug, 2011) rather than a simple ejecta mantling.

The presence of boulders adjacent to an impact site on Lutetia suggests that boulder generation is a common feature of large impacts on this asteroid (Sierks *et al.*, 2011). In fact, the fragments of ejecta deposits can be size-sorted through an impact event. Even though some interaction may occur between ejecta fragments in the denser parts of the ejecta curtain, general motion of the fragments is likely dominated by ballistics and thus follows a nearly parabolic trajectory above the asteroid before falling back to the surface. The size of the ejecta fragments near the base of the ejecta curtain is expected to be larger than the fragments higher in the curtain.

One may wonder if ejecta may selectively escape from the surface of an asteroid never to return to mantle its original surface. This idea has been tested against the observations of Itokawa, for which 530 boulders larger than 5 m in size have been identified on its surface (Michikami *et al.*, 2008). Assuming the slope value on the cumulative plot (Fig. 3) from Saito *et al.* (2006), the cumulative number ( $N$ ) of boulders may be approximated as

$$N(>d) = 4.8 \times 10^4 d^{-2.8} \quad (12)$$

where  $d$  is the diameter of a boulder. If we assume that the above size distribution is continuous down to the size of a pebble, the volume of pebbles (4 mm to 6.4 cm in size) can be estimated as  $1.9 \times 10^5 \text{ m}^3$ . Note, however, that smaller particles that exist on the asteroid surface are difficult to observe, because they are overlapped by larger boulders; the size distribution may therefore be different from that observed for larger boulders by 0.2–0.3 in the slope of log-

log plot. This estimate is nonetheless on the same order as that estimated from the areas and depths of smooth terrains [ $2.3 \times 10^5 \text{ m}^3$  (Miyamoto *et al.*, 2007)]. It might therefore be appropriate to assume that no particular pebble-sized blocks have selectively escaped or accumulated (Miyamoto, 2014).

**5.1.2. Seismic shaking.** Crater excavation resulting from an impact onto an asteroid is associated with a shock wave that severely shakes the terrain. Such shaking may induce local movements that cause a net downslope movement of loose surface material (Richardson *et al.*, 2005b), and this effect can be more important for a smaller asteroid because the seismic energy is unable to attenuate over a large volume.

Indeed, the first evidence for such seismic shaking on an asteroid was presented by Thomas and Robinson (2005). They showed that the formation of a relatively young crater (7.6 km in diameter) on asteroid Eros resulted in the removal of other craters as large as 0.5 km over nearly 40% of the asteroid's surface. As burial by ejecta cannot explain the observed pattern of crater removal, and the areas with low small-crater densities correlate well with radial distance from the Shoemaker crater, they conclude that seismic shaking is the most probable mechanism.

Assuming that the seismic energy is completely supplied by the kinetic energy of an impactor, the ratio of the maximum acceleration to the surface gravity,  $a/g$ , can be written as

$$\frac{a}{g} = \frac{3fv_i}{G} \sqrt{\eta \frac{\rho_i D_i^3}{\rho_a^3 D_a^5}} \quad (13)$$

where  $f$  is the seismic frequency in Hertz,  $v_i$  is the velocity of the impactor,  $G$  is the gravitational constant,  $\eta$  is the seismic efficiency factor (the fraction of the original kinetic energy converted to seismic energy),  $\rho_i$  is the bulk density of the impactor,  $\rho_a$  is the bulk density of the asteroid,  $D_i$  is the radius of the impactor, and  $D_a$  is the diameter of the asteroid. For the case of a rubble pile, the seismic energy may attenuate significantly. In this case, a diffusive scattering theory as adopted by Richardson *et al.* (2005b) might be a realistic approach. In this theory,  $a/g$  on a diffusive body may be written as in equation (13) but multiplied by the scale factor

$$\exp\left(-\frac{fD_a^2}{K\pi Q}\right)$$

where  $K$  is the seismic diffusivity and  $Q$  is the seismic quality factor. Note that the exact values of some of the parameters for the above equations, such as  $f$ ,  $K$ ,  $Q$ , and  $\eta$  are difficult to properly obtain. However, most importantly, both models show that the size of an asteroid is an important factor in determining the surface acceleration against the gravity; smaller asteroids vibrate easier than larger asteroids. Although it is difficult to constrain reasonable ranges of values for many parameters, the above equations generally suggest that very small impactors may produce global shaking. Thus, repetitive impacts on asteroids may cause significant shaking, believed

to be responsible for the depletion of craters on Itokawa and small craters on Eros.

**5.1.3. Mass movements.** Once an asteroid is seismically shaken, reverberation continues until internal friction and collisions finally convert it entirely into heat. Similarly, some other disturbances such as heating and cooling may occur. When the formation of faults, rapid landslides, or other processes occur, releasing horizontal stress, such disturbances generally make the ground surface expand perpendicularly to the slope. When the disturbance ceases, the ground surface contracts along the direction of gravity, which is not necessarily parallel to that of the above surface expansion (especially on a surface inclined against the local gravity). When such expansion and contraction occur cyclically, the materials covering the surface show overall migrations, which are essentially downslope displacements. This kind of downslope mass movement of dry, unconsolidated material is a common geological process on terrestrial planets (Meunier et al., 2013). However, geophysically, that on terrestrial planets is generally interpreted in terms of the competition between gravity or inertia and intergranular friction. Naturally, for the case of a relatively smaller asteroid, the situation may be more complicated, since other forces such as cohesive forces can play a significant role, as discussed in section 4.

A slow and cyclic creep process is not the only type of mass movement on an asteroid. More rapid examples include landslides, which take place when the acceleration due to the ambient gravity exceeds the ability of a rock on a slope to resist. Roughly speaking, the conditions for this phenomenon to occur can be described by Coulomb's equation,  $\sigma_s = c + \sigma_n \tan \varphi$  (see Fig. 8). If the shear of a block of rock exceeds the maximum sustainable shear stress, the block slips and may be recognized as a landslide. This kind of mass movement can be found as small-scale, streak-like features such as observed on crater walls of Vesta (section 2). Indeed, mass movements can expose an interior, often recognized through differences in color, as described in section 2.

When a block of rock slips on a slope, sometimes the balance of shear stress and sustainable shear stresses inside the block changes. This causes a flow-like phenomenon, sometimes referred to as a debris flow or granular flow (Legros, 2002). Some of the above-mentioned mass movements may be better explained by this process.

When we consider a case in which a block of rock is resting on a slope at angle  $\alpha$ ,  $\sigma_s = \left(\frac{mg}{A}\right) \sin \alpha$ , where  $m$  is the mass of the block and  $A$  is its basal area. Similarly,  $\sigma_n = \left(\frac{mg}{A}\right) \cos \alpha$ . Assuming the case in which the sliding rock is actually loose debris (a case in which cohesion is negligible in a terrestrial environment, and thus flow occurs rather than simply sliding), the largest shear stress in the block is achieved at the base of the rock. In this situation,  $\sigma_s = \sigma_n \tan \varphi$ , which gives the condition of  $\alpha = \varphi$ . In other words, in this case, the angle of repose is the same as the angle of internal friction and is independent of the gravitational acceleration.

The overall migrations of such flows are sometimes considered as gravity flows, whose speed  $U$  may be described

as  $U \sim D(\rho gh)^{1/2}$ , where  $D$  is a coefficient of drag force,  $\rho$  is the density of the flow, and  $h$  is the thickness of the flow. The speed of the flow therefore depends on the square root of gravity (Jop et al., 2006), indicating that the flow can be much slower than typical ones on Earth.

Another type of mass movement is electrostatic dust levitation (see also section 4), which is proposed to be responsible for particle migrations on airless bodies exposed to both direct sunlight and the solar wind (Lee, 1996). Smaller levitated particles on an asteroid may escape into space through the solar wind, but larger particles may settle back onto the surface. This may explain the smooth ponds on the surface of Eros (Robinson et al., 2001), the formation of which clearly involves the settling of fines (much less than centimeter-sized particles) in gravitational lows by a secondary process, after crater formation [section 2 (Cheng et al., 2002b; Robinson et al., 2002)].

Cheng et al. (2002b) suggest, however, that the pond material derives from the flanks of the bounding depression seismically shaken down to the bottom of the depression. Another idea for the formation of ponds is eroding of boulders; repeated day/night cycling causes material fatigue leading to erosion of the boulders (Dombard et al., 2010). However, recent morphological analyses indicate that the deposited material most likely originates from a source external to the ponds themselves (Roberts et al., 2014a). In addition, the morphology, geography, color, and albedo of the ponds may be consistent with formation by electrostatic levitation rather than seismic shaking (Riner et al., 2008; Richardson et al., 2005b).

**5.1.4. Regolith segregation.** In addition to the size segregation that occurs during impact ejecta mantling, in granular flows where particles have different physical properties, particle segregation also occurs (as discussed in section 3). One example of such segregation is in a granular avalanche. The dominant mechanism for segregation in granular avalanches is kinetic sieving (Bridgwater, 1976) rather than the effects of diffusive remixing, particle-density differences, or grain inertia (Thomas et al., 2000). As the grains avalanche downslope, there are fluctuations in the void space and the smaller particles are more likely to fall, under gravity, into gaps that open up beneath them because they fit more easily into the available space than the coarse grains. The fine particles, therefore, percolate toward the bottom of the flow, and force imbalances squeeze the large particles toward the surface (Gray and Chugunov, 2006).

A further example of regolith segregation, which may be responsible for the presence of large boulders on the surface of asteroids such as Itokawa and Eros (Asphaug et al., 2001; Miyamoto et al., 2007), is the "Brazil-nut effect" (Rosato et al., 1987). The idea is that seismic shaking may cause the larger regolith particles to move up to the surface. If this is the case, the interiors of rubble-pile asteroids having experienced this kind of evolution are likely to be composed of smaller particles than those observed at the surface. This may also lead to some variations of macroporosity with depth inside the asteroid.

The mechanism driving the Brazil-nut segregation is still under debate (Kudrolli, 2004). It has been suggested that the segregation may result from the percolation of small particles in a similar fashion to the kinetic-sieving mechanism, but here the local rearrangements are caused only by the vibrations (e.g., Rosato *et al.*, 1987; Williams, 1976). However, other experimental results from Knight *et al.* (1993) have shown that vibration-induced size segregation may arise from convective processes within the granular material and not always from local rearrangements.

Granular convection is in fact a process often invoked by the community of small-body scientists to interpret the surface geology of asteroids (Miyamoto *et al.*, 2007; Asphaug, 2007). However, as discussed in Murdoch *et al.* (2013b), kinetic sieving and granular convection are strongly dependent on the gravitational acceleration (Thornton, 2005; Murdoch *et al.*, 2013c). A weak gravitational acceleration may therefore reduce the efficiency of particle size segregation. Indeed, recent numerical simulations and parabolic flight experiments of the Brazil-nut effect have shown that the speed at which a large intruder in a granular material rises is reduced as the external gravity decreases (Tancredi *et al.*, 2012; Güttsler *et al.*, 2013; Matsumura *et al.*, 2014). Therefore, all convective and particle segregation processes in a granular material on or near the surface of a small body may require much longer timescales than the same processes would require in the presence of a strong gravitational field.

## 5.2. Endogenic Phenomena

For terrestrial planets, “endogenic processes” are geological processes associated with energy originating from the interior of the planet, including tectonics, magmatism, metamorphism, and seismic activities. However, in the case of asteroids, the ultimate cause of tectonics or seismic activities may be difficult to clearly separate.

Internal magmatism and volcanic processes are not often expected to occur on asteroids. However, differentiated early-forming asteroids should have experienced various kinds of volcanic activity, especially as a result of incorporating the heat-generating isotope  $^{26}\text{Al}$ . The howardite-eucrite-diogenite (HED) class of meteorites, whose parent body is believed to be the asteroid Vesta, have been studied in detail, and the magmatic origins of these rocks and their compositions as surface lavas or intrusions are well understood (e.g., Taylor, 1993). Nevertheless, observations of Vesta show no conclusive evidence of volcanic features. The surface of Vesta, particularly the northern hemisphere, appears to be saturated with craters  $>10$  km in diameter (Marchi *et al.*, 2012). This indicates that the surface regolith to depths of more than 1 km is significantly overturned. On the other hand, Wilson (2013) predicted that typical lava flow dimensions are  $\sim 10$  m thick, much shallower than the thickness of overturned regolith, which might be the reason for the lack of clear evidence of lava flows or pyroclastics on the surface of Vesta.

Even though volcanism is not a common process on an asteroid, some features indicate phase-changing of materi-

als and their transportation to the surface. Possible melting flows identified on Vesta might be good examples. Also, more than 10 active (mass-shedding) asteroids have been reported (Jewitt, 2012), and the possible mechanisms for producing mass loss include dehydration stresses and thermal fracture. Although comets are not the focus of this chapter, we note that, in fact, strange features exist in the nuclei of both Tempel 1 and Wild 2. These features are interpreted as pits and scarp retreats resulting from venting of subsurface volatiles (Veverka *et al.*, 2013).

Some pitted terrains of Vesta (Fig. 6f) are also believed to be related to subsurface volatiles; morphologic similarities of pitted terrains between Mars and Vesta suggest volatile release as an origin. However, because meteorites thought to originate from Vesta indicate low endogenic volatile content, it has been suggested that the volatiles have been delivered to Vesta’s surface and are not endogenic. The source may be carbonaceous chondrites, which have been observed as clasts in howardites (meteorites most likely originating from the surface of Vesta), or perhaps comets. Later impacts into this water-bearing regolith would result in devolatilization due to impact heating and melting (Denevi *et al.*, 2012).

Tectonic features are surface features created by internal stresses that fracture or deform the surface layer. Numerous tectonic features are documented on asteroids. For example, Vesta displays examples similar to those found on small saturnian satellites such as Iapetus. Also, Rahe Dorsum on Eros is a ridge extending for about 18 km around the asteroid that resembles thrust fault structures on the terrestrial planets (Prockter *et al.*, 2002). Tectonic deformation cannot occur without forces to drive it. However, many sources of tectonic stress exist of both internal and external origin, and a clear separation and exclusive classification is difficult.

For example, on Eros, the large “spiral” pattern southwest of Psyche is suggestive of extensional tectonics, whereas the spatial distributions of other ridge systems, as well as its estimated shear strength, indicate that the ridges are in fact thrust faults that were formed by impact-induced compression (Watters *et al.*, 2011; Cheng *et al.*, 2002b; Veverka *et al.*, 2000). However, the ridge system on asteroid (2867) Šteins (hereafter simply Šteins), which is the most prominent feature recognized on its surface, may be formed through the change in rotation rate due to the effect of solar radiation known as the YORP effect. The effect spins Šteins, making the surface seek for the object’s potential-energy minimum, which may cause tectonic arrangements or landslide-like surface modifications toward the equator (Harris *et al.*, 2009). Either process can explain the formation of the ridge at the equator. A similar origin is proposed for an equatorial ridge of 1999 KW<sub>4</sub> (Walsh *et al.*, 2008).

Grabens or linear depressions are found on many asteroids (see section 2), which may seem strange given the fact that asteroids are covered by loose fragmental debris. It is possible that these fractures are evidence of competent rock below the regolith. It has been suggested that they result from stresses from large impact events, which have refocused and caused fracture far from the crater (Fujiiwara

and Asada, 1983; Asphaug et al., 1996), or that they are due to thermal stresses (Dombard and Freed, 2002) and/or body stresses induced by changes in spin. However, faulting can occur even in a granular matrix when it is cohesive relative to the applied stress.

Grooves have been reported on Gaspra, Eros, Šteins, Lutetia, and many other asteroids observed at high resolution. A subset of the grooves appear to be chains of pits (or crater-like indentations) in an almost linear arrangement. The global extent of a series of pitted chains found on Steins indicates these are not impact craters, because the chances of formation of many chains of these craters of similar size is highly improbable. Instead, partial drainage of loose surface material into a fracture within stronger, deeper material is considered as a likely origin (Richardson et al., 2002; Keller et al., 2010). This explanation of how pitted grooves form was suggested to explain the features seen on Phobos (Thomas et al., 1979). Experiments have demonstrated that, in such a model, the spacing of the pits along the groove is equal to the thickness of the regolith in which they form and is independent of regolith bulk density, grain size, shape, angularity, and angle of repose (Melosh, 1989; Prockter et al., 2002). Short and well-defined grooves can also be caused by a boulder that has bounced and rolled a short distance, but very few (<5) such tracks have been positively identified on the surface of Eros (Prockter et al., 2002; Robinson et al., 2001).

### 5.3. Tidal and Rotational Effects

There might be some morphological or even larger modifications of asteroids due to tidal forces. Modest influences are expected to include exposing layers of surface materials; to explain the fact that the laboratory spectra of ordinary chondrite meteorites are a good match to Q-type asteroids, Binzel et al. (2010) and Nesvorný et al. (2010) pointed out the possibility that Q-type NEAs underwent recent encounters with the terrestrial planets and the tidal force exposed fresh ordinary chondrite material on the surface. More considerable outcomes may include splitting the asteroid into a binary (Walsh and Richardson, 2008) or even catastrophically disrupting it in a manner similar to Comet Shoemaker-Levy 9 at Jupiter. Such tidal effects by a terrestrial planet are considered as one of the most likely creation scenarios for asteroid families (Fu et al., 2005). Also, strange shapes of some NEAs as revealed by radar images may have resulted from the tidal disruption processes and reaccumulations of disrupted fragments (e.g., Bottke et al., 1999).

YORP can modify both the rotation rate and the spin-axis orientation of small asteroids and has been identified as an important process driving their physical and dynamical evolution (Vokrouhlický et al., 2003). Asteroids of 5 km and smaller in radius in near-Earth orbits and a few tens of kilometers in the inner main belt are subject to the YORP effect. The spinup of asteroids can have dramatic consequences (Scheeres et al., 2007; Walsh et al., 2008). For example, the deficiency in small craters on Steins is attributed to surface reshaping (through landslides) due to

spinup by the YORP effect (Keller et al., 2010). The shape of the northern hemisphere of Steins is reminiscent of that of the NEA 1999 KW<sub>4</sub>, which has been attributed to spinup by the YORP effect. A plausible scenario is that Šteins was spun up by YORP, leading to material sliding toward the equator to form the typical top-shape (Keller et al., 2010). Mass shed from the equator of a critically spinning asteroid can accrete into a satellite (Walsh et al., 2008). Alternatively, an asteroid may spin up by the YORP effect until it reaches its fission spin limit and the components enter orbit about each other (Scheeres et al., 2007). Asteroid pairs may be formed by the rotational fission of a parent asteroid into a protobinary system, which subsequently disrupts under its own internal system dynamics (Pravec et al., 2010). These binary asteroid formation mechanisms may explain the fact that asteroid pairs ubiquitously exist. For more information on asteroid binaries, see the chapter by Walsh and Jacobson in this volume.

## 6. INVESTIGATING REGOLITH DYNAMICS

Regolith processes on asteroid surfaces may not have ready terrestrial analogs. In order to study regolith dynamics in the unique asteroid environment described in section 4, both experimental methods and numerical simulations can be used.

### 6.1. Experimental Methods

**6.1.1. Creating reduced-gravity conditions.** One of the major challenges for investigating the behavior of regolith at the surface of an asteroid is to recreate the proper gravitational conditions. Microgravity, the condition of relative near weightlessness, can only be achieved on Earth by putting an object in a state of free-fall. Here we introduce some of the techniques used to perform experiments in reduced-gravity conditions.

Drop towers have been extensively used for microgravity experiments related to dust and regolith dynamics [e.g., Hofmeister et al. (2009) studying granular flow under reduced-gravity, and Schräpler et al. (2012) and Beitz et al. (2011) investigating low-velocity collisions between dust agglomerates]. Parabolic flights can also provide a microgravity environment for regolith experiments [e.g., Murdoch et al. (2013a,c) performing experiments of granular shear and granular convection, Güttinger et al. (2013) investigating granular convection and the Brazil-nut effect, and Dove and Colwell (2013) investigating particle charging and the dynamics of charged particles on the surfaces of airless bodies]. Such flights are normally operated using modified commercial aeroplanes, but smaller aircraft have also been used (e.g., Kleinhans et al., 2011). Other ways of achieving microgravity are using a sounding rocket [e.g., Krause and Blum (2004) studying the formation of dust agglomerates] or flying an experiment on the International Space Station [e.g., Colwell (2003) investigating low-speed impacts into dust]. Additional methods of simulating microgravity exist as well, such as magnetic levitation and neutral buoyancy. However,

in order to perform an experiment with particles using these techniques, every particle in the experiment would have to be neutrally buoyant or magnetically levitated. If, for example, only the experiment container is levitated or buoyant, the individual grains would still feel the gravitational field.

**6.1.2. Creating the electrostatic environment.** The electrostatic part of the asteroid environment is provided by the solar wind, which is essentially a stream of plasma (electrons and protons) that originates in the upper atmosphere of the Sun. The energy of this plasma ranges between 1.5 and 10 keV. Although there are many ways to obtain plasma, the one technique that is chiefly employed to study lunar and asteroid environments uses an emissive filament within a cylindrical stainless steel vacuum chamber. Argon plasma is created by the impact ionization using electrons emitted from a negatively biased and heated filament in the bottom of the chamber (Wang *et al.*, 2012; Hartzell *et al.*, 2013). However, the experiments have a higher density and lower temperature than the solar wind.

Efforts are being made to improve these experimental techniques so that the obtained results are not only *qualitatively* but also *quantitatively* correct, and so they can be directly translated to the asteroid environment. In spite of this, they come with size, time, and cost constraints, and even in the best possible conditions, sometimes fall short of the real environments that are the object of study. These constraints are what make computer simulations and their development and understanding attractive from a scientific point of view. Of course, computer simulations also have a cost, as there are many simplifications and assumptions that have to be made (see section 6.2). This means that there must be a trade off between their complexity and their realism. A trade off that calls for a very careful look at the results and their interpretations as computational artifacts must be distinguished from fact. If research is carefully conducted, simulations can be used to guide better experiments and predictions of simulations can be tested so that nature is understood.

## 6.2. Numerical Methods

With advances in computer hardware and software, numerical modeling has become increasingly important to the study of granular systems in general, and to granular systems in exotic environments such as the surfaces of small bodies, where conditions are difficult to replicate experimentally. The different types of numerical approaches can be divided into the broad categories of continuum and discrete. In the realm of numerical simulation, continuum approaches and discrete approaches have relative advantages and disadvantages that depend on the specific investigation at hand. In general, discrete approaches attempt to treat material as individual particles, sometimes with large particles as proxies for groupings of smaller ones. Continuum approaches average the physics of nearby particles, and use smooth transitions to account for variance. Continuum approaches are particularly well suited for high-speed collisions, where material phase changes and the finite propagation speed of sound waves are

important. In low-speed granular regimes, however, discrete approaches have the advantage of being able to capture the inherently discrete nature of granular systems and being able to describe in great detail the properties of individual grains. These properties are then used to solve for the frictional and cohesive forces that arise when grains come into contact with each other. Discrete codes are also much better suited toward capturing the physics of slowly evolving granular systems such as those that take place on the surfaces of small bodies.

**6.2.1. Numerical modeling of granular systems in planetary science.** For many years, numerical continuum approaches have been used to address issues related to granular dynamics in the field of planetary science [e.g., Holsapple (1993) investigating scaling laws for impact-induced catastrophic disruption, and Benz *et al.* (1994) investigating different classes of two-body collisions]. Continuum approaches have since grown significantly in sophistication [some in current use for the modeling of asteroid shapes and the scaling laws for disruption are, e.g., Holsapple and Michel (2008), Holsapple (2009), and Sharma *et al.* (2009)]. Discrete numerical approaches, described below, have been in use in the field of planetary science since, e.g., Brahic (1975, 1977), who simulated Saturn's rings; Asphaug and Benz (1994), who simulated the breakup of Comet Shoemaker-Levy 9 using a soft-sphere discrete element method (SSDEM); and Richardson *et al.* (1998), who conducted a more generalized numerical investigation into tidal breakups of small bodies using a hard-sphere discrete element method (HSDEM). In light of advances in computer processor speeds, only quite recently have robust versions of SSDEM begun to be applied to the realm of planetary science, and specifically to the study of regolith dynamics in microgravity environments. SSDEM granular physics codes are now developed or adapted specifically for planetary applications by various groups (e.g., Wada *et al.*, 2006; Sánchez and Scheeres, 2011; Schwartz *et al.*, 2012; Tancredi *et al.*, 2012) using various integration schemes and strategies to account for the types of friction between grains. Other codes, using continuum approaches, have also been developed to investigate, for instance, collisions between porous aggregates (Sirono, 2004; Jutzi *et al.*, 2013). However, owing to the granular nature of the relevant dynamical processes involved, the regolith surfaces of small bodies are more commonly modeled using discrete-element methodologies, specifically (although not exclusively) SSDEM.

**6.2.2. The continuum approach to regolith modeling.** Continuum numerical modeling of granular material usually begins by defining a systematic approach to averaging the physics across many particles (and thereby treating the granular material as a continuum). The approach typically will involve dividing a parameter space or dimensional space into regions, and then integrating the system forward in time.

In describing fluid mechanics equations for dense flows, relevant conservation laws are followed, often in a Navier-Stokes framework (e.g., Haff, 1983). At minimum, these conservation laws should include mass conservation, momentum conservation, and the conservation of energy together with the first law of thermodynamics. These regions may be

described in Eulerian terms, where a volume in space is held constant, with material passing in and out of this volume, or in Lagrangian terms, where a region is described by the material itself as it moves around in space [e.g., see *Springel and Hernquist* (2002) for a fully conservative derivation of a Lagrangian treatment in a SPH code]. The numerical viscosity problems that stem from continuum codes [a known problem since *von Neumann and Richtmyer* (1950), a result of the homogenization of material properties] are somewhat easier to mitigate in Eulerian approaches (*Springel*, 2010), whereas the principle advantage to the Lagrangian approach is that the resolution of the system adjusts automatically to the movement of the material [see, e.g., the *Benz et al.* (1994) handling of two-body collisions]. Sophisticated codes have been developed that use hybrids of Eulerian and Lagrangian descriptions together with complex physical laws and computational parameters [see *Monaghan* (1988) for an early perspective]. In addition, there have been significant advances in continuum coding approaches that mitigate some of the problems of numerical viscosity, including sophisticated differencing schemes (see, e.g., *Marti and Mulet*, 2014).

In the modeling of granular media, the continuum approach often treats the material as a deformable solid and models it with some chosen finite-element [e.g., *Crosta et al.* (2009), who make use of the definition of bulk plastic and elastic moduli] or mesh-free (Lagrangian) method suited for the particular situation at hand (e.g., *Elaskar et al.*, 2000). Stability problems (e.g., the stability of granular piles or cliffs) require an elastoplastic framework that defines, at minimum, some type of yield criterion (consider the simple one-dimensional Coulomb yield criterion — conditions are static until the tangential force exceeds the product of the coefficient of static friction and the normal force).

Depending on the system, a continuum approach could incorporate viscosity in some useful form (e.g., *Lagréé et al.*, 2011) and treat the material as a fluid and use computational fluid dynamics (useful in describing outflows from, e.g., crater walls). However, since successful simulations of asteroid surface dynamics entail the capturing of the discrete nature of individual particles, the effects of such homogenization must be examined thoroughly. *Haff* (1983), in his article describing his efforts to treat granular media as a fluid analytically, considers many of the potential hazards and payoffs of using fluid dynamics from his analytical approach. These same considerations that arise analytically (i.e., the sharp boundary conditions on grain surfaces, including the complex frictional forces at play on these surfaces), also arise numerically.

**6.2.3. The discrete approach to regolith modeling.** The discrete-element method (DEM) is a general term applied to the class of discrete approaches to the numerical simulation of particle motion, where particles usually represent actual grains (or collections of grains), unlike the continuum approach, which uses averages to homogenize the material. However, as continuum approaches use homogenization schemes to simplify the complex and rapidly varying physical quantities within a material, in discrete approaches, the physics within individual particles are averaged, and thus the

particles are defined only by their *effective* behavior, described by quantitative parameters. Nevertheless, these parameters are typically borrowed directly from continuum mechanics, either by explicitly defining quantities such as Poisson's ratio and Young's, bulk, and shear moduli, or by using derived quantities including spring constants and friction coefficients.

Discrete-element-method collisional routines are typically built off an N-body routine. In an N-body framework, at the beginning of each timestep, forces on each of the N number of particles (bodies) in a given simulation are solved for and used to advance the simulation ahead through time in small quantized steps. These forces can include, e.g., external gravity or electromagnetic fields, and can incorporate the effects that the particles themselves have on the field (e.g., interparticle gravity). The collisional routines are then built on top of this framework, and define a new set of forces to account for the physical interactions that particles have with each other (of course these interactions are also electric at the molecular level).

In the standard implementation, particles are approximated as having perfect spherical geometry (more complex geometries are also possible). Since DEMs tend to compute the motions of large numbers of individual particles, it is relatively computationally intensive, which tends to limit either the length of a simulation or the number of particles in the simulation.

**6.2.3.1. Hard-sphere discrete-element method (HSDEM):** The numerical approach to solving the equations of motion in HSDEM is to discretize the simulation in time, with variables progressing in small steps (timesteps) by forward-advancing along derivatives. Collisions are predicted in advance by analyzing particle motion and checking for potential contacts that may occur within the current timestep. Particles are not allowed to penetrate each other (overlaps are not allowed). HSDEM codes carry out collisions between spheres by treating collisions as instantaneously occurring at a single point of contact that lies on the particles' surfaces; the sound speed through a particle is also instantaneous. Thus this methodology treats motions and mutual interactions of nondeformable, indestructible (hard) particles. The assumption of hard particles allows collisions to be carried out analytically, with post-collision velocities and rotations given by, e.g., *Richardson* (1994, 1995).

**6.2.3.2. Soft-sphere discrete element method (SSDEM):** The SSDEM is commonly used in the study of granular materials, and has often been applied to industrial problems (e.g., *Tsuji et al.*, 1992; *Cleary and Sawley*, 2002; *Kosinski and Hoffmann*, 2009). The methodology is known in other disciplines of physics, such as chemical physics, as molecular dynamics (MD), where it is used to compute motions of atoms and molecules and interactions between them [in fact, this application and nomenclature predates SSDEM's use in granular physical contexts (*Alder and Wainwright*, 1959)]. In the complex case of simulating regolith dynamics, one must treat each of the relevant frictional forces by generalizing and applying the rules of interaction between grains. The basic methodology having been developed by *Cundall and Strack*

(1979), SSDEM treats macroscopic particles as deformable spheres, allowing overlaps between particles to act as proxies for actual deformation. Particles are taken to be in contact if and only if their surfaces are touching or mutually penetrating. The greater the extent of this penetration, the more repulsive the force that is generated. The majority of codes either assume a linear force dependence or a Hertzian dependence on penetration depth ( $F \propto x$  or  $F \propto x^{3/2}$ , where  $x$  is the penetration in units of length). Once a contact is established, particles are subject to frictional forces, often making use of material parameters based on continuum mechanical theory; these forces will vary depending on the specific SSDEM code [see *Radjai and Dubois* (2011) for a comprehensive overview of the different classes of SSDEM codes and common variations].

**6.2.4. Benefits and drawbacks between these numerical approaches.** In contrast to HSDEM, where collisions are solved for analytically, based on the positions and momentum states of the particles along with some basic material parameters to describe the behavior, SSDEM must resolve each collision numerically. As such, collisions typically require dozens of timesteps to resolve. In HSDEM, however, since collisions are predicted in advance and then treated as instantaneous, it is the external dynamics (e.g., gravity) that drives the choice in step size rather than the collision handling; although the timestep may also be limited by concerns over missing a collision, timesteps in SSDEM can often be smaller than those used in identical HSDEM simulations by factors of  $10^2$ . In dense regimes, however, the speed of the integration in HSDEM is typically limited by collisional bottlenecks owing to the fact that collisions must typically be computed one at a time in sequence, limiting the efficiency of parallel processing.

During the finite amount of time that it takes for two real particles to collide, the particles are in contact, exchanging energy and momentum. In sufficiently dense regimes, a third particle may intrude on this collision by making contact with either particle or with both particles, changing the outcome. This exposes another drawback of HSDEM's treatment of collisions between particles: Multiple contact effects are not taken into account in HSDEM, where collisions are separate and instantaneous. Multi-contact systems of rigid, indestructible particles can, however, be solved using an algorithm known as contact dynamics (CD), which treats these rigid particles as subject to Coulomb static frictional forces (*Moreau*, 1994). The HSDEM methodology also must account for the problem of inelastic collapse, which occurs when a group of particles collides infinitely often in a finite time, causing the simulation to grind to a halt [see, e.g., *Petit and Henon* (1987) and *Bernu and Mazighi* (1990) for early numerical encounters of this effect, and, e.g., *McNamara and Young* (1992) and *McNamara* (2000) for more complete quantitative descriptions]. Although sophisticated collision-handling schemes have been tailored to help mitigate this problem (*Petit and Henon*, 1987; *Luding and McNamara*, 1998), the simplest way to avoid the finite-time singularity in HSDEM is straightforward: It requires setting some minimum impact speed or energy under which the coefficient of

restitution is unity (no dissipation). This results in particles, even those in “stable” configurations, always maintaining some minimum energy state (temperature), which may not appropriately capture certain low-energy granular regimes. Problems of inelastic collapse do not arise in SSDEM or CD methodologies.

Nevertheless, SSDEM is the appropriate choice over CD in very dense regimes of large numbers of particles because CD must solve, through iteration between each timestep, the contact forces between each particle in a contact chain. Still, HSDEM and CD can be a more appropriate collisional routine in more dilute regimes, where collisions do not involve networks consisting of large numbers of particles (e.g., higher energy, “granular gas” regimes; see section 3 of this chapter), and where sound propagation speed is unimportant (the sound speed can be controlled in soft-sphere methodologies via a stiffness parameter). However, even in two-body collisions, HSDEM can make errors. Particles can rotate significantly during realistic, finite, oblique collisions, altering the outcome of the collision — an effect that does not occur between perfectly rigid particles (*Müller and Pöschel*, 2012). In addition to CD, attempts have been made to use HSDEM with added analytical corrections to account for rotations of the multi-body system while particles are colliding (*Müller and Pöschel*, 2013), and to account for finite collision times (by “pausing” collisions). These are most effective in regimes when (third-) particle intruders can be safely ignored. Also, when two real (deformable) grains just “graze” each other, depending on the rigidity of the grains, they may interact very weakly; however, these types of contacts are given too much significance when using hard spheres (the assumption of grain incompressibility in HSDEM and CD leads to the exchange of too much energy and momentum during oblique impacts).

Despite these drawbacks, HSDEM and/or CD can be the appropriate choice in certain dilute/ballistic regimes (cf. *Richardson et al.*, 2011; *Murdoch et al.*, 2012), where they are advantageous over continuum models for their speed and accuracy, and often over SSDEM for their speed given the ability to handle large timesteps. These are regimes where collisional timescales may be long compared to other dynamical timescales (the “granular gas” regime; see section 3 of this chapter), where contacts between grains do not persist and thus complex frictional forces are less relevant, and where the propagation of disturbance waves (material sound speeds) are unimportant.

For the simulation of dense environments, however, including many granular regimes in which grain deformation, finite sound speed, multicontact physics, and the complexity of higher-order frictional forces during contact cannot be neglected, SSDEM is the better choice. Although the use of small timesteps can limit its speed, it is well suited for true parallelization (without the HSDEM drawback of having to compute collisions in serial order). Presently it is possible to follow the evolution of millions of grains in close contact and over a fairly large range of simulation conditions, something not possible with HSDEM.

The search for contacts in SSDEM is a simpler task than the search for contacts (collisions) in HSDEM. Before integrating over the next timestep, HSDEM must ask, will there be a collision at any moment during the following timestep? In contrast, SSDEM needs only to ask if there are any overlaps presently occurring. Effectively, this means that contact searches are a four-dimensional problem in HSDEM (three spatial dimensions and one temporal dimension) and a three-dimensional problem in SSDEM (three spatial dimensions). More complex wall boundary geometries are more easily included in SSDEM [the SSDEM code implemented in *pdkgrav*, for example, allows for a wider set of wall boundaries; these include the triangle, which can allow for sophisticated three-dimensional polyhedral shapes, along with those discussed in *Schwartz et al.* (2012)].

As a direct comparison of the two DEM collisional methodologies, HSDEM and SSDEM, simulations of low-speed rubble-pile collisions were performed using both SSDEM and HSDEM in the same numerical code (*Richardson et al.*, 2012b). In the tests, self-gravitating rubble piles (without friction or cohesive forces) were collided together at low speed. The results from the two collisional routines were generally similar; SSDEM often, but not in all cases, showed a somewhat higher final ellipticity of the largest collisional remnant, suggesting a higher shear strength that may arise from its more careful treatment of contact forces and finite collisional times.

In terms of computational efficiency, continuum codes in general are inherently conducive to parallelization, especially fixed-grid continuum codes. Several DEM codes also take advantage of parallel processing capabilities to scale up the number of particles or length of the simulation (e.g., *Richardson et al.*, 2000; *Cleary and Sawley*, 2002; *Kacianauskas et al.*, 2010; *Schwartz et al.*, 2012); HSDEM codes that have to compute collisions one at a time face more challenges in this regard, whereas SSDEM codes, like continuum codes, can accommodate true parallelization.

Due to the nonzero angle of repose exhibited by granular materials, which is the case even when the grains are cohesionless and support no grain-grain surface friction, perfect rubble piles (no cohesion) can maintain nonspherical shapes without bulk spin, unlike a fluid. Rubble piles can also spin faster than a perfect fluid before shedding mass. A study was performed by *Richardson et al.* (2005a) using HSDEM to compare the results of rubble-pile equilibrium shapes in simulation to continuum theory. Investigated were the shape and spin limits of self-gravitating rubble piles that consist of identical HSDEM particles in a hexagonal-close-pack configuration and no sliding friction, and this entirely discrete approach was found to be consistent with the theory for the more general continuum rubble-pile model as analyzed by *Holsapple* (2004) for a friction angle of 40°. Rubble piles that reassembled following a catastrophic disruption reconfigured themselves to lie within stability limits predicted by the continuum theory. In the Holsapple model, the Mohr-Coulomb prescription was used to describe pressure-dependent yield to obtain rubble-pile stability limits; later, the same analysis was performed using the Drucker-Prager relation, giving

very similar results (*Holsapple and Michel*, 2006). As an additional follow-up to these continuum studies, a comprehensive analysis was performed that extended the continuum theory for (cohesionless) rubble piles to give an upper bound on actual load limits of bodies with cohesion (*Holsapple and Michel*, 2008). To compare with these results, preliminary work was performed that included gravitational aggregates with and without cohesion (*Richardson et al.*, 2008) using a portion of the numerical tools described in *Schwartz et al.* (2013). This work expanded upon the discrete numerical work from *Richardson et al.* (2005a). More recently, SSDEM has been used to analyze equilibrium shapes of rubble piles without the use of cohesion (*Sánchez and Scheeres*, 2012), and compared their results with the Holsapple analyses and HSDEM models of *Walsh et al.* (2012).

In general, SSDEM approaches are inherently well suited to capturing the discrete nature of granular systems, and tend to rely upon fewer free parameters to reproduce the correct behavior of many granular systems. Also, continuum codes typically have a difficult time conserving angular momentum due to the effects of numerical viscosity (section 6.2.2). This can particularly be a problem in certain planetary science applications when considering isolated bodies in space. However, in comparison with the continuum approach, DEM is not well suited to the treatment of supersonic motion, particle fragmentation, or phase-changing material.

**6.2.5. The use of numerical simulation in the field of regolith dynamics.** Several DEM numerical codes have been written with the specific aim of investigating and solving for regolith dynamics. *Walsh et al.* (2008, 2012) used the HSDEM collisional routine in *pdkgrav* (*Stadel*, 2001; *Richardson et al.*, 2000) to study grain displacements and lofting due to YORP spinup. Soft-sphere collisional methodologies have been used to study regolith dynamics in low-gravity environments, which include subsonic impact cratering into regolith (*Wada et al.*, 2006; *Schwartz et al.*, 2014), the Brazil-nut effect (*Tancredi et al.*, 2012; *Matsumura et al.*, 2014), and regolith motion due to tidal forces (*Yu et al.*, 2014). Also in the realm of asteroid surface science, several numerical investigations to study avalanche run-outs and angles of repose of regolith have been performed using both continuum codes [e.g., *Holsapple* (2013), using a finite-differencing method] and using DEM [e.g., *Richardson et al.* (2012a), using soft-sphere].

The inclusion of cohesion in numerical coding can be adapted to many different granular dynamics applications in planetary science, including the study of regolith dynamics [e.g., in SSDEM (*Schwartz et al.*, 2013; *Sánchez and Scheeres*, 2014)]. Attractive interparticle forces may be used to treat ionic or covalent molecular bonds, weaker intermolecular dipole-dipole bonds such as hydrogen bonds and London dispersion forces, or electrostatic forces. Recently, *Sánchez and Scheeres* (2014) performed a simulation using two spherical, meter-sized particles (boulders) with small (approximately a few centimeters) cohesive particles (regolith) between them, and measured the force necessary to pull the large particles apart. The cohesion conforms to Hamaker's

generalized van der Waals force law for interacting spheres (equation (3)). These intermolecular cohesive forces, of regolith especially, may be of importance in low-gravity environments and could be helpful to explain the rotation rates of some of the smallest asteroids catalogued by *Pravec et al.* (2005) and, more recently, *Statler et al.* (2013) and *Rozitis et al.* (2014). It is beyond a doubt that many fast rotators spin in excess of what gravity alone could hold together. Some could be monoliths, but it has been shown that a small amount of cohesion is sufficient to explain these rotation rates (*Holsapple*, 2007; *Richardson et al.*, 2008; *Sánchez and Scheeres*, 2014; *Hirabayashi and Scheeres*, 2015).

Innovative uses of numerical tools have had the capacity to advance the field of planetary science in general, and, more recently, the specific realm of small-body regolith dynamics. Part of what it will take to push this area of research forward will inevitably entail recognizing creative applications and the usage of new techniques, aided by further bridging between the research communities of planetary science and granular dynamics, the latter of which continues to expand and develop (e.g., *Luding and Tomas*, 2014).

## 7. CONCLUSIONS

In this chapter we have presented a brief overview of the observations of granular surfaces of asteroids, our current understanding of the geophysical processes that may have occurred, and the state-of-the-art experimental and computational methods used to study them and make new predictions. The field of regolith dynamics in varying gravitational environments, including the study of NEAs as self-gravitating aggregates, is a new field of planetary science that will continue to evolve with the development of better computational tools and experimental techniques, refinements in the theoretical models, and new *in situ* observations from upcoming space missions such as the NASA's Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) and JAXA's Hayabusa-2.

**Acknowledgments.** We would like to thank D. C. Richardson and D. J. Scheeres for their comments on our chapter and L. Staron and O. Barnouin for their very helpful reviews.

Asteroid surveys are the backbone of asteroid science, and with this in mind we begin with a broad review of the impact of asteroid surveys on our field. We then provide a brief history of asteroid discoveries so as to place contemporary and future surveys in perspective. Surveys in the United States (U.S.) have discovered the vast majority of the asteroids, and this dominance has been consolidated since the publication of *Asteroids III*. Our descriptions of the asteroid surveys that have been operational since that time are focused on those that have contributed the vast majority of asteroid observations and discoveries. We also provide some insight into upcoming next-generation surveys that are sure to alter our understanding of the small bodies in the inner solar system and provide evidence to untangle their complicated dynamical and physical histories. The Minor Planet Center, the nerve center of the asteroid discovery effort, has improved its operations significantly in the past decade so that it can manage the increasing discovery rate, and ensure that it is well-placed to handle the data rates expected in the next decade. We also consider the difficulties associated with astrometric follow-up of newly identified objects. It seems clear that both of these efforts must operate in new modes in order to keep pace with expected discovery rates of next-generation ground- and spacebased surveys.

## 1. INTRODUCTION

Without asteroid surveys there would be no asteroid science. The cumulative efforts of more than 200 years of asteroid surveying has resulted in the discovery of over half a million asteroids in the inner solar system that range from just a tenth of an astronomical unit from the Sun to beyond Jupiter's orbit. The surveys have identified asteroids that are the targets of spacecraft missions, that are the remnants of larger asteroids that were catastrophically disrupted long ago, and that allow us to untangle the complicated processes that formed our solar system billions of years ago. The surveys' capabilities have improved over the decades as they took advantage of every new available technology to push their performance in area coverage, limiting magnitude, and data rates. Their efforts have enabled our community to advance our understanding of the past, current, and future interactions

of both the small and large objects in our solar system. This chapter provides a historical perspective on asteroid surveys, then focuses on their current capabilities and discoveries since *Asteroids III*, discusses the importance of targeted astrometric follow-up for critical objects, and concludes with a speculative forecast on how the next decade of asteroid surveying will unfold.

The benefits of a database containing a large number of asteroid orbit elements and basic physical properties have mostly been achieved over the past couple decades as a result of the NASA-funded near-Earth object (NEO) surveys (Table 1). They attempt to optimize their surveying for the discovery of unknown NEOs but, in the process, discover and recover known asteroids throughout the solar system. While it seems obvious that “more is better,” it is not necessarily straightforward to justify the argument for different asteroid populations — How many asteroids are necessary

for science? Is a complete survey required, or is a statistical sample sufficient?

The first decade of intensive asteroid surveying at the end of the last century was motivated by NASA's goal of detecting NEOs that are larger than 1 km in diameter. The impact on Earth of one of those objects is expected to have global consequences and the set of about 1000 NEOs of that size or larger was thought to incorporate 90% of the impact risk (e.g., Morrison, 1992; Harris, 2008). Thus, the surveys had a relatively well-defined goal that was motivated by planetary defense rather than science: Identify most of the largest hazardous asteroids that could threaten Earth. Progress toward achieving that goal could be measured against the derived population size or by the rediscovery rate (e.g., Jedicke et al., 2003; Harris, 2007). It is possible that there remain undiscovered large objects on an impact trajectory with Earth, but the probability is small.

The last decade of asteroid discovery, roughly since *Asteroids III*, has mostly retired the risk of an unanticipated impact of a globally devastating asteroid (e.g., Harris, 2008; Mainzer et al., 2011b). Having achieved that goal, the surveys are now focusing on detecting even smaller asteroids with the goal of discovering >90% of the potentially hazardous objects (PHOs) larger than 140 m diameter because they (1) represent the lower limit of those that can cause serious regional ground destruction and (2) contribute roughly 90% of the residual hazard to Earth from unknown impactors. The discovery rate for objects less than 140 m in diameter is currently about 400 per year, so *Asteroids VII* could potentially be published before the goal is reached unless new technologies are brought to bear in the coming decades.

Thus, for PHOs, there are well-defined and clearly motivated practical goals for discovering a specific number of objects, but the situation is not so clear for other asteroid populations in the inner solar system. How many main-belt

asteroids are necessary? To what absolute magnitude should we strive to be complete for Jupiter's Trojan asteroids? Without the NEO surveys driving the discovery of asteroids to fainter apparent magnitudes and smaller sizes, we would not have discovered, for example, extremely young asteroid families that can be traced back in time to their collision origin (e.g., Nesvorný et al., 2006; see also the chapter by Nesvorný et al. in this volume), widely separated asteroid pairs on nearly identical orbits that point to Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) spinup and tidal disruptions of large asteroids (e.g., Vokrouhlický and Nesvorný, 2008; see the chapters by Walsh and Jacobson and Vokrouhlický et al. in this volume), main-belt comets that provide evidence of a water reservoir that may have allowed life to thrive on Earth (e.g., Hsieh and Jewitt, 2006; Jewitt, 2012; see the chapter by Jewitt et al. in this volume), and contemporary catastrophic disruptions of main-belt asteroids that suggest that YORP driven rotational spinup might be the dominant cause of their breakup (e.g., Jewitt et al., 2010; Denneau et al., 2015). In addition, we would not have been able to measure the ages of main-belt asteroid families through fitting the characteristic Yarkovsky/YORP-induced "V" shape of the families' absolute magnitude vs. proper semimajor axes distributions (e.g., Vokrouhlický et al., 2006; see the chapter by Vokrouhlický et al. in this volume) to constrain the dynamical and collisional evolution of the main belt since its formation (e.g., O'Brien and Greenberg, 2005; see the chapters by Morbidelli et al. and Bottke et al. in this volume).

The surveys' capabilities are now so synoptic that most slow-moving objects brighter than about  $V = 21$  are routinely detected multiple times in a lunation, and will be re-detected regularly in the future, so that they require no specific allocation of resources for targeted follow-up observations. Indeed, 80% of the known main-belt asteroids with  $H < 16.5$

TABLE 1. Top 10 NEO surveys (2003–2014).

\*2.75"/pix in the 3.4, 4.6, and 12-μm channels and 5.5"/pix in the 22-μm channel.

The top 10 NEO surveys discovered >96% of all NEOs identified during the time period from January 1, 2003, through November 18, 2014. Columns are the rank and number of NEOs discovered, survey name or acronym, location of the survey site, name of the original or current principal investigator (P.I.), telescope aperture in meters, f-ratio (focal length of primary mirror divided by its aperture), FOV in square degrees, image scale in arcseconds per pixel, and site's IAU observatory code.

are now numbered, meaning that their orbits are good enough to predict their future ephemerides to within 2" for at least the next decade. On the other hand, rapidly moving, nearby NEOs that may pose an Earth impact hazard in the future usually require rapid follow-up to measure their astrometric positions (Ticha et al., 2002) over as long an arc as possible during their discovery opposition to (1) accurately assess their Earth impact hazard (e.g., Milani et al., 2005; see the chapter by Harris et al. in this volume) and (2) increase the probability that detections of the object in future apparitions can be associated with the discovery apparition observations (e.g., Milani et al., 2012; see the chapter by Farnocchia et al. in this volume).

We think that continued asteroid survey efforts in the next decades are justified in order to expand upon the rich asteroid science yield of the past decades, to provide exciting new discoveries that will generate unexpected insights into our solar system's formation and continuing evolution, and to further reduce the NEO impact hazard risk. The remainder of this chapter provides an introduction to the history of asteroid surveys before *Asteroids III*, the continuing survey improvements and their current status as of publication of this volume, the importance and state of the art of follow-up efforts, and our perspective on upcoming surveys and technologies as we look forward to *Asteroids V*.

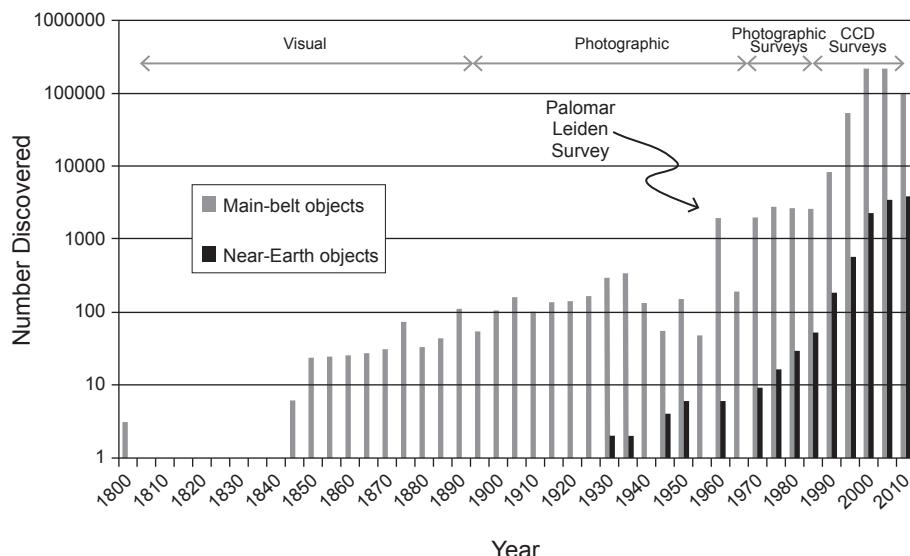

## 2. A BRIEF HISTORY OF ASTEROID DISCOVERY (PRIOR TO ASTEROIDS III)

The first asteroid to be discovered, (1) Ceres, was visually identified by Father Giuseppe Piazzi, director of the

Palermo Observatory, on the morning of January 1, 1801, the first day of the nineteenth century. Piazzi was identifying and correcting the positions of stars in an existing catalog when he noticed that one "star" in Taurus shifted position from night to night. He followed the object until February 11, 1801, but his discovery was not announced until the summer of that year. It was recovered on December 7, 1801, only after Karl Gauss, with characteristic genius, provided an elliptic orbit for (1) Ceres that allowed an accurate-enough ephemeris prediction. Three more asteroids were discovered shortly thereafter: Heinrich Olbers identified the second and fourth asteroids, (2) Pallas and (4) Vesta, in 1802 and 1807 respectively, while Karl Harding discovered (3) Juno in 1804. It was another 41 years until (5) Astraea was discovered in 1845, and the discovery rate would remain less than about one per month until about the time of the advent of astrophotography. There were only 10 known asteroids by mid-century and 447 by 1900 (see Fig. 1).

The era of photographic asteroid discovery began in 1891 when Max Wolf compared the images on three successive photographic plates to detect the motion of (323) Brucia, the first of Wolf's 321 asteroid discoveries. Trailed detections of asteroids on single long-exposure photographic plates were also used to identify asteroids and Gustav Witt discovered the trailed image of the first near-Earth object, (433) Eros, at the Urania Observatory in Berlin in 1898.

The pioneering photographic asteroid surveys in the 1970s and early 1980s marked the beginning of the modern NEO discovery era (see Fig. 1). Gene Shoemaker and Eleanor Helin began using the 18-inch Palomar Schmidt telescope in southern California for finding NEOs in 1973

**Fig. 1.** Main-belt and near-Earth object discovery statistics since 1800 in five-year intervals. The time periods corresponding to serendipitous visual and photographic asteroid discovery is indicated, as are the time periods for photographic and CCD surveys. The Palomar-Leiden Survey (PLS) (Van Houten et al., 1970) in 1960 was particularly ahead of its time as it discovered  $>10\times$  more asteroids in a few months than were being discovered over five years at the time. It took another decade before the discovery rates regularly matched the PLS rate.

and were joined by Carolyn Shoemaker in the early 1980s (*Helin and Shoemaker*, 1979). Their early photographic surveys identified asteroids using manually-operated blink comparators and stereomicroscopes that enabled visual comparison of images of the same portion of sky taken several minutes apart. The vast majority of the objects in the images were stationary stars and galaxies, but a moving NEO would be in a slightly different position on each photograph so that it would appear to jump back and forth when each image was quickly viewed in turn with the blink comparator. Alternately, the NEO's image would appear to "float" above the background stars when two different images were examined at the same time with a stereomicroscope. [For more details concerning these pioneering NEO search efforts, see, e.g., *Cunningham* (1988), *Stokes et al.* (2002), and *Yeomans* (2013)].

The surveys entered the modern era in 1984 when the Spacewatch telescope (see section 3.1) became the first survey to employ a camera with a charge-coupled device (CCD) focal plane (see Fig. 1). Their first  $320 \times 512$ -pixel CCD detector was replaced in 1989 with a large format  $2048 \times 2048$  CCD that was used for three years until they obtained a high-efficiency (~70%) thinned  $2048 \times 2048$  CCD. The system was operated for about 23 nights per month with the CCD read out in a time-efficient "drift-scanning" mode in which the right ascension axis was stationary so that the star field would drift through the telescope's field-of-view (FOV) while the CCD detector was read out at the same rate. This technique allowed the survey to image about  $200 \text{ deg}^2$  each month to a limiting V-band magnitude of  $\geq 21$ . Each scan was repeated three times with about 30 minutes separation and automated software identified moving objects in the field (*Rabinowitz*, 1991).

The NEO discovery rate increased dramatically in the late 1990s (see Fig. 1) when NASA increased the funding available for NEO surveys, partly in response to impact awareness generated by the 1994 impact of Comet Shoemaker-Levy 9 with the planet Jupiter. The perfect storm of increased funding coupled with the decreasing cost of CCDs and the availability of frame-transfer CCDs enabled the rise of the LINEAR (section 3.4) and Catalina (section 3.5) NEO surveys that dominated the modern survey era for about two decades leading up to and through *Asteroids III*.

*Stokes et al.* (2002) provides more details of the history and state of asteroid surveys leading up to *Asteroids III*.

### 3. ASTEROID SURVEYS (SINCE ASTEROIDS III)

All contemporary asteroid surveys use extremely efficient CCDs to record digital images of the sky. While CCD detectors are far more sensitive and accurate than film, their application to asteroid discovery is similar. Three or more CCD images are taken of the same region of the sky with successive images separated in time by about 30 minutes. The images are then compared in software to identify detections that have systematically moved to different positions from one image to the next. The rate of motion of the detec-

tions from one image to the next, the direction they appear to be traveling, and their apparent brightness are helpful in identifying interesting objects and can provide first-order estimates of an object's distance from Earth, its size, and its general orbital characteristics. For example, an object that appears to be moving very rapidly from one image to the next ( $>1^\circ/\text{day}$ ) is almost certainly an NEO. New NEO discoveries are usually still verified with the human eye even though sophisticated and automated software analyses of the CCD images have replaced manual identification of moving objects.

In 1998, NASA established the goal of discovering 90% of NEOs larger than 1 km in diameter, and in 2005 Congress extended that goal to include 90% of the NEOs larger than 140 m (George E. Brown, Jr. Near-Earth Object Survey Act). There are thought to be about 1000 NEOs larger than 1 km in diameter and roughly 26,000 larger than 140 m (e.g., *Granvik et al.*, 2014); see the chapter by Harris et al. in this volume). The desire to meet the NEO goals has enabled the funding and driven the success of the asteroid surveys over nearly the past two decades.

Asteroid surveys that search the largest area of sky each month will discover the most NEOs (*Bowell and Muinonen*, 1994), all other things being equal. How much sky each telescope surveys depends upon several factors, including the number of clear nights available for observing, the telescope aperture and FOV, and the sensitivity and efficiency of the CCD detector. That being said, not all regions of the sky are equally productive for discovering new NEOs (e.g., *Bowell and Muinonen*, 1994; *Chesley and Spahr*, 2004; *Vereš et al.*, 2009). Once the most effective regions are fully surveyed, it is important to extend the search to greater distances from Earth or, in other words, to fainter limiting magnitudes.

Spacebased asteroid surveys have advantages over groundbased observing in that they are not hindered by weather, can search continuously, and can observe in the infrared where asteroids are brighter and there are fewer background sources; in addition, space telescopes can observe NEOs when they are much closer to the Sun (see the chapter by Mainzer et al. in this volume). A case in point is the ~18-m-diameter asteroid that injured more than 1500 people when it airburst over Chelyabinsk, Russia, on February 15, 2013, that was not detected by groundbased surveys since it came from a sunward direction (e.g., *Brown et al.*, 2013). Of course, spacebased surveys are expensive, risky, can be data-rate-limited due to the availability and limitations of the downlink from the spacecraft to the ground, and are not repairable in the event of a major failure.

The asteroid surveys have discovered about 90% of the NEOs larger than 1 km in diameter since NASA's initiation of its NEO Observations (NEOO) program in 1998 (*Mainzer et al.*, 2011b), and a good fraction of those larger than 140 m. Progress toward meeting the goals can be monitored on the NEO discovery statistics page at <http://neo.jpl.nasa.gov/stats/>. The vast majority of those NEO discoveries were made by NASA-supported groundbased telescopic surveys,

and in the following subsections we briefly describe the major surveys that were or are operational since *Asteroids III* in roughly chronological order by start date [the Jet Propulsion Laboratory (JPL) maintains a list of NASA-supported NEO survey programs at <http://neo.jpl.nasa.gov/programs/>].

### 3.1. Spacewatch (1983–Present)

The Spacewatch team was a pioneer in digital detection of NEOs (e.g., Rabinowitz, 1991). They discovered the first NEO on digital images in 1989 and reported the first automated (software) discovery in 1990. They led the effort to automate the discovery and follow-up of NEOs, culminating in the modernization of their 0.9-m and 1.8-m telescopes, which can both be operated from a single control room by a single observer.

They began using their custom-built 1.8-m-aperture telescope for NEO surveying and follow-up in 2002. Later that same year their 0.9-m telescope was instrumented with a large-scale mosaic camera consisting of four  $4608 \times 2048$  CCDs to take advantage of its new optical system, which provides a  $2.9\text{-deg}^2$  FOV. The 0.9-m telescope's new optical configuration required that it operate in the conventional "stare" mode, whereas the 1.8-m telescope continued to be operated in the "drift-scan" mode until 2011. From 2005 through 2008, Spacewatch gradually shifted its emphasis from NEO surveying to follow-up as other surveys began to dominate NEO discovery. Finally, the imaging detector on the 1.8-m telescope was replaced in October 2011 with a stare-mode CCD with finer pixel resolution, faster readout, and flatter focus. The new camera allowed Spacewatch to increase their NEO follow-up rate by more than 50% while at the same time halving the astrometric residuals. The Spacewatch 1.8-m telescope is currently among the world's leaders in faint-object follow-up, especially in terms of critical follow-up of the most challenging faint objects.

### 3.2. Near-Earth Asteroid Tracking (NEAT) (1995–2007)

Beginning in 1995, the JPL NEAT program (Pravdo et al., 1999) operated survey telescopes on the summit of Haleakala, Hawaii, in cooperation with the Air Force. The Ground-based Electro-Optical Deep Space Surveillance (GEODSS) 1-m telescope was equipped with a  $4k \times 4k$  CCD and initially utilized 12 nights per month centered on new Moon (December 1995 to December 1996), subsequently reduced to 6 nights per month (January 1997 to February 1999). In February 2001 NEAT began using a modified 1.2-m telescope, part of the U.S. Air Force Space Surveillance System in Maui, Hawaii. Nightly pointing lists were generated at JPL for the telescope control computer in Maui and small subimages of candidate NEOs were transferred back to JPL for inspection by JPL scientists. In 2001 the NEAT program transitioned to the 1.2-m Schmidt telescope at Palomar Mountain in southern California before ceasing operations in 2007.

### 3.3. Lowell Observatory Near Earth Object Survey (LONEOS) (1993–2008)

LONEOS (Bowell et al., 1995) operated from 1993 through 2008 using the Lowell Observatory 0.6-m Schmidt telescope at Anderson Mesa near Flagstaff, Arizona. The relatively small aperture telescope was competitive because it had a large FOV of about  $8\text{ deg}^2$  instrumented with two  $2k \times 4k$  cooled CCDs. LONEOS collected four 45-s exposures of each field that were automatically searched for moving objects down to  $V \sim 19.3$ . The LONEOS system's productivity eventually declined due to competition with larger-aperture survey telescopes, so they switched their primary objective to photometric observations of NEOs and finally ceased operations in 2008.

### 3.4. Lincoln Near-Earth Asteroid Research (LINEAR) Program (1996–2013)

The LINEAR survey (Stokes et al., 2000) was operated out of Socorro, New Mexico, by the Massachusetts Institute of Technology (MIT) Lincoln Laboratory team, which was based in Lexington, Massachusetts. The legacy 1-m LINEAR telescope system is located at Lincoln Laboratory's Experimental Test Site near Stallion Range Center on the U.S. Army's White Sand Missile Range in central New Mexico. It began operations in early 1996 but was in routine use from March 1998 through May 2013. The survey used two 1-m-aperture telescopes originally designed as prototypes for Earth-orbiting debris tracking. LINEAR's success was driven by the application of electro-optical sensor technology, originally developed for U.S. Air Force Space Surveillance, to the problem of discovering near-Earth asteroids and comets. Their frame transfer CCDs allowed large areas of sky to be surveyed extremely efficiently because the camera required effectively zero readout time. Furthermore, the rapid-readout CCDs and access to fast-computing resources allowed them to apply an advanced image processing technique involving generating a median of five images of the same field and subtracting the median from the sum of the same five images to generate difference images that contained only transients and relatively few artifacts. The differenced images were then searched for transient detections moving in roughly straight lines (tracklets). During the late 1990s and early 2000s they could survey several thousand square degrees per night to  $V \sim 19$ , enabling the program to single-handedly discover more than one-third of all NEOs 1 km in diameter or larger. Lincoln Laboratory discontinued use of the 1-m system in 2013 while it transitions to the use of the 3.5-m Space Surveillance Telescope (SST) (see section 7.2).

### 3.5. Catalina Sky Survey (CSS) (1992–Present)

The University of Arizona's CSS (Larson et al., 1998) has been the primary NEO discovery system over much of the time since *Asteroids III* and has done so while remaining cost-competitive. Their success can be traced to remaining

focused on their primary objective of discovering NEOs; employing dedicated, professional, skillful observers; and standardizing equipment and software across their different sites. For instance, all the cameras at their three sites are identical, thinned,  $4\text{k} \times 4\text{k}$  back-illuminated detectors packaged by Spectral Instruments, Inc., of Tucson, Arizona, that are cooled with a closed-cycle cryocooler. The use of identical cameras has minimized hardware and software development as well as maintenance and operations costs. Their dedication to continual improvement, comprehensive sky coverage, human vetting of candidate discoveries, and onsite recovery capability have further contributed to their success over the last decade.

The CSS was preceded by the Bigelow Sky Survey (BSS), which photographically searched for new asteroids and comets between 1992 and 1996 (*Spahr et al.*, 1993, 1996). The experience gained in operating the BSS informed and motivated modifications to the telescope, camera, and software beginning in 1997 so that the CSS's CCD survey began producing observations in 1998.

The CSS has used 3 different telescopes in the past 10 years and in 2013 alone discovered 603 NEOs, easily making it the top survey program that year. Their 2 primary telescopes are the Catalina Schmidt and the Mt. Lemmon telescopes, but their third site, the Siding Spring Schmidt in Australia, has delivered enough NEOs to place it in the top 6 NEO discovery sites in each of the past 10 years. About 20% of CSS observing time is devoted to post-discovery follow-up observations (see section 5).

The Catalina Schmidt in the mountains north of Tucson, Arizona, was upgraded to a f/1.8, 0.7-m telescope from 2003 to 2004, which increased their sensitivity to  $V \sim 20.0$ . Its  $8.2\text{-deg}^2$  FOV enabled the site to survey 1000 to 1500 deg $^2$  per night and vaulted the CSS program into the lead in terms of annual discoveries.

In 2004–2005 the CSS team procured a  $4\text{k} \times 4\text{k}$  CCD and then built and installed a prime-focus camera that delivers a  $1.2\text{-deg}^2$  FOV on their Mt. Lemmon 1.5-m telescope. Its limiting magnitude reaches  $V \sim 21.5$  under good conditions and they can survey  $\sim 200$  deg $^2$  on an average night. This survey excels at finding very small objects that are very close to Earth (*Jedicke et al.*, in preparation) and demonstrates the need to shift to larger optical systems in order to complete the inventory of smaller, yet still threatening, NEOs. For example, the CSS identified the only two Earth impactors that were discovered in advance of impact [2008 TC (*Kowalski et al.*, 2008) and 2014 AA (*Kowalski et al.*, 2014)].

The 0.5-m Uppsala Schmidt telescope at Siding Spring, Australia, was operated by the CSS for several years when it was the only NEO survey in the southern hemisphere. However, in 2013 the Australian dollar became much stronger relative to the U.S. dollar-based funding from the NASA NEOO program compared to when the survey was established. The combination of the exchange rate shift and the telescope's modest aperture and FOV reduced the cost-effectiveness of the survey compared to the CSS's northern

hemisphere assets, and the decision was made to end support for this facility.

### 3.6. Panoramic Survey Telescope and Rapid Response System (Pan-STARRS) (2010–Present)

The 1.8-m Pan-STARRS1 (PS1) (*Wainscoat et al.*, 2013) telescope on Haleakala, Hawaii, was developed by the University of Hawaii's Institute for Astronomy and operated by the PS1 Science Consortium (PS1SC) until early 2014. It was the prototype telescope for the four-telescope Pan-STARRS system (*Kaiser et al.*, 2002), which was supposed to be operational late in the last decade but may never be completed. The PS1 CCD camera was the largest in the world when it was originally built, with a focal plane consisting of an almost complete  $8 \times 8$  array of CCDs (the four corner CCDs were left out of the focal plane) with a total of about 1.4 gigapixels. The large focal plane combined with the system's f/4 optics yields an  $\sim 7\text{-deg}^2$  FOV that has moved PS1 to be the leading PHO discovery site beginning in calendar year 2012. In 2014 it will discover about 4× more PHOs than the second most successful site.

The first PS1 NEO discoveries were recorded in the second half of 2010 but only about 5% of the observing time was devoted to NEO discoveries at that time. The NEO survey time fraction was increased to 11% beginning in November 2012. In addition, 56% of the observing time was used for a “ $3\pi$ ” sky survey in three filters that was also executed in a manner that led to the discovery of NEOs. The time devoted to the NEO search was increased to 100% beginning in April 2014 with funding provided by NASA's NEOO program after the end of the PS1SC.

PS1's strength lies in having the faintest magnitude limit of any active NEO survey, reaching  $V \sim 22$  under good conditions. This allows the team to discover NEOs that are too faint to be detected by the other systems. Their excellent site in the middle of the Pacific Ocean allows PS1 to survey the “sweet spots” near the Sun where the sky-plane PHO density is highest if the system can reach fainter than  $V \sim 21$  (*Chesley and Spahr*, 2004; *Vereš et al.*, 2009).

PS1 developed a sophisticated image processing pipeline (IPP) (*Magnier*, 2006) that feeds transient detections to the Moving Object Processing System (MOPS) (*Denneau et al.*, 2013), which uses kd-trees to quickly link transient detections into tracklets (*Kubica et al.*, 2007). The final observations are extremely accurate with astrometry good to  $\lesssim 0.1''$  (*Milani*, 2012), which allows the MPC to tightly constrain NEO orbital solutions and uncertainty maps to facilitate the recovery of PS1 NEO candidates.

### 3.7. Near Earth Object Wide-field Infrared Survey Explorer (NEOWISE) (2010–Present)

The NEOWISE program (e.g., *Mainzer et al.*, 2011a; see also the chapter by Mainzer et al. in this volume) observes and discovers NEOs and other asteroids in the near-infrared

(IR) with the 0.4-m telescope onboard the Wide-field Infrared Survey Explorer (WISE) spacecraft (e.g., *Cutri et al.*, 2012; *Wright et al.*, 2010). The spacecraft was launched on December 14, 2009, into a “Sun-synchronous” polar orbit around Earth (the spacecraft’s orbital plane is always roughly perpendicular to the Earth-Sun line) and as it orbited it continuously surveyed a 47'-wide strip of sky in the opposite direction from Earth. WISE operated for 10 months in 2010, performing an all-sky astronomical survey in four bands centered at 3.4, 4.6, 12, and 22  $\mu\text{m}$ . When the hydrogen coolant for the two longest wavelength detectors was exhausted, a secondary post-cryogenic mission continued for four more months using just the two shorter-wavelength detectors, and then the spacecraft was decommissioned and hibernated on February 17, 2011. After more than two-and-a-half years the spacecraft was awakened from hibernation and NEOWISE was reactivated in September 2013 for a planned three-year observing period using just the 3.4- $\mu\text{m}$  and 4.6- $\mu\text{m}$  passbands (*Mainzer*, 2014). Its first NEO discovery in the new operational phase, 2013 YP<sub>139</sub>, occurred on December 29, 2013.

NEOWISE’s Sun-synchronous survey mode imposes a time limit of about 36 hours during which images at a specific location can be acquired. Hence, the program requires groundbased NEO candidate follow-up by a dedicated network of amateur and professional astronomers to secure their orbits (see section 5). NEOWISE also detected tens of thousands of known asteroids in the IR that allowed diameter measurements of thousands of objects, thus enabling a range of studies of the origins and evolution of the small bodies in our solar system [e.g., NEOs (*Mainzer et al.*, 2011b), main-belt objects (MBOs) (*Masiero et al.*, 2014), and Jupiter Trojans (*Grav et al.*, 2012; see also the chapter by Mainzer et al. in this volume)].

### 3.8. Other Contributions

Amateur astronomers have historically played a role in advancing the astronomical fields, but their contribution to NEO discovery has been limited due to their access to telescopes of relatively modest apertures. From 1998 through 2013 only about 1.8% of the 10,044 discovered NEOs were found by the amateur community. The most productive team was the Las Sagra Survey (LSS) operated in Spain by J. Nomen, R. Stoss, and others. They discovered 79 NEOs prior to being funded professionally by the European Space Agency (ESA) for space debris tracking. During the same time period only 99 other NEOs were discovered by amateurs from the rest of the world combined.

A small number of asteroids are discovered serendipitously by professional observers or other astronomical surveys in the course of their work that is not always primarily associated with asteroids. For instance, the International Scientific Optical Network (ISON) (*Molotov*, 2010) is designed to identify and track Earth-orbiting space-debris, but its capabilities naturally serve asteroid identification pro-

cesses, as illustrated by their discovery of the spectacular Comet ISON (C/2012 S1). Similarly, the Palomar Transient Factory (PTF) (e.g., *Polishook and Ofek*, 2011) is an all-sky astronomical survey designed to identify transient and variable objects that has also identified many asteroids and NEOs.

## 4. THE MINOR PLANET CENTER (MPC)

All the candidate detections of minor planets identified by the surveys are delivered to the Minor Planet Center (MPC) (<http://minorplanetcenter.net>) — the IAU’s official international repository and distributor of asteroid astrometric observations, minor planet orbits, and identifications. The MPC’s goal is to identify and/or link all reported minor planet observations in nearly real time. This is a challenging process because the MPC has experienced a 7 $\times$  increase in reported observations over the time since *Asteroids III* (see Fig. 1) and the time required for orbit determination and linking increases faster-than-linearly with the number of observations in the database. Fortunately, Moore’s Law and the implementation of improved operational procedures have allowed the MPC to handle the increased data and analysis rate. Today, the MPC can automatically and seamlessly receive and process a few million observations of a few hundred thousand minor planets each day from both ground- and spacebased observatories.

The MPC concentrates on expeditiously processing NEO discoveries and observations because they are of interest to NASA and the public. Ephemerides need to be provided promptly so that follow-up telescope facilities can quickly recover the objects. The MPC checks all reported NEO candidate “tracklets” (sets of detections that are claimed to be of the same object) for identification with known objects, computes the likelihood that unknown objects are new NEOs, and posts the best candidates on the NEO Confirmation Page (NEOCP) for follow-up (the NEOCP is available at <http://www.minorplanetcenter.net/iau/NEO/ToConfirm>; follow-up efforts are described in section 5). The ESA’s NEO Coordination Centre also maintains a parallel and prioritized follow-up list at <http://neo.ssa.esa.int/web/guest/priority-list>.

The NEOCP was handily validated in October 2008 when the MPC identified a CSS discovery that would impact Earth only 20 hours after discovery (*Kowalski and Chesley*, 2008). The international network of observers monitoring the NEOCP quickly responded (see section 5) and reported more than 800 astrometric observations, multiple light curves, and even a spectrum, over a timespan of less than a day. As a result of this coverage JPL predicted that the object now known as 2008 TC<sub>3</sub> would impact in a small desert area in northern Sudan. This prediction was subsequently confirmed by visual and satellite reports and with the collection of meteorite fragments on the ground (e.g., *Jenniskens et al.*, 2009; see also the chapter by Jenniskens in this volume).

The MPC’s database (see Table 2) mostly contains optical observations of main-belt asteroids even though much of the MPC’s time and effort is devoted to dealing with

TABLE 2. Minor Planet Center holdings as of November 6, 2014.

Type	Objects
Numbered	415,688
Multi-opposition	133,306
Single-opposition	115,042
Two-night	~165,000
One-night	$\mathcal{O}(3,000,000)$

The MPC data files contained a total of 118,328,160 observations as of November 6, 2014.

NEOs. As of this writing there are almost 400,000 minor planets classified as “numbered” (most of them in the main belt), meaning that their orbits are of sufficient accuracy that their ephemeris uncertainties in the next decade are no more than a few arcseconds. To be numbered, an object usually needs to be observed over a period of at least four oppositions with detections on more than one night in most of the apparitions. This rule of thumb applies to MBOs that typically have only optical sky-plane positions — NEOs may have secure orbits with just two apparitions of data because of the power of parallax for nearby objects to reduce the uncertainty on the orbit elements. Similarly, the range and range-rate accuracy available with radar may be combined with optical observations from just a single apparition to yield good orbits (e.g., Ostro *et al.*, 2004). In total, the numbered objects have increased by more than a factor of 10 since *Asteroids III* and about 90% of those objects were discovered by just 10 surveys or sites (see Table 3). Many of the objects that are now numbered were discovered more than a decade ago, before *Asteroids III*, because it requires about 10 years before a typical MBO has been detected in enough apparitions to allow it to be numbered. Thus, the tremendous number of new discoveries by contemporary NEO surveys (see section 3) will only be numbered as this decade progresses toward the publication of *Asteroids V*.

The unfortunate reality of the difference between the capabilities of professional and amateur facilities is that only 0.6% of the numbered objects in the top 10 list were contributed by amateur observatories. Eight of the top 10 most productive programs are, or were, funded directly by NASA specifically for discovery or follow-up of NEOs. Thus, it is clear that the discovery of minor planets is almost uniquely a NASA-funded survey effort based in the U.S. Indeed, fully 80% of the discoveries were realized at just a handful of NASA-funded NEO search programs led by the LINEAR program (see section 3.4).

The MPC database contains observations and orbits of objects that were detected in multiple oppositions, a single opposition, and even on only two nights. The sum total of all these objects is currently comparable to the number of numbered objects (see Table 2). The accuracy of the ephemerides for each successive class of objects decreases dramatically such that single-opposition orbits might be suitable for predicting the location of the object for only

TABLE 3. Top 10 asteroid discovery surveys (of all time).

Rank	Survey or Observer	Obs. Code	Discoveries	Operations
1	LINEAR	704	141,577	1997–2010

\*Belgian professional astronomer.

Rankings are from September 14, 2014. Columns are the rank of the survey in terms of the number of asteroid discoveries credited to the survey; survey name, acronym, or observer, site’s IAU observatory code; current number of asteroid discoveries credited to the survey; and time period of survey operations.

another 1 or 2 years while objects observed on only 2 nights can typically only be used for about 10 days.

Finally, the MPC maintains a publicly available file of all single-night detections that currently cannot be linked or identified with other minor planets. This file, pejoratively dubbed “One Night Stand” (ONS) by Brian Marsden in the mid 1990s, now contains over eight million observations. While it is likely that many of the observations in this file represent duplicates, false detections, and errors, it is also likely that the file includes several hundred thousand uncatalogued minor planets. The MPC currently employs a graduate student (J. Myers, University of Arizona) who is developing advanced linking techniques to extract as many objects as possible from the ONS file, but it will always contain a high fraction of unlinkable and likely false detections.

One challenge at the MPC is linking and processing datasets of very different observational quality. For example, the mean astrometric residual for observations prior to the CCD era (ca. 1995) is about 1–2”, while residuals from the modern Pan-STARRS program (section 3.6) are ~0.1” — an improvement of a factor of 10 to 20! Even today, the mean residuals for survey data from the professional surveys range from about 0.05” to 0.7”.

## 5. ASTROMETRIC FOLLOW-UP, RECOVERY, AND PRECOVERY

Modern survey telescopes are specifically designed to have a wide FOV and rapid readout in order to image as much sky as possible, so using them for targeted follow-up of specific objects is an inefficient use of their capabilities. Instead, the surveys identify and report likely asteroid tracklets to the MPC on a nearly real-time or nightly basis and then continue to survey the sky for other candidates. They rely on other “follow-up” facilities to obtain more observations of the objects for verification and to secure their orbits. Follow-

up usually refers to obtaining astrometric and photometric observations of an object to secure its orbit and determine its absolute magnitude, but may also include various types of “physical characterization,” including obtaining an object’s light curve to determine its rotation rate and, perhaps, shape, or spectra to determine its taxonomy (and mineralogy). This chapter and subsection will concern itself almost exclusively with astrometric follow-up.

The most challenging follow-up is for the NEOs. More distant objects tend to move slowly so that their ephemeris uncertainties are relatively small and, in any event, they will be redetected in the course of normal ongoing survey operations. The first detections of a new candidate NEO typically span a temporal arc of less than an hour and represent just the beginning of the lengthy and complex discovery process. First, the candidate must be confirmed as being a real and unknown object — it is not uncommon for reported candidates to be false because of processing errors such as mislinking of two different asteroids or combining false detections in an image into a false tracklet. Once an object is established as being real and recoverable, discovery observations must be followed by an observational campaign to establish the object’s orbit with enough accuracy to enable it to be “recovered” in the future. (Recovery is the process of obtaining new observations that can be attributed to an object.) The extension of the observed arc is essential for more accurate orbit determination, which leads to a better understanding of the object’s dynamics either because of its scientific interest or because of its possible impact threat to Earth (e.g., Milani *et al.*, 2000). Some candidate NEOs may be real but are moving so fast that they are effectively unrecoverable due to timing considerations, weather, and/or ephemeris uncertainties.

The most critical follow-up takes place within about three days of discovery because the initial observations are usually insufficient to even broadly identify the orbital properties of the new object. This is because a small number of observations by a single observatory over a short timespan do not contain enough information to determine the geocentric distance of the object — they contain very little parallax information and, as a result, ephemerides rapidly become extremely uncertain or useless. Obtaining follow-up observations of an asteroid is so essential that only those with confirmatory observations are eligible for official designation and assignment of discovery credit by the MPC.

An illustration of the need for rapid follow-up is asteroid 2014 JR<sub>24</sub>, which was discovered at magnitude V ~ 17.2 on May 6, 2014, by the CSS. Its diameter is in the 4–8-m range (based on its absolute magnitude, H = 29.3), and it made a close approach to Earth of about 0.3 lunar distances on May 7, 2014, when it reached a peak magnitude of V ~ 15.6. Although some astrometric follow-up was obtained, there was no physical characterization of this interesting close flyby and potential radar target, and its apparent magnitude dropped to V ~ 27 within three days of discovery, thereby eliminating the opportunity for further follow-up. It will not have a favorable apparition for more than a decade, at which time the recovery will necessarily be serendipitous because the ephemeris uncertainty will be large.

There are a variety of assets for follow-up of recently discovered asteroids ranging from self-funded, highly-productive, submeter-class telescopes (e.g., *Birtwhistle*, 2009), to NASA-funded 1–2-m-class telescopes, and, increasingly common, even access to “big glass” in the 4–8-m range (*Abell*, 2013) for characterization studies (Table 4). FOVs for the facilities extend from arcminute scales to about a

TABLE 4. Top 10 asteroid astrometric follow-up sites (2011–2014).

Observatory	Obs. Code	Location	Lead(s)	Telescope(s) Aperture	Limiting V mag	NEOs Total 2011–2014	NEOs V > 20 2011–2014

The sites are ranked and listed by total number of NEOs observed at each observatory from June 2011 through June 2014. Columns are the observatory name or acronym; site’s IAU observatory code; site’s location; name of the current lead, observer, or principal investigator; telescope aperture in meters; limiting magnitude in the V band; total number of NEOs observed during the four years from 2011 to 2014 inclusive; and number of NEOs observed at each facility with V > 20 (and fraction of NEOs with V > 20). The last column is provided to illustrate that some facilities excel at faint object follow-up.

degree; bigger fields facilitate astrometric follow-up when ephemeris uncertainties are large. The Astronomical Research Observatory (ARO), located in Westfield, Illinois, currently tops the NEO follow-up list while at the same time contributing to astronomical education and public outreach by involving amateur astronomers and students. They have recently included a southern hemisphere site at Cerro Tololo, Chile, to follow up objects that are too far south for most of the follow-up facilities that are located in the northern hemisphere. Large-aperture telescopes with faint limiting magnitudes that can gather good signal-to-noise detections even through thin clouds are valuable tools for faint objects or when weather conditions are less than optimal (e.g., Mauna Kea and Magdalena Ridge in Table 4). Unfortunately, these large-aperture observatories are typically only available for follow-up on a few nights per lunation because they are not dedicated NEO facilities. The researchers and sites within the University of Hawaii network (*Tholen et al.*, 2013; *Wainscoat et al.*, 2013) give preference to follow-up of NEO candidates discovered with the PS1 telescope using their 2-m-class and larger telescopes on Mauna Kea, a big advantage for follow-up of the smaller/fainter objects being discovered by PS1. The Magdalena Ridge Observatory's (MRO) fast-tracking 2.4-m telescope (*Ryan et al.*, 2002), located in New Mexico, has the ability to accurately track rapidly moving targets that is essential for follow-up of challenging faint objects or for physical characterization (i.e., to keep the moving object on the spectrograph's slit). MRO performs follow-up astrometry and real-time characterization (spin rates and composition), achieves subarcsecond point spread functions (PSFs) even close to the horizon (pushing the limits to lower declinations than typical for the northern hemisphere), and can have multiple instruments mounted simultaneously (for rapid switching between photometry and spectroscopy).

It is common, natural, and unfortunate that a recently discovered object receives a lot of attention primarily during the few days after discovery when often hundreds of astrometric and physical observations are collected by professional and amateur observers. The attention is explicable because objects tend to be discovered near a maximum in apparent brightness so that all aspects of follow-up are easier. However, the major determinant in orbit-element accuracy is the temporal coverage, not the number of observations; i.e., there is an opportunity cost of too many observations because most of them will not contribute to improving the orbit. It is therefore desirable that observers that have access to large-aperture telescopes obtain astrometric measurements of the most important targets down to the limiting magnitude of their instrumentation [e.g., V ~ 26 for 8–10-m-class telescopes such as that achieved in the ESA's efforts with the Very Large Telescope (VLT) (*Micheli et al.*, 2014) and Large Binocular Telescope (LBT)]. Only this additional optical and orbital-arc coverage will make it possible to determine an orbit accurate enough to recover the object in its next apparition, which may be many years or even decades in the future, unless radar data are available (e.g.,

*Ostro et al.*, 2004). The wasted effort and lack of temporal coverage for important objects suggest that there is a need in our community for an enhanced follow-up coordination effort beyond the current capability of the NEOCP. A centralized scheduling site that assigns available observing sites to specific targets based on weather, limiting magnitude, location, etc., could increase the efficiency of the overall follow-up effort (we note that this effort could be a component of the “Management Action” called out by NASA’s Office of Inspector General’s report on the NEO effort; IG-14-030, September 15, 2014). The ESA NEO Coordination Centre is already coordinating follow-up observations of high-relevance targets by a worldwide network of cooperating observatories by providing them with rapid triggers when an observational opportunity arises appropriate for their systems. Over the past year their coordination efforts have contributed to the removal of 20 high-rated virtual impactors from their impact risk list.

The subsequent recovery of an object in a future apparition, enabled by a well-orchestrated follow-up effort in the discovery apparition, would result in a dramatic decrease in its orbit-element uncertainty and correspondingly extend the ephemeris accuracy for decades into the future. However, in some (rare) cases an object’s dynamics may be so complex that, even then, predicting its motion is nontrivial. This often occurs when there are future close encounters with major planets or when nongravitational forces become relevant. In these cases, observational coverage extending over multiple apparitions is often necessary to model the phenomena to a sufficient level of accuracy to accurately predict the object’s future behavior (e.g., *Farnocchia et al.*, 2013; *Chesley et al.*, 2014; see also the chapter by Farnocchia et al. in this volume).

The rationale for, and scientific benefits of, observations of asteroids at the Arecibo radar facility (Puerto Rico) and Goldstone Deep Space Network (California) are unassailable, but radar follow-up and characterization is expensive in time and resources. Radar directly and uniquely provides range, range-rate, shape, spin, and size data that complement the optically derived physical information (e.g., *Ostro and Giorgini*, 2004) and enables computation of asteroid ephemerides much further into the future than ephemerides derived from optical-only astrometry because of radar’s exquisite precision in measuring the object’s range and range-rate. However, the only way that a radar facility can detect an object is with an accurate orbit provided by optical assets. Thus, radar is typically employed only for the most “interesting” objects.

The follow-up effort is more complicated for spacebased discoveries (e.g., from NEOWISE; see the chapter by Mainzer et al. in this volume). Delays in posting the candidate NEO’s ephemerides caused by scheduling the Deep Space Network for data transmission from the spacecraft (by several days) can result in untenable ephemeris errors. Furthermore, if an NEO has been discovered in a passband that is not a groundbased standard (e.g., an IR space telescope), then the transformation from the spacecraft’s passband to groundbased passbands can generate significant errors in the predicted apparent magnitudes. The apparent magnitude can

be much fainter than expected if the object is of low albedo (dark), such that acquiring good signal-to-noise detections for the object is difficult or impossible from the ground. Future wide or deep spacebased surveys will need to carefully consider groundbased follow-up requirements or build self-follow-up into their survey strategy.

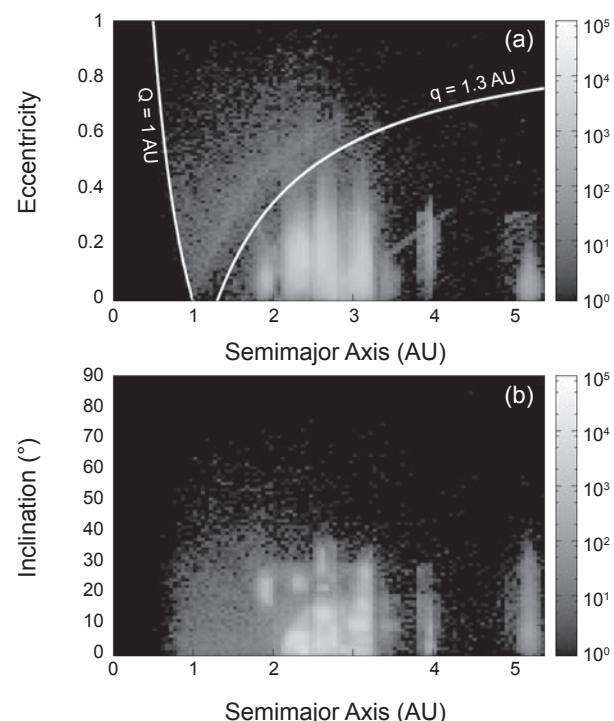

The future needs for asteroid follow-up and rapid physical characterization are clear — neither will keep pace with the expected discovery rates of future surveys (see section 7). The mean V-magnitude of asteroids at discovery is now about 20, which limits follow-up and characterization sites to professional telescopes or a handful of the most advanced amateur astronomers. As the capabilities of the ground- and spacebased survey telescopes continue to improve, pushing the mean discovery magnitude to even fainter values, the follow-up contribution from the amateur community will drop. This will require the survey telescopes to adopt self-follow-up survey strategies that reacquire their own discoveries several times per month. Indeed, the advent of deep *and* wide surveys has changed the cost-benefit analysis of separating surveying and follow-up such that it may now simply be more efficient to do both with the same system in an integrated discovery and follow-up survey program. The reobserving strategy will reduce the possible discovery rate, but the good news is that the strategy will extend the main-belt minor planet catalog to much smaller sizes.

In many important cases it has been possible to dramatically increase the known arclength for an object that has become unobservable by identifying “precovery” observations in historical images. Over the last decade most professional observatories and surveys have developed online repositories of all their astronomical images, including digitizing very old photographic plates with associated astrometry and photometry of all sources in the images. Most of the images were acquired for projects unrelated to asteroids, but some of them contain unrecognized detections of known asteroids. The most obvious example is the MPC’s ONS file (section 4), which is automatically searched by the MPC for precoveries when feasible. In other cases, and increasingly more commonly, a survey’s archival detection database can provide precovery observations. Although the survey’s images were already inspected for moving objects, there may be cases where an object was too faint to be detected or reported with confidence, but a precovery tracklet can be identified given a new object’s ephemeris. The success of the precovery efforts coupled with the relatively modest cost of archiving images suggests that surveys should “save all the bits,” i.e., every bit of every pixel of every image should be stored and, even better, searchable and accessible in an online repository.

## 6. POPULATION STATISTICS

We tend to think of distinct populations of asteroids in the inner solar system even though we know that they are actually interrelated. For instance, the NEOs are fragments created in the collisions of main-belt asteroids that have been

transported to near-Earth space by orbital evolution driven by gravitational dynamics and thermal recoil forces (e.g., see the chapter by Binzel et al. in this volume). Furthermore, we are now beginning to understand that many main-belt asteroids may be implanted objects that were originally formed elsewhere in the protosolar system. Thus, in this section we attempt to address inner solar system asteroids holistically, providing orbit-element distributions of NEOs, MBOs, and Jupiter’s Trojans on the same scales and figures and touch upon the transfer of objects between them (Fig. 2). That being said, we cannot avoid the conventional nomenclature for the populations, so when we refer to NEOs, we explicitly mean those objects with perihelion  $q \leq 1.3$  AU and

**Fig. 2.** (a) Eccentricity and (b) inclination vs. semimajor axis for all known asteroids in the inner solar system available in the MPC database as of June 8, 2014. Note that the completeness, the fraction of the actual population that is known, varies as a function of semimajor axis, so these images do not provide a good representation of the actual distribution of asteroids (see Fig. 3). The clump of objects with  $2 \text{ AU} \leq a \leq 3.5 \text{ AU}$  are the main-belt objects and the clump just under  $4 \text{ AU}$  are the dynamically separated Hilda population. The group just beyond  $5 \text{ AU}$  are the Jupiter Trojan objects (JTO). The near-Earth objects are those above the (solid white)  $1.3\text{-AU}$  perihelion line in (a). Objects on the left of the aphelion line at  $1 \text{ AU}$  in (a) have orbits entirely inside Earth’s orbit. The enhancement of NEOs along the  $q \sim 1 \text{ AU}$  curve in (a) is an observational selection effect that makes it easier to detect those objects from Earth. The “diagonal feature” in (a) near  $a = 3.7 \text{ AU}$  and  $e = 0.2$  are all WISE spacecraft discoveries that lack proper follow-up observations and only have a very rough, eccentricity-assumed orbit.

semimajor axis  $a < 4.2$  AU. The MBOs are defined as those with  $q > 1.3$  AU and  $a < 4.8$  AU, while jovian Trojan objects (JTO) have  $q > 4.2$  AU and  $4.8 \text{ AU} < a < 5.4$  AU.

In what follows we will frequently refer to “unbiased” and “debiased” distributions. We use the term “unbiased” to refer to the true distributions, whereas “debiased” means that the observed distributions have been corrected for observational selection effects. A perfect debiasing procedure would lead to identical unbiased and debiased distributions. We can only provide unbiased distributions in circumstances for which there is evidence that the entire population is already known, e.g., main-belt asteroids larger than 10 km in diameter. A good introduction to various types of selection effects is given by Jedicke *et al.* (2002) and recent advances for quantifying these effects are described by Jedicke *et al.* (in preparation).

We will present the asteroid’s absolute-magnitude ( $H$ ) distributions in terms of their cumulative number,  $N(< H) \propto 10^{\alpha H}$ , where  $\alpha$  is referred to as the “slope.” When available or appropriate, we may provide the diameter ( $D$ ) number distribution, where  $N(> D) \propto D^{-b}$  and  $b$  is also called the “slope.” Both the  $H$  and  $D$  versions are often colloquially referred to as the “size” distribution. The slopes are generally not constant with  $H$  or  $D$  but are often approximately constant over some intervals. The two slope parameters are related by  $b = 5\alpha$  under the assumption of a constant albedo within a population.

## 6.1. Near-Earth Objects

The Bottke *et al.* (2002) NEO population model has been extremely successful for the past 12 years, especially considering that it was calibrated with only 137 known NEOs. Their modeling approach utilized dynamical constraints provided by the orbital-element “residence-time” distributions for NEOs originating in different source regions (essentially likelihood maps in orbital-element space). The only notable improvement to the model was the recalculation of the residence-time distributions by Greenstreet *et al.* (2012a) using smaller timesteps and more particles to reduce the statistical noise and provide an improved orbital model. They did not refit the observed NEO population but provided an improved NEO model using the Bottke *et al.* (2002) source weights and slope ( $\alpha = 0.35$ ) of the  $H$  distribution. The Greenstreet *et al.* (2012b) NEO model suggested that there exist dynamical pathways from prograde MBO orbits to retrograde NEO orbits and estimated that there are about four  $H < 18$  NEOs on retrograde orbits at any time. They also concluded that one of the currently known retrograde NEOs is likely an asteroid rather than a comet.

Preliminary results from the WISE mission suggested that there are  $981 \pm 18$  NEOs with  $D > 1$  km and that the cumulative diameter distribution could be represented by a broken power-law with  $b = 5$  for  $D > 5$  km,  $b = 2.1$  for  $1.5 < D < 5$  km, and  $b = 1.32 \pm 0.14$  for  $D < 1.5$  km (Mainzer *et al.*, 2011b). Their subsequent preliminary analysis (Mainzer *et al.*, 2012) of the four NEO subpopulations

(Atiras, Atens, Apollos, and Amors) suggested that there are fewer high-inclination Aten asteroids than predicted by Bottke *et al.* (2002), a result that was soon verified by Greenstreet *et al.* (2013).

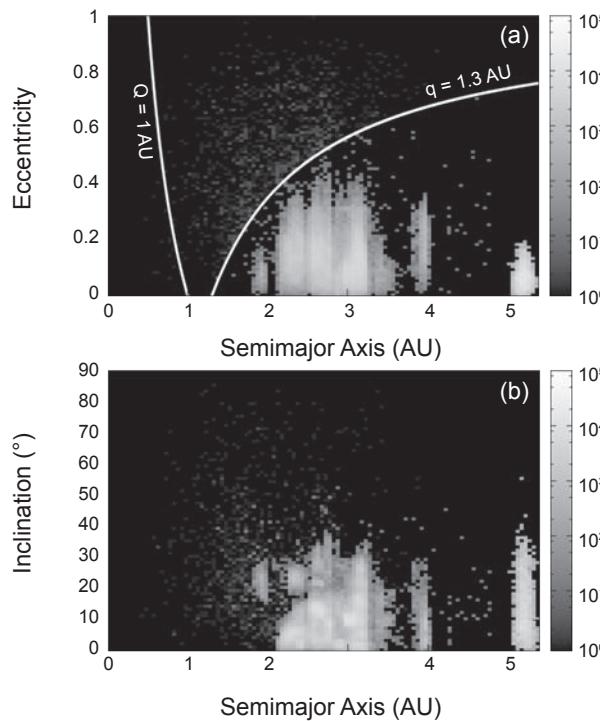

Zavodny *et al.* (2008) derived the absolute-magnitude and orbit distribution for Atiras — objects orbiting the Sun entirely inside the orbit of Earth (IEO) — using data obtained by the CSS. They found that the Bottke *et al.* (2002) NEO orbit distribution is consistent with the CSS observations and derived a nearly independent measurement of the slope of the absolute magnitude distribution ( $\alpha = 0.44^{+0.23}_{-0.22}$ ), again, consistent with both Bottke *et al.* (2002) and Stuart (2001).

Temporarily captured natural Earth satellites are a recently recognized NEO subpopulation (Granvik *et al.*, 2012). The average length of capture in the Earth-Moon system is about 9 months for these “minimoons” and the largest object at any given time has a diameter of about 1 to 2 m assuming that their size distribution follows that observed for small Earth-impacting asteroids (Brown *et al.*, 2002, 2013). Only one minimoon has been positively identified [2006 RH<sub>120</sub> (Kwiatkowski *et al.*, 2009)] due to their small sizes and rapid sky-plane motions, but the discovery rate will most likely increase in the future as the next generation of asteroids surveys come online (Bolin *et al.*, 2014) (see section 7).

Figures 3 and 4 illustrate the orbit and absolute-magnitude distributions for NEOs from the preliminary work of Granvik *et al.* (2014) because (1) they used the largest currently available single-survey NEO dataset (from CSS) and (2) their work is an independent data product in the sense that its development did not rely on any other NEO models; i.e., the WISE measurements were debiased assuming the orbital distribution by Bottke *et al.* (2002), and Greenstreet *et al.* (2012b) also used the source ratios and size distributions from Bottke *et al.* (2002). The Granvik *et al.* (2014) estimate for the number of  $H < 18$  NEOs agrees with Stuart (2001), and the number of  $H < 17.75$  NEOs is consistent with the number of  $D > 1$ -km NEOs predicted by Stuart and Binzel (2004) and Mainzer *et al.* (2011b). The advantage of using the results of Granvik *et al.* (2014) is that they provide (1) the debiased ( $a, e, i$ ) orbital-element distributions and (2) an extended range in the debiased absolute magnitude number distribution to  $H = 25$ . The functional form of their  $H$  distribution allows for a “wave” (a nonconstant slope) as suggested by, e.g., Harris (2013), but does not require it. They also allow a different  $H$  distribution for each of their seven source regions so that the observable NEO  $H$  distribution is the sum of seven analytic functions and the NEO orbit distribution changes slightly as a function of  $H$ .

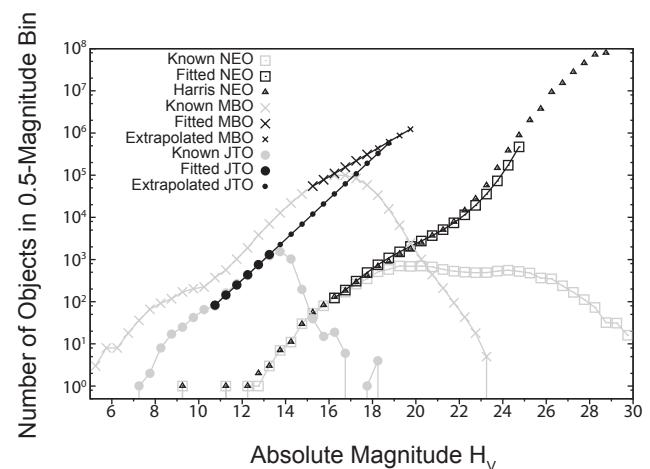

## 6.2. Main-Belt Objects

It is challenging to develop debiased size and orbit distributions for MBOs that extend to sizes smaller than the completeness level [currently about  $H \sim 17$  (Denneau *et al.*, 2015)] because asteroid families induce discontinuities into the distributions and, contrary to NEOs, MBOs are not replenished from outside sources. In other words, the MBO

**Fig. 3.** Debiased (a) eccentricity and (b) inclination vs. semimajor axis for asteroids with  $H < 18$  in the inner solar system. For NEOs we use the Granvik et al. (2014) model. For MBOs and JTOs we assume a negligible correlation between orbital elements and size, and extrapolate the orbit distribution from the assumed completeness levels of  $H = 15$  and  $H < 12.5$ , respectively, using the slopes shown in Fig. 4. The total number of NEOs, MBOs, and JTOs with  $H < 18$  are predicted to be about 1500, 1,300,000, and 600,000, respectively. The near-Earth objects are those above the 1.3-AU solid white perihelion line in (a). Objects on the left of the aphelion line at 1 AU in (a) have orbits entirely inside Earth's orbit.

population is not in a steady state — it continues to erode through collisional grinding, and dynamical- and radiation-induced orbit evolution. There are two population models for the MBO orbit and absolute-magnitude distributions: the Statistical Asteroid Model (SAM) (Tedesco et al., 2005) and the Pan-STARRS Synthetic Solar System Model (S3M-MBO) (Grav et al., 2011a). Both models were developed by starting from the unbiased orbital-element distribution of large MBOs. The MBOs were extrapolated to smaller sizes assuming a negligible correlation between size and orbit, and that the slope of the H-distribution is constant beyond the H completeness limit at the time of the model's development. The S3M-MBO uses a single slope for all subcomponents of the main asteroid belt, whereas SAM employs different slopes for each of 15 families and 3 background populations. The maximum absolute magnitude in the S3M is correlated with perihelion distance so that it only contains synthetic objects that can reach  $V < 24.5$  at perihelion at opposition, i.e., those that might be detectable by the four-telescope

**Fig. 4.** Known, fit, and extrapolated H-distributions of NEOs, MBOs, and JTOs. The “known” population is the number of objects in the MPC database as of June 8, 2014. The “fitted” populations represent the debiased distributions over specific H ranges for NEOs and MBOs as derived by Granvik et al. (2014) and Gladman et al. (2009), respectively. The “Harris” NEO HFD is provided for reference and described in the chapter by Harris et al. in this volume. For JTOs we use a slope of  $\alpha = 0.48$  and assume that there are  $10^6$  JTOs with  $H < 18.5$  — the slope is slightly shallower but still in statistical agreement with that derived by Szabo et al. (2007). The NEO H-distribution has to become shallower for  $H > 25$  to match the bolide data (Brown et al., 2013). The “extrapolated” populations for MBOs and JTOs are simple linear extensions of the HFD to larger H (smaller diameters) for the purpose of comparison with the other populations in an extended H range.

Pan-STARRS, equivalent to modeling all objects in the main belt with  $D \geq 300$  m but including objects as small as 100 m in diameter on the inner edge. SAM attempted to reproduce the distribution of all MBOs with  $D > 1$  km.

While these models are the most comprehensive MBO models to date, they represent only the first steps in modeling this complex population. The actual population at the smallest sizes and most extreme orbits cannot be simply extrapolated from larger objects and more common orbits, as demonstrated by:

- *Subkilometer Main-Belt Asteroid Survey (SMBAS):* The SMBAS (Yoshida et al., 2003) with the Subaru telescope demonstrated that the cumulative size distribution slope is shallower for subkilometer MBOs ( $0.5 \text{ km} < D < 1 \text{ km}$ ) than for  $D > 5 \text{ km}$  MBOs,  $b \sim 1.2$  vs. 1.8, respectively. The depletion of subkilometer MBOs is more pronounced in the outer belt ( $a > 2.5$  AU) than the inner belt ( $a < 2.5$  AU).
- *Sub-Kilometer Asteroid Diameter Survey (SKADS):* The pencil-beam-type SKADS (Gladman et al., 2009) derived a debiased H-magnitude distribution of  $\alpha = 0.30 \pm 0.02$  throughout the main belt in the range  $15 < H_R < 18$ . Limiting the analysis to the inner main

belt allowed them to extend the absolute magnitude interval to  $15 < H_R < 19.5$ , for which the slope is marginally shallower with  $\alpha = 0.23 \pm 0.04$ . A fit to the SKADS dataset does not *require* a decrease in the slope for  $H \geq 18$  but cannot rule it out.

- *Terai et al. (2013)*: Terai et al. suggest that high- and low-inclination MBOs have different size-frequency distributions based on observational data collected with the Subaru telescope. They interpret this as a consequence of the larger impact speed for high-inclination asteroids.

### 6.3. Trojan Asteroids

Trojan asteroids orbit the Sun in a 1:1 mean-motion resonance with a planet and populate two distinct “clouds” leading or trailing the planet by  $\sim 60^\circ$ , the Lagrange 4 ( $L_4$ ) and Lagrange 5 ( $L_5$ ) clouds, respectively. In what follows we will primarily discuss JTOs but also touch upon Trojans of other planets in the inner solar system.

The Nice model (e.g., *Morbidelli et al.*, 2005) suggests that the JTOs originated in the outer reaches of the protoplanetary disk with semimajor axes in the range  $15 \text{ AU} < a < 30 \text{ AU}$  and were dynamically captured by Jupiter during the repositioning of the planets after the formation of the solar system. Interestingly, the number of JTOs in the clouds appears to be unequal: *Szabo et al.* (2007) estimated that the  $L_4:L_5$  number ratio is  $1.6 \pm 0.1$  based on SDSS data, whereas *Grav et al.* (2011b) derived an independent ratio of  $1.4 \pm 0.2$  using WISE measurements. Assuming that the two values are truly independent, the error-weighted ratio of  $1.58 \pm 0.08$  is more than  $7\sigma$  from unity. The combined clouds have an H-distribution with a slope of  $\alpha = 0.64 \pm 0.05$  in the range

$9 < H < 13.5$  (*Szabo et al.*, 2007). The equivalent slope of the cumulative size distribution is  $b = 2.2 \pm 0.25$ , in agreement with the preliminary result from WISE of  $b \sim 2$  (*Grav et al.*, 2011b). Similar slopes have recently also been obtained by *Yoshida and Nakamura* (2005) using a substantially smaller sample size.

Trojan objects have also been discovered for Mars (MTO) [see *de la Fuente Marcos and de la Fuente Marcos* (2013) and *Christou* (2013) for the most recent tally], Venus (VTO) (*de la Fuente Marcos and de la Fuente Marcos*, 2014) and Earth (ETO) (*Connors et al.*, 2011). Based on the uneven distribution of objects in the Mars  $L_4$  and  $L_5$  clouds (1 vs. 7), and the compactness of the orbital distribution in  $L_5$ , both *de la Fuente Marcos and de la Fuente Marcos* (2013) and *Christou* (2013) suggest that the objects in  $L_5$  have a common origin in either a collisional or a rotational breakup event. Whereas the eight known MTOs are on orbits that are stable on gigayear timescales, the known ETOs and VTOs appear to be transient captures of NEOs with kiloyear lifetimes.

## 7. ANTICIPATING THE FUTURE

The next decade of NEO discovery will likely be dominated by the large-aperture, wide-FOV, groundbased telescopes or the spacebased near-IR discovery systems described below, with details provided in Table 5. But this NEO-centric viewpoint belies the important contributions to the detection and monitoring, follow-up, and characterization of all the asteroids in the inner solar system. Some or all of these efforts might still be dominated by smaller-aperture and visible-light groundbased systems. Furthermore, we specifically address an emerging new camera technology that could impact the way we detect all types of asteroids — early tests

TABLE 5. Anticipated improved and new sky surveys.

Survey	Site	Lead(s)	Aperture (m)	f-Ratio	FOV (deg <sup>2</sup> )	Pixel Scale ("/pix)	IAU Obs Code

\* LSST is operated by the LSST Corporation.

<sup>†</sup> LSST will have an unusually large secondary mirror and “dual-purpose” primary mirror, so we also provide the system’s effective aperture.

Listed in alphabetical order by survey name. Fly-Eye, Gaia, LSST, and SST are not focused on NEO or asteroid discovery but could make major contributions to the inventory. We provide site-specific information even for surveys that use multiple sites and/or telescopes. The list includes only funded surveys as the time of this writing. The columns are survey, site, P.I., telescope aperture in meters, f-ratio (focal length of primary mirror divided by its aperture), FOV in square degrees, image scale in arcseconds per pixel, and IAU observatory code.

are promising, but its actual implementation awaits funding and verification.

This section is divided into three subsections that present our current understanding of upcoming improvements and expected new ground- and spacebased assets. The facilities in each subsection are presented alphabetically.

## 7.1. Upgrades to Existing Facilities

**7.1.1. Catalina Sky Survey (CSS).** The CSS team has distinguished itself in their ability to constantly improve their systems, and are currently in the process of installing monolithic  $10k \times 10k$  CCD cameras on both the CSS Schmidt and MLS telescopes. This will effectively double the surveying capability of the CSS Schmidt, allowing 3000 to 5000 deg $^2$  of sky to be surveyed nightly to V  $\sim$  20. The MLS telescope will enjoy a factor of 5 increase in area coverage through the addition of reducing optics, and will be capable of surveying  $\sim$ 1000 deg $^2$ /night to V  $\sim$  21.5. It is possible that the CSS Schmidt will be used to survey most of the observable sky over the course of a night or two. The repeated survey coverage will yield a more complete main-belt minor planet catalog because it will be easier to link asteroid detections from night to night, and then to other apparitions.

Further improvements will be realized by pushing the capability of linking detections to faster rates and nonlinear motion. Most surveys currently require that detections on a single night follow a linear trajectory even though the closest object's paths will be curved on the sky plane; since most surveys ignore the curvature, it implies that many nearby, perhaps even geocentric, objects are not being identified by the current surveys. Yet another seemingly mundane  $\sim$ 30% reduction in the time required for the telescope to step + settle + readout will yield a 10–12% increase in overall area coverage and, presumably, discovery rate.

The combined CSS and MLS telescopes should extend the completeness of the main-belt minor planet catalog to an absolute magnitude well beyond the current 17.5 (Denneau et al., 2015), perhaps as deep as H  $\sim$  19 (about 800 m diameter). The increased discovery rate is not expected to have any impact on the MPC processing of the reported observations.

**7.1.2. Panoramic Survey Telescope and Rapid Response System (Pan-STARRS).** Beginning in March 2014 and continuing through at least March 2015, PS1 has been dedicated 100% to the NEO survey, after which it will continue to devote 90% of its time to the search. It will be joined in late 2015 by a second, nearly identical, telescope, Pan-STARRS2, and both telescopes will be used for the NEO survey at the 90% level through at least September 2017. Doubling the number of telescopes will not double the NEO discovery rate because not all areas of the sky are equally rich in unknown NEOs.

Upgrading the CCDs in both telescopes has the potential to dramatically increase the NEO discovery rate, but is dependent on whether funding can be identified. The existing CCDs each have a cell structure consisting of an  $8 \times 8$  grid of  $600 \times 600$  pixels, which makes the system less efficient

for finding faster-moving objects because they can move over the cell gaps (which are not sensitive to light), dividing the asteroid's trail in two. Larger monolithic commercial-grade low-noise CCDs will eliminate this problem, correct cosmetic problems in the existing CCDs that decrease the effective fill factor, and allow deeper NEO searches due to lower noise.

The IPP (Magnier, 2006) and MOPS (Denneau et al., 2013) (see section 3.6) are both being continually tuned and improved to enhance the NEO detection efficiency.

## 7.2. Exciting New Facilities and Technologies

**7.2.1. Asteroid Terrestrial-impact Last Alert System (ATLAS).** The University of Hawaii's ATLAS project (Tonry, 2011) is expected to be operational in 2015 when it will begin robotically surveying the entire sky multiple times each night. The system will have two identical 50-cm Wright-Schmidt telescopes, each located in separate domes: one on Mauna Loa, Hawaii, and the other on Haleakala, Maui. The telescopes will have 7.4° FOVs instrumented with STA-1600 110-megapixel CCDs. They expect to identify asteroids roughly in the range  $13 < r < 20$  with each primary system and to identify asteroids in the  $6 < r < 14$  range with auxiliary cameras co-mounted on each of the primary telescopes. (The r wavelength band is similar to the Johnson-Cousins R band.) Thus this system could monitor the entire main belt visible in the night sky to about r = 20 multiple times each night.

**7.2.2. Fly-Eye.** The ESA is planning a network of small telescopes with a novel "Fly-Eye" optical concept to completely scan the sky each night to identify space debris and NEOs (Cibin et al., 2012). The system's name captures the idea that the optics create 16 subimages of a field that are seamlessly stitched together to create a composite image with a 100% "fill-factor" [the fraction of the image plane or sky that is actively instrumented; e.g., the PS1 mosaic camera system has a fill factor of  $\sim$ 75% (Denneau et al., 2013)]. A prototype system is currently being built that has a  $6.7^\circ \times 6.7^\circ$  FOV (about 45 deg $^2$ ) with performance equivalent to a 1-m-diameter telescope.

**7.2.3. Gaia.** The ESA's Gaia mission (e.g., Lindegren et al., 2008) will measure the positions of about a billion stars spanning the entire sky to about 24 parsec precision. As of June 13, 2014, there were already over 260 published, refereed articles about the Gaia mission despite the fact that the primary survey had not even begun; 35 of those papers had both Gaia in the title and "asteroid" as a keyword. There is no doubt that Gaia's astrometric and photometric catalog will transform our ability to measure an asteroid's position and brightness, and the spacecraft should provide spectrophotometry of asteroids with V  $<$  20. Gaia is expected to detect about 350,000 asteroids and yield spectral classifications for about a quarter of that sample (e.g., Delbo et al., 2012; Mignard et al., 2007).

**7.2.4. Large Synoptic Survey Telescope (LSST).** The LSST has the potential to be an extremely powerful asteroid

detection and discovery telescope. With an expected limiting magnitude of  $R \sim 24$ , it could discover millions of new MBOs and hundreds of thousands of NEOs during its operational lifetime. The system is expected to repeat the same fields every four nights, thus providing its own follow-up. A system this robust could obviate most other groundbased observing systems for discovery (but asteroids brighter than  $R \sim 18$  would saturate the system and probably not be reported). Its actual performance for discovering asteroids will remain to be demonstrated because LSST intends to acquire only two frames per night separated by a small time interval. This strategy should pose little difficulty for linking detections to known objects, but its application to discovering new objects could be limited by the false detection rate.

**7.2.5. Space Surveillance Telescope (SST).** The U.S. Defense Advanced Research Projects Agency's (DARPA) SST has a 3.5-m-diameter mirror and an  $f = 1.0$  Mersenne-Schmidt optical system that is currently located on Atom Peak in New Mexico, at 2400 m elevation within the White Sands Missile Range, but is scheduled to be moved to Australia. The extremely fast telescope has a curved focal plane instrumented with *curved* CCDs developed specifically for the purpose. It is capable of covering several thousand square degrees per night to  $V > 20$ . The SST's primary goal is to survey the geosynchronous belt, but DARPA is considering providing some of the survey time to an asteroid survey (Monet *et al.*, 2013), much like the LINEAR system (Stokes *et al.*, 2000) was tasked for NEO surveying when not searching for satellites. LINEAR set the performance bar when it joined the NEO search and there is little doubt that the SST could do the same if it brings its new-technology, large-aperture, large-field, fast-optics, and rapid-readout system to bear on the NEOs.

**7.2.6. Synthetic tracking.** Shao *et al.* (2014) describe the application of two new technologies to asteroid detection that might, if successful, advance the field over the next decade. They combine new low-noise fast-readout CCDs with the computational power of graphics processing units (GPU). Their CHIMERA camera, with a  $2.5' \times 2.5'$  FOV, has already been tested on the Palomar 5-m telescope where they obtained images at 2 Hz (much faster rates will be used in standard operations) and then implemented the standard shift-and-add technique on their GPU to "synthetically track" an asteroid. They hope to upgrade their camera to a  $8' \times 8'$  FOV in the next couple of years, which will enable rapid searching, albeit over limited areas, for fast-moving asteroids to as faint as  $V \sim 25$ .

### 7.3. Possible Future Spacebased Missions

**7.3.1. Near-Earth Object Camera (NEOCam).** NEOCam is a proposed NASA Discovery-class mission whose goal is to survey for NEOs from a spacebased platform operating from near the Earth-Sun  $L_1$  point. Given the success of the NEOWISE mission (Mainzer *et al.*, 2011a), we expect that the substantially larger telescope surveying 100% of the time

for NEOs will be extremely successful. NEOCam should excel at detecting NEOs due to strong emission in the proposed 6–10- $\mu\text{m}$  band. Loosely translating this to the R-band suggests that the NEOCam survey could reach a groundbased equivalent depth of  $R \sim 24$ –25, making it an extraordinarily powerful survey capable of discovering hundreds of thousands of NEOs and more than  $10^6$  MBOs. NEOCam plans to adopt a self-follow-up cadence such that each field will be imaged at least  $4\times$  per day and each field will be visited every  $\sim$ 6 nights. Preliminary tests of the observing cadence have already been accomplished with the MPC and their existing software can easily link NEOs observed in this fashion.

**7.3.2. Sentinel.** The philanthropic nonprofit B612 organization (<https://b612foundation.org>) is attempting to raise private donations to fund the construction, launch, and operations of a spacecraft specifically designed to identify "threatening asteroids whose orbits approach Earth," i.e., PHOs, and identify many other NEOs and MBOs in the process. They hope to launch the spacecraft in 2017–2018 into a Venus-like elliptical orbit for its 6.5-yr mission. The orbit is particularly effective for identifying PHOs since they must pass through a torus of 0.05 AU diameter centered on Earth's orbit that is always exterior to the spacecraft's orbit. They expect to survey  $\sim$ 165 deg $^2$ /h with a 24-million-pixel IR camera (5–10.2  $\mu\text{m}$ ) with an 11-deg $^2$  FOV.

## 8. SUMMARY AND CONCLUSIONS

The NEO surveys have improved dramatically since publication of *Asteroids III*, yielding 8 $\times$  more NEOs and 10 $\times$  more MBOs in the last five years than in the five years leading up to *Asteroids III*. This accomplishment is all the more impressive considering that none of the current survey telescopes was designed with NEO observations in mind — they are all repurposed instruments originally designed for entirely different operations.

The situation could change in the next decade with the introduction of new groundbased and/or spacebased surveys specifically designed for NEO observations (e.g., ATLAS, NEOCam, Sentinel). These new facilities suggest that we can expect an increased discovery rate of asteroids in the near future, but they will require a concomitant operational evolution. For instance, existing NEO surveys still rely on human vetting of asteroid tracklet candidates, but this process might not be tenable if the discovery rate increases another order of magnitude. It seems clear that the surveys will need to implement regular self-follow-up, improved software processing, and coordination of surveying and follow-up efforts through a centralized organization (cf. NASA's Office of Inspector General's report on the NEO effort; IG-14-030, September 15, 2014).

Improvements to the existing surveys and the development of the next-generation surveys will push the completeness limits of all the inner solar system's asteroid subpopulations to ever smaller sizes to allow us to study the unbiased orbit and size distributions. Debiasing the populations to even

smaller sizes requires attention to the surveying plan and measuring the system's detection efficiency from the outset. Indeed, the limiting factor in generating good debiased models of the inner solar system's asteroid populations is the lack of well-calibrated survey data, e.g., detection efficiencies, per detection astrometric and photometric uncertainties, etc.

Most of the largest, globally devastating PHOs larger than 1 km diameter are now known, but there remains a residual impact risk from the remaining unknown ~10% and sporadic long-period comets. Perhaps surprisingly, that risk is now comparable to that of <100-m-diameter objects because of (1) the reduced slope of the NEO SFD in the 100-m to 1-km-diameter range and (2) the partial discovery of some of the objects in the intermediate range. In any event, there are active plans and funding to address the residual risk in the next decade, mostly funded by NASA and mostly based in the U.S. The scientifically interesting and spacebased resource utilization options for the much more numerous objects of <100 m diameter remains to be explored. About one-third of the discovered NEO population is <100 m in diameter (almost 4000 objects!), but about three-fourths of them have a minimum orbit intersection distance (MOID) of <0.05 AU, placing them in the sub-PHO category only by virtue of their mass. These objects may be discovered days to weeks before impact by groundbased surveys like the upcoming ATLAS and LSST projects, but the maximum groundbased detection efficiency for objects on the scale of the Chelyabinsk impactor is only about 50% because about half of them will approach Earth from the direction of the Sun — like the Chelyabinsk impactor. The only way to detect and characterize these objects before impact is with a spacebased detection system like NEOCam or Sentinel.

It is likely that physical characterization of asteroids will lag ever farther behind their discovery simply because of the much larger phase-space of possible “physical characterization” and the dedicated resources that must be applied for each measurement to individual asteroids. It seems that the only solution is to continue the process of limiting physical characterization to the most interesting targets and developing new systems that allow characterization in a multi-object mode. For instance, NEOWISE, NEOCam, and Sentinel have or plan to measure accurate asteroid diameters in the IR while they survey for unknown NEOs. Similarly, the already operational Gaia mission will measure main-belt asteroid masses, densities, shapes, pole orientations, and the impact of the Yarkovsky effect on their orbital evolution.

In closing, the only certainty about the future of asteroid discovery, characterization, and exploration is that we can expect great progress in the next decade leading to the publication of *Asteroids V*.

**Acknowledgments.** We wish to thank E. Christensen (CSS), L. Denneau (Pan-STARRS), R. McMillan (Spacewatch), G. Stokes (LINEAR), and R. J. Wainscoat (Pan-STARRS) for providing information and perspective on their surveys. C. Hergenrother and A. W. Harris (U.S.) provided helpful feedback as reviewers.

In this chapter we review the methods currently in use to compute asteroid orbits and make ephemeris predictions. Despite a well-consolidated theory, the increasing number and ever higher quality of observational data, together with the goal of pushing forward the horizon for ephemeris predictions, pose new challenges in estimating asteroid trajectories. We discuss how to develop a realistic statistical error model for astrometric observations by removing star catalog systematic errors and suitably weighting astrometric data. Moreover, since the dynamical model has to be accurate enough to fit the observational data and reliably predict an asteroid's position in the future, we analyze the relevance of the different components of the force model. In particular, we show that nongravitational forces can be relevant at a high level of precision. We also address the problem of estimating asteroid orbits when only a short arc of observations is available. Solving this problem has relevant implications for modern surveys, where the amount of observational data requires innovative methods to compute an orbit catalog avoiding an excessive computational load. Finally, we discuss the Earth impact hazard assessment. We describe the standard methods that have been in use for the last 15 years as well as newer techniques that allow long-term impact monitoring, including going beyond scattering planetary encounters and accounting for nongravitational perturbations.

## 1. INTRODUCTION

Determining asteroid orbits is a challenging problem that the scientific community has faced since 1801, when Piazzi discovered (1) Ceres, the first main-belt object. Shortly after discovery Ceres was heading for conjunction, thus making it impossible to keep collecting observations. To prevent Ceres from being lost, Gauss computed its orbit using the observations collected by Piazzi and successfully predicted where Ceres would be observable after emerging from the Sun. Interestingly, the orbit determination of Ceres represents the first remarkable application of the famous method of least squares, which since then has been one of the most used mathematical tools with applications in disciplines such as statistics, physics, biology, geodesy, economics, and indeed every physical science.

One of the reasons why, after more than two centuries, orbit determination continues to be a fascinating branch of celestial mechanics is that it strikes an impressive fusion between a scientifically sound theory and several relevant applications. Celestial mechanics rigorously describes the motion of celestial bodies and the large number of observations of space bodies allows one to extensively test

the validity of the theory. In particular, for asteroid orbit determination we have a rigorous mathematical theory to compute trajectories and more than 650,000 asteroids (as of September 2014) whose observations continuously serve as validation of the theoretical computations. Just to give an idea of the level of accuracy that can be reached, there are asteroids for which the available observational data reveal accelerations with a precision of a few  $\text{fm s}^{-2}$  ( $10^{-15} \text{ m s}^{-2}$ ).

Asteroid orbit determination has several important applications. By computing an orbit along with its uncertainty, we can inform astronomers on when and where they should observe the night sky so that they can collect additional observations. If a mission to an asteroid is planned, estimating trajectories is important to select a viable target, and reliable ephemerides are required to successfully navigate the spacecraft to the asteroid. When two asteroids get close enough we can measure the gravitational interaction between them and obtain an estimate of an asteroid's mass. Perhaps the most interesting application is planetary defense. When an asteroid's orbit is computed we can figure out where the object will be in the future and whether or not there are upcoming planetary encounters. In particular, it is possible to compute the probability of an Earth impact and contribute

to the study of mitigation measures, such as deflection, in case they are deemed necessary.

## 2. BASIC THEORY

### 2.1. Orbits

The equations of motion for celestial bodies are ordinary differential equations with a smooth righthand side. An orbit is defined by the evolution of the Cartesian heliocentric position  $\mathbf{r}$  and velocity  $\mathbf{v}$  of the asteroid, which is determined by the initial conditions  $(\mathbf{r}_0, \mathbf{v}_0)$  at a time  $t_0$ . In fact, the initial Cartesian state can be integrated to any given time according to the accelerations  $\mathbf{a}$  acting on the asteroid

$$\dot{\mathbf{r}} = \mathbf{v}, \quad \dot{\mathbf{v}} = \mathbf{a}(t, \mathbf{r}, \mathbf{v}, \psi) \quad (1)$$

The main component of the righthand side  $\mathbf{a}$  is the Newtonian attraction of the Sun. Therefore, as a first approximation, asteroids follow Keplerian motion (e.g., Roy, 2005). However, as discussed in section 4.1, there are several other accelerations contributing to  $\mathbf{a}$  such as the Newtonian attraction from other bodies (planets, Moon, Pluto) and relativistic perturbations. In some cases the orbit also depends on dynamical parameters  $\psi$ , e.g., parameters defining nongravitational perturbations acting on the asteroid (see section 4.2). In general,  $\mathbf{a}$  is a function of time  $t$ , current Cartesian state  $(\mathbf{r}, \mathbf{v})$ , and some dynamical parameters  $\psi$ .

### 2.2. Observations

Observations are the data needed to compute the orbit of an asteroid. There are primarily two kinds of observations used in asteroid orbit determination: optical and radar.

Optical observations provide the angular position of an asteroid in the sky. The information is expressed by spherical coordinates, typically right ascension ( $\alpha$ ) and declination ( $\delta$ ), in an inertial reference frame, e.g., J2000 (Kaplan, 2005). Optical observations can be obtained from groundbased observatories as well as spacebased telescopes, provided that their position is accurately known.

Radar observations provide the distribution of echo power in time delay and Doppler frequency. Besides giving valuable information on an asteroid's physical properties, the superior precision of radar observations puts exceptional constraints on asteroid orbits, thus allowing reliable predictions over longer time intervals (Ostro *et al.*, 2002) (see also the chapter by Benner *et al.* in this volume).

If the initial Cartesian state is available and  $\mathbf{a}$  is known, observations can be predicted by an explicit computation. Theoretical predictions and measured observations do not generally coincide and the differences O–C, observed minus computed, form the vector of residuals  $\mathbf{v}$ .

### 2.3. Differential Corrections

The first step in orbit determination is to select a list of parameters  $\mathbf{x}$  defining the orbit to be determined from the

available observations. The most common case is when  $\mathbf{x}$  is given by the asteroid's Cartesian position  $\mathbf{r}_0$  and velocity  $\mathbf{v}_0$  at the initial epoch  $t_0$ . However,  $\mathbf{x}$  can also include some of the dynamical parameters  $\psi$ . Note that the number of parameters to be determined can be no larger than the number of scalar observations (optical observations give two scalar observations), otherwise the problem is underdetermined and cannot be solved.

The basic tool of the classical theory of orbit determination (Gauss, 1809) is the definition of a cost function

$$Q = \mathbf{v}^T \mathbf{W} \mathbf{v}$$

where  $\mathbf{W}$  is the weight matrix, i.e., the inverse of the observational covariance matrix. For instance,  $\mathbf{W}$  can be a diagonal matrix whose elements are  $1/\sigma_i^2$ , where  $\sigma_i$  is the uncertainty of the corresponding observation. The cost function  $Q$  measures how close the orbital solution is to the observations. Therefore, the nominal solution  $\bar{\mathbf{x}}$  for  $\mathbf{x}$  corresponds to the minimum of  $Q$ , i.e.,  $\bar{\mathbf{x}}$  satisfies the equation

$$0 = \frac{\partial Q}{\partial \mathbf{x}} = 2\mathbf{v}^T \mathbf{W} \mathbf{B}, \quad \mathbf{B} = \frac{\partial \mathbf{v}}{\partial \mathbf{x}} \quad (2)$$

The matrix  $\mathbf{B}$  is called the design matrix. Equation (2) generally has no explicit solutions but can iteratively be solved as follows

$$\mathbf{x}_{k+1} - \mathbf{x}_k = -\Gamma \mathbf{B}^T \mathbf{W} \mathbf{v}, \quad \Gamma = \mathbf{C}^{-1}, \quad \mathbf{C} = \mathbf{B}^T \mathbf{W} \mathbf{B} \quad (3)$$

This iterative scheme is essentially a Newton method that is applied to equation (2) where  $\partial^2 Q / \partial \mathbf{x}^2$  is approximated with  $2\mathbf{C}$ . The matrix  $\mathbf{C}$  is called the normal matrix (or information matrix). Equation (3) can be solved by using standard linear algebra algorithms such as singular value decomposition or Cholesky factorization. If the sequence  $\mathbf{x}_k$  converges to  $\bar{\mathbf{x}}$ , the limit has to be a (local) minimum of  $Q$ . This method is called differential corrections and is applied by asteroid data processing centers such as the Minor Planet Center (MPC), the Jet Propulsion Laboratory (JPL), and the Near Earth Objects Dynamic Site (NEODyS) thousands of times per day to determine the orbits of asteroids and comets.

There are several methods to determine a preliminary orbit to be used as a starting estimate for differential corrections, e.g., the methods of Gauss, Laplace, Vaisala, and Herget. A description of these methods is beyond the scope of this chapter and can be found in textbooks such as Dubyago (1961) and Escobal (1965).

### 2.4. Probabilistic Interpretation

Since observations come with an uncertainty, the orbit observational uncertainty maps to the orbital uncertainty.

If we assume that the observation errors are normally distributed, with zero mean and uncertainty expressed by the observational covariance matrix  $\mathbf{W}^{-1}$ , then the probability density function of the residuals is

$$f_v = \frac{1}{\sqrt{(2\pi)^{n_{\text{obs}}} \det W^{-1}}} \exp\left(-\frac{1}{2} v^T W v\right) \quad (4)$$

where  $n_{\text{obs}}$  is the number of scalar observations. In the case of independent observation errors the observational covariance matrix is a diagonal matrix whose elements are the squares of observation uncertainties  $\sigma_i$ . (We discuss the validity of these assumptions in section 3.)

If we linearize around  $\bar{x}$ , we have that  $\Delta v = B\Delta x$ , where  $\Delta v = v - \bar{v}$ ,  $\Delta x = x - \bar{x}$ , and  $\bar{v} = v(\bar{x})$ ; the variation of  $Q$  around its minimum is

$$\Delta Q = \Delta v^T W \Delta v = \Delta x^T C \Delta x \quad (5)$$

Since  $v$  is normally distributed with zero mean and covariance matrix  $W^{-1}$ ,  $x$  is normally distributed with mean  $\bar{x}$  and covariance matrix  $\Gamma_x = \Gamma$ . [For a rigorous proof, see section 5.7 of Milani and Gronchi (2010).] The level curves of  $\Delta Q$  correspond to the boundary of the confidence ellipsoids for different values of  $\sigma$ . The probability that the actual orbit is within a given ellipsoid can be computed by using the distribution of  $\chi^2$  with the number of determined parameters as degrees of freedom. For instance, if  $x = (r_0, v_0)$  we have six degrees of freedom and the probability of being inside the  $3\sigma$  ellipsoid, i.e.,  $\Delta Q < 9$ , is 82.64%.

## 2.5. Predictions

Once an orbit is determined, we want to make predictions. For example, we want to compute the ephemerides in the sky so that observers can collect additional observations or we may want to compute the probability that an asteroid strikes Earth. In any case, the prediction  $p$  is going to be a function of our parameters  $x$ . Therefore, from the nominal orbit  $\bar{x}$  we can compute a nominal prediction  $\bar{p}$ . As an example, if we want to predict the Cartesian state of an asteroid in the future, we take the initial state and integrate the equations of motion to the desired epoch.

Since orbits are determined along with an uncertainty, we need to compute the resulting uncertainty in the prediction. In the linear approach we have that  $\Delta p = A\Delta x$ , where  $A = \partial p / \partial x$ . Since  $\Delta p$  is a linear combination of  $\Delta x$ , and  $\Delta x$  is normally distributed,  $\Delta p$  is normally distributed, too. If we indicate the normal matrix of  $p$  with  $C_p$ , we have that:

$$\Delta p^T C_p \Delta p = \Delta x^T A^T C_p A \Delta x = \Delta x^T C \Delta x$$

Therefore,  $C = A^T C_p A$  or, equivalently, the covariance matrix of  $p$  is  $\Gamma_p = A \Gamma A^T$ . [Again, for a rigorous proof, see section 7.5 of Milani and Gronchi (2010).]

For example, we can map the uncertainty of the initial Cartesian state  $(r_0, v_0)$  at epoch  $t_0$  to the uncertainty of the Cartesian state  $(r, v)$  at a different epoch  $t$ . All we need are the partial derivatives

$$A = \begin{pmatrix} D & E \\ \dot{D} & \dot{E} \\ \ddot{D} & \ddot{E} \end{pmatrix}$$

where  $D = \partial r / \partial r_0$ ,  $\dot{D} = \partial v / \partial r_0$ ,  $E = \partial r / \partial v_0$ , and  $\dot{E} = \partial v / \partial v_0$ . These matrices can be computed by solving the classical variational equation

$$\begin{cases} \ddot{D} = \frac{\partial \mathbf{a}}{\partial v} \dot{D} + \frac{\partial \mathbf{a}}{\partial r} D, \quad D(t_0) = \mathbb{I}, \quad \dot{D}(t_0) = 0 \\ \ddot{E} = \frac{\partial \mathbf{a}}{\partial v} \dot{E} + \frac{\partial \mathbf{a}}{\partial r} E, \quad E(t_0) = 0, \quad \dot{E}(t_0) = \mathbb{I} \end{cases}$$

where  $\mathbb{I}$  is the identity matrix of rank 3 and  $\mathbf{a}$  represents the acceleration acting on the asteroid as in equation (1). Note that the variational equation was already needed to compute the design matrix  $B$  of equation (2).

When  $x$  includes some of the dynamical parameters  $\psi$ , we also need the partials  $F = \partial r / \partial \psi$  and  $\dot{F} = \partial v / \partial \psi$ , which can be obtained by solving

$$\ddot{F} = \frac{\partial \mathbf{a}}{\partial v} \dot{F} + \frac{\partial \mathbf{a}}{\partial r} F + \frac{\partial \mathbf{a}}{\partial \psi}, \quad F(t_0) = 0, \quad \dot{F}(t_0) = 0$$

## 3. TREATMENT OF THE ASTROMETRY

The computation of an asteroid's orbit as described in section 2 relies on the accuracy of the observational error model. Thus, possible limitations arise from making simplified assumptions on the observational error model. In particular, observation errors are usually assumed to be distributed according to a Gaussian distribution with zero mean. Moreover, the astrometric uncertainty is often taken as a simple function of the epoch of the observation only (e.g., 3" before 1890, 2" between 1890 and 1950, 1" after 1950) (see Baer et al., 2011a), and observation errors are assumed to be uncorrelated. The above assumptions are unrealistic as shown by Carpino et al. (2003), who proved the presence of biases, non-Gaussian statistics, and correlations between observations close in time. Moreover, the accuracy of the astrometry depends not only on the epoch of observation, but also on the observer. For instance, the Panoramic Survey Telescope and Rapid Response System (Pan-STARRS) PS1 (Hodapp et al., 2004) telescope achieves  $\sim 0.1''$  quality, thus its data cannot be assumed to have the same accuracy of any other observation made since 1950. Unrealistic assumptions compromise the orbital solution and the interpretation of the probabilistic distribution of the orbit within the uncertainty region.

### 3.1. Systematic Errors Due to Star Catalogs

The vast majority of asteroid astrometry is given by optical observations describing the position of an asteroid on the celestial sphere at a specified time. The corresponding

angular measurements are obtained with respect to nearby reference stars, whose positions are provided by a star catalog. Therefore, the presence of systematic errors in the star catalog affects the quality of the observation. *Chesley et al.* (2010) showed that some of the most widely used star catalogs can have position biases up to 1''–2'', which are comparable to (if not larger than) the expected quality of the data. Moreover, *Tholen et al.* (2013) show that even the lack of proper motion information can produce significant systematic errors for Pan-STARRS PS1, one of the best surveys in terms of data quality (*Milani et al.*, 2012).

To correct for systematic errors due to star catalogs, one can select a reference catalog to which the other catalogs are compared. The reference catalog has to be dense, accurate, and include proper motions. *Chesley et al.* (2010) used Two Micron All Sky Survey (2MASS) (*Skrutskie et al.*, 2006) as reference catalog because of its accuracy and density, but 2MASS does not include proper motions. A possible choice would be the Position and Proper Motion Extended-L (PPMXL) catalog (*Roeser et al.*, 2010), which includes proper motions and is a merge of 2MASS and U.S. Naval Observatory (USNO)-B1.0 (*Monet et al.*, 2003) obtained after a critical reprocessing of the data. However, the astrometric position of the PPMXL stars selected from USNO-B1.0 are not sufficiently accurate. Therefore, *Farnocchia et al.* (2015a) select the subset of PPMXL corresponding to 2MASS-based stars as a reference catalog. This set of stars is dense, has accurate star positions, and includes proper motions.

To compare the different star catalogs to the selected reference catalog we map the star positions at epoch J2000.0 and divide the celestial sphere in 49,152 equal-area tiles by using the JPL Hierarchical Equal Area isoLatitude Pixelisation (HEALPix) package (*Górski et al.*, 2005). For each tile we find stars in common by using a 2'' radius and compute the average position and proper motion differences in right ascension  $\alpha$  and declination  $\delta$ . As an example, Figs. 1a,b show the position corrections for the USNO-A2.0 catalog (*Monet*, 1998), which as of September 2014 has been the most widely used catalog to reduce asteroid astrometry. Position errors are as large as 1'' and are therefore extremely relevant at the expected level of uncertainty of asteroid astrometric observations. The transition around  $\delta = -20^\circ$  shows how USNO-A2.0 splits in its northern and southern parts (*Assafin et al.*, 2001). Figures 1c,d show the proper-motion corrections to be applied to observations reduced with USNO-A2.0, which does not include proper motions. It is easy to see that astrometric observations can be significantly affected if the catalog used for the astrometric reduction has large proper motion errors, as in the case of Pan-STARRS PS1 (*Tholen et al.*, 2013). Each observation can be corrected by subtracting the quantities

$$\begin{aligned}\Delta\alpha &= \Delta\alpha_{2000} + \Delta\mu_\alpha \Delta t \\ \Delta\delta &= \Delta\delta_{2000} + \Delta\mu_\delta \Delta t\end{aligned}$$

where  $\Delta t$  is the observation time with respect to epoch J2000.0,  $\Delta\alpha_{2000}$  and  $\Delta\delta_{2000}$  are the position corrections,

and  $\Delta\mu_\alpha$  and  $\Delta\mu_\delta$  are the proper-motion corrections for the tile corresponding to the catalog used for the astrometric reduction and the observed  $\alpha$  and  $\delta$ . For more details, see *Farnocchia et al.* (2015a).

### 3.2. Astrometric Weighting

Each observation should be weighted according to its expected quality. Ideally, observers should provide rigorous and reliable uncertainty information. For instance, this information is available for radar observations (<http://ssd.jpl.nasa.gov/?radar>). However, optical observations are distributed by the MPC without including uncertainty information (<http://www.minorplanetcenter.net/iau/info/OpticalObs.html>). Therefore, to infer what the data quality is, one needs to analyze the statistics of astrometric errors.

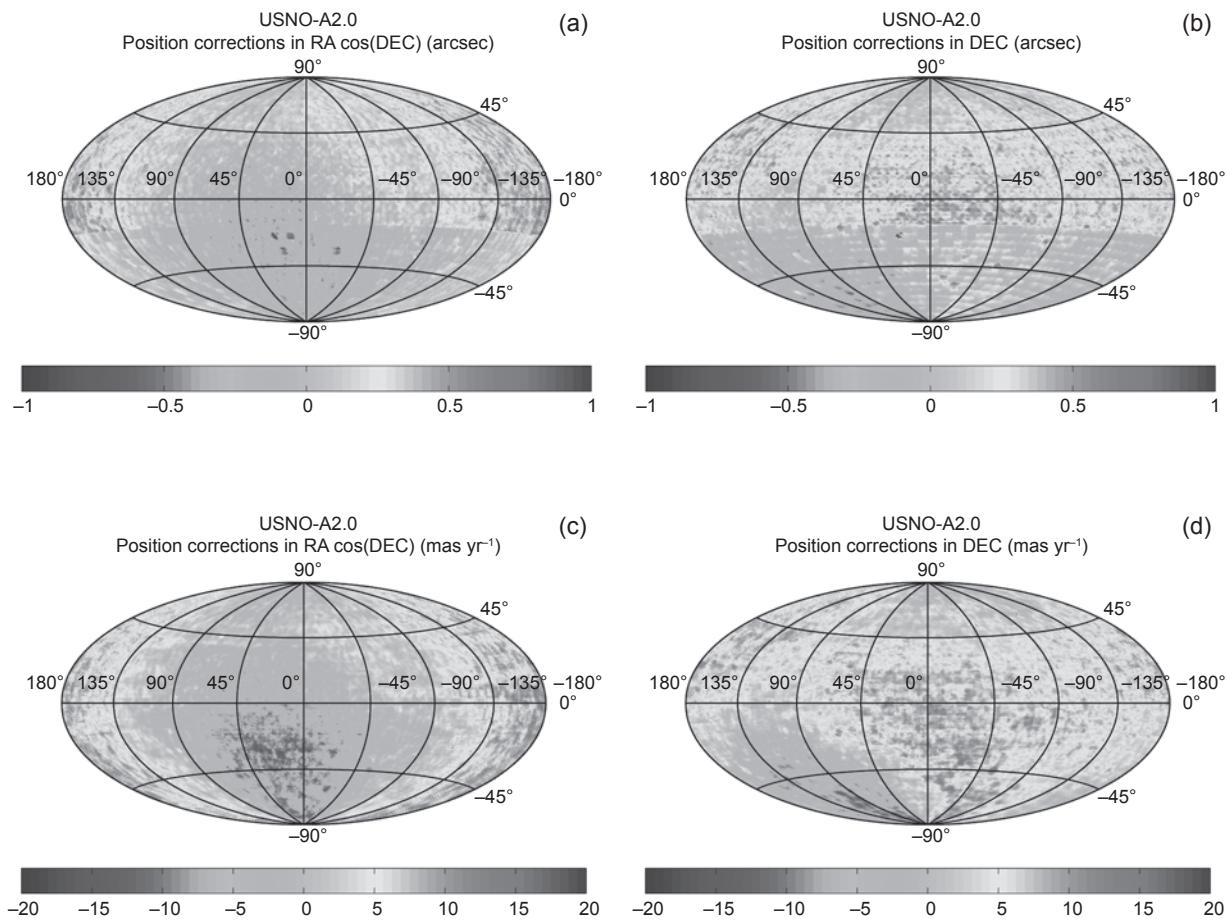

The  $\alpha$  and  $\delta$  accuracy,  $\sigma_\alpha$  and  $\sigma_\delta$ , of an optical astrometric observation can be easily seen as dependent on (1) epoch of the observation; (2) observation type, e.g., charge-coupled device (CCD) or photographic (see <http://www.minorplanetcenter.net/iau/info/OpticalObs.html> for the list of observation types); (3) observer (see <http://www.minorplanetcenter.net/iau/lists/-ObsCodesF.html> for the list of observatories and their codes); and (4) star catalog used to reduce the astrometry (see <http://www.minorplanetcenter.net/iau/info/CatalogueCodes.html> for the list of catalogs and their codes).

*Chesley et al.* (2010) analyzed the observation quality for different observatories, star catalogs, etc., by computing the root mean square (RMS) of the  $\alpha$  and  $\delta$ . Table 1 shows examples of station-specific expected accuracies for CCD observations according to the star catalog used for the astrometric reduction. The reported  $\sigma_\alpha$  and  $\sigma_\delta$  can be converted to weights as  $w = 1/\sigma^2$ . Note that  $\sigma_\alpha$  includes the spherical metric factor  $\cos \delta$ . For a more comprehensive list of weighting rules, see *Farnocchia et al.* (2015a).

### 3.3. Correlations

The statistics of the residuals shows that observation errors are not independent, especially for single-station observations closely spaced in time (*Carpino et al.*, 2003). The presence of correlations is in large part due to unresolved biases. As a matter of fact, *Chesley et al.* (2010) demonstrate that correcting for star catalog position biases significantly reduces correlations. Although star catalog errors are the most important source of systematic errors in asteroid astrometry, there are other possible sources of systematic errors. For instance, a well-known problem is due to timing errors. If the reported observation epoch is wrong, there is a corresponding positional error along the direction of the angular motion of the asteroid. Correcting for all sources of systematic errors can be extremely difficult (if not impossible), and yet the error model needs to account for them.

*Baer et al.* (2011a) develop an error model that accounts for correlations between same-station observations. Given two observations, the correlation coefficient is computed as a linear combination of exponential functions that decrease as

**Fig. 1.** See Plate 27 for color version. Sky map of position corrections in (a)  $\alpha \cos \delta$  and (b)  $\delta$  for USNO-A2.0. Sky map of proper motion corrections in (c)  $\alpha \cos \delta$  and (d)  $\delta$  for USNO-A2.0. Reprinted from *Star Catalog Position and Proper Motion Corrections in Asteroid Astrometry*, January 1, 2015, with permission from Elsevier.

the time separation between the two observations increases: The farther in time the observations, the smaller the correlation. The coefficients defining the linear combination are empirically derived for different stations and different observation epochs. These correlation coefficients can be used to populate the nondiagonal elements of the observational covariance matrix  $W^{-1}$  defined in section 2.

Since correlations are mostly due to unresolved biases and the computation of the correlation coefficients is cumbersome, an alternative approach is to mitigate the effect of

unresolved systematic errors and correlations by relaxing the weights. This simple approach is conservative and allows one to keep the observational covariance matrix diagonal. Chesley et al. (2010) already found that applying a safety factor 2 to the  $\sigma$  values listed in Table 1 results in more statistically consistent predictions, i.e., the prediction error distribution is closer to that of a theoretical normal distribution. As discussed in Farnocchia et al. (2015a), a better way to mitigate unresolved systematic errors is to account for the number  $N$  of observations from the same station in

TABLE 1. Examples of station specific weighting rules for CCD observations.

Station	Catalog	$\sigma_\alpha$	$\sigma_\delta$	Station	Catalog	$\sigma_\alpha$	$\sigma_\delta$
644	USNO-A2.0	0.24"	0.28"	644	USNO-B1.0	0.18"	0.17"
691	USNO-A2.0	0.32"	0.34"	691	USNO-B1.0	0.25"	0.28"
699	USNO-A2.0	0.47"	0.39"	699	USNO-B1.0	0.42"	0.41"
703	USNO-A2.0	0.62"	0.57"	703	UCAC	0.49"	0.46"
704	USNO-A2.0	0.62"	0.60"	F51	2MASS	0.15"	0.15"
G96	UCAC	0.25"	0.21"	E12	UCAC	0.41"	0.43"

the same night. Since the error in the mean decreases with  $\sqrt{N}$ , the larger the number of observations, the more systematic errors affect the orbit computation. To compensate for that, the weights can be relaxed by a factor  $N$ , i.e.,  $w = 1/(N\sigma^2)$ , which is equivalent to inflating  $\sigma$  by  $\sqrt{N}$ . It is worth pointing out that for a typical survey observation batch  $N = 4, 5$  and thus the  $\sqrt{N}$  factor is similar to the *Chesley et al.* (2010) safety factor of 2.

### 3.4. Outlier Rejection

The observational dataset of an asteroid can be contaminated by “bad” observations (outliers) that may corrupt the orbital computation. The presence of outliers may arise from unusual circumstances such as human error, software bugs, and difficult observing conditions. Therefore, these outliers have to be identified and removed from the orbital fit. There are several techniques to reject outliers, e.g., Chauvenet’s criterion (*Taylor*, 1997) and Pierce’s criterion (*Gould*, 1855). These techniques reject all the observations whose residuals are beyond a fixed number of standard deviations. A more sophisticated outlier rejection algorithm is that of *Carpino et al.* (2003), which not only accounts for the residuals with respect to the fitted model, but also for the *a posteriori* prediction uncertainty.

Following the *Carpino et al.* (2003) approach, we indicate the initial orbital parameters with  $\mathbf{x}_0$ , the convergent solution with  $\bar{\mathbf{x}}$ , the prefit residuals with  $\mathbf{v}_0$ , and the postfit residuals with  $\bar{\mathbf{v}}$ . From equation (3), in the linear approximation we have that

$$\bar{\mathbf{x}} - \mathbf{x}_0 = -\Gamma \mathbf{B}^T \mathbf{W} \mathbf{v}_0$$

The first-order Taylor expansion for the residuals is

$$\bar{\mathbf{v}} = \mathbf{v}_0 + \mathbf{B}(\bar{\mathbf{x}} - \mathbf{x}_0) = (\mathbf{I} - \mathbf{B}\Gamma\mathbf{B}^T \mathbf{W}) \mathbf{v}_0$$

Therefore, since  $\mathbf{W}^{-1}$  is the observational covariance matrix, the covariance of the postfit residuals is

$$\Gamma_{\bar{\mathbf{v}}} = \mathbf{W}^{-1} - \mathbf{B}\Gamma\mathbf{B}^T \quad (6)$$

For a given observation one can compute a  $\chi^2$  value as

$$\chi_i^2 = \mathbf{v}_i^T \gamma_i^{-1} \mathbf{v}_i$$

where  $\gamma_i$  is the block of  $\Gamma_{\bar{\mathbf{v}}}$  corresponding to that observation. Similarly,  $\mathbf{v}_i$  is a subset of  $\bar{\mathbf{v}}$  corresponding to the considered observation. For optical observations,  $\gamma_i$  has rank 2 and  $\mathbf{v}_i$  is a two-element vector. For radar observations, both  $\gamma_i$  and  $\mathbf{v}_i$  are scalar. In a similar way, the covariance matrix for discarded observations is obtained by adding (rather than subtracting)  $\mathbf{B}\Gamma\mathbf{B}^T$  to  $\mathbf{W}^{-1}$  in equation (6). At this point, one can select a threshold  $\chi_{\text{rej}}^2$  and reject observations with  $\chi_i^2 > \chi_{\text{rej}}^2$ . Similarly, a threshold  $\chi_{\text{rec}}^2$  is used to recover the observations previously excluded if  $\chi_i^2 < \chi_{\text{rec}}^2$ . The selection of the parameters  $\chi_{\text{rec}} < \chi_{\text{rej}}$  is not obvious, although the theoretical distribution of  $\chi^2$  can serve as a reference. Our current

choices for these parameters are  $\chi_{\text{rej}} = 3$  and  $\chi_{\text{rec}} = 2.8$ . For more details on the implementation of this algorithm, see *Carpino et al.* (2003).

## 4. DYNAMICAL MODEL

### 4.1. Gravitational Perturbations

To make reliable predictions the force model needs to be accurate enough. In particular, when an orbit is very well constrained, it may be impossible to match the observational data unless all the relevant perturbations are accounted for.

While the main acceleration acting on asteroids is the Newtonian attraction of the Sun, one certainly needs to include the contribution of the planets. These perturbations are usually based on precomputed ephemeris tables from which the Cartesian states of the planets, Pluto, and the Moon can be retrieved. We use JPL’s planetary ephemerides (<http://ssd.jpl.nasa.gov/?ephemerides>), but other planetary ephemerides are available as well, such as the ones provided by the Institut de Mécanique Céleste et de Calcul des Éphémérides (<http://www.imcce.fr/langues/en/ephemerides>). As an example, Fig. 2a shows the Newtonian attraction of the Sun, Earth, Jupiter, and Uranus acting on asteroid (6489) Golevka computed using JPL’s DE431 ephemerides (*Folkner et al.*, 2014).

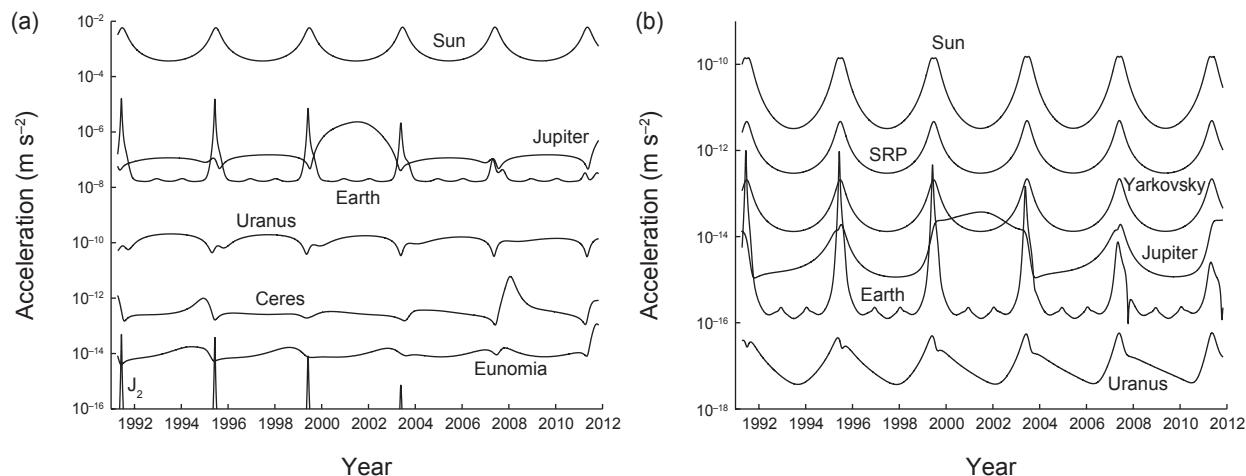

The gravity of large bodies in the main belt, such as (1) Ceres, (2) Pallas, and (4) Vesta, can also be relevant. Therefore, we include the Newtonian attraction of the 16 most massive main belt objects (see Table 2). These accelerations are based on mutually perturbed trajectories for these 16 objects computed starting from DE431. As an example, Fig. 2a shows the contribution of (1) Ceres and (15) Eunomia for Golevka.

Relativity is an important component of the force model. For most objects a general relativistic model for the Sun [see equation (2.5) in *Damour and Deruelle* (1985)] is enough

$$\mathbf{a}_{\text{REL}} = \frac{GM_{\odot}}{c^2 |\mathbf{r}|^3} \left[ \left( \frac{4GM_{\odot}}{|\mathbf{r}|} - |\mathbf{v}|^2 \right) \mathbf{r} + 4(\mathbf{r} \cdot \mathbf{v}) \mathbf{v} \right]$$

where  $G$  is the gravitational constant and  $M_{\odot}$  the mass of the Sun. However, for asteroids experiencing planetary encounters, it can be important to include the relativistic contribution of the planets (see Fig. 2b). For instance, *Chesley et al.* (2014) show that the Earth relativistic term causes a  $3\sigma$  change in the orbital solution of asteroid (101955) Bennu due to the significant short range effect during Earth encounters. Thus, for these asteroids one can use the Einstein-Infeld-Hoffman formulation for relativity (*Moyer*, 2003, section 4.4.1), which is an N-body relativistic model that accounts for the contribution of the planets.

For objects experiencing Earth close encounters there are more stringent requirements on the accuracy of the force model. In fact, when observing these objects from the ground, their angular velocity in the sky is usually larger and therefore observations have more leverage. Moreover,

**Fig. 2.** Magnitude of the accelerations acting on asteroid (6489) Golevka. **(a)** Newtonian attraction of the Sun, Earth, Jupiter, Uranus, Ceres, and Eunomia, as well as the contribution of the Earth oblateness ( $J_2$ ). **(b)** Nongravitational perturbations, i.e., solar radiation pressure (SRP) and the Yarkovsky effect, and the Einstein-Infeld-Hoffman relativistic terms due to Sun, Earth, Jupiter, and Uranus.

objects passing close to Earth are more likely to be observed by radar telescopes, which provide observations of extremely high quality. For these objects it can be important to include the effect of the nonspherical shape of Earth. As an example, asteroid 2011 MD experienced an Earth encounter in 2011 at a geocentric distance of 19,000 km, and it is not possible to fit the data before and after the close approach unless the  $J_2$  term of the Earth geopotential (Battin, 1987, chapter 8) is accounted for. Thus, whenever an object is close enough to Earth [e.g., within 0.1 AU of Earth (see Chesley et al., 2014)] one should add the perturbation due to the second-degree zonal harmonics of Earth. The  $J_2$  parameter can be obtained by the JPL ephemerides or the EGM96 geopotential model (Lemoine et al., 1998). Figure 2a shows the  $J_2$  contribution for asteroid Golevka.

#### 4.2. Nongravitational Perturbations

Despite their small size, nongravitational perturbations can be significant in modeling asteroid trajectories. Solar radiation pressure (Vokrouhlický and Milani, 2000) is due to energy and linear momentum carried by light and transferred

to an asteroid upon impact of photons on the surface. This perturbation is along the radial direction  $\hat{r}$ , i.e., the Sun-to-asteroid direction. The Yarkovsky effect (Bottke et al., 2006; see the chapter by Vokrouhlický et al. in this volume) arises from the anisotropic reemission at thermal wavelengths of absorbed solar radiation. The Yarkovsky perturbation has a component in the along-track direction  $\hat{t}$  and therefore causes asteroids to undergo a secular variation in semimajor axis.

Nongravitational perturbations are intrinsically different from the other accelerations described in section 4.1. As a matter of fact, they depend on the individual physical properties of the asteroid we are dealing with and thus they are generally unknown. As an example, nongravitational perturbations are proportional to the asteroid's area-to-mass ratio and therefore inversely proportional to the diameter  $d$ . A possible approach is to model nongravitational perturbations as follows (Farnocchia et al., 2013a)

$$\mathbf{a}_{\text{NG}} = (A_1 \hat{\mathbf{r}} + A_2 \hat{\mathbf{t}}) g(r) , \quad g(r) = (1 \text{ AU}/r)^2$$

where  $r$  is the heliocentric distance and  $A_1$  and  $A_2$  are free parameters to be determined through the orbital fit to the

TABLE 2. The 16 most massive main belt perturbers and their gravitational parameters.

observations as dynamical parameters, i.e.,  $\psi = (A_1, A_2)$ .  $A_1$  accounts for solar radiation pressure and the radial component of the Yarkovsky effect, while  $A_2$  models the tangential component of the Yarkovsky effect. The dependence on the heliocentric distance is contained in the  $1/r^2$  factor, which matches the level of absorbed radiation. In case of other effects such as outgassing,  $g(r)$  can be replaced with a different function (e.g., Marsden *et al.*, 1973). Figure 2b shows the magnitude of nongravitational perturbations acting on (6489) Golevka. Solar radiation pressure and the Yarkovsky effect are computed according to Chesley *et al.* (2003).

Determining  $A_1$  from the orbital fit is complicated. Because of the  $1/r^2$  dependency, the radial component of  $\mathbf{a}_{NG}$  essentially reduces the size of solar gravity. Since the orbital period is constrained by the observational data,  $A_1$  and the semimajor axis  $a$  are strongly correlated and they adapt to match the observed orbital period. Therefore,  $A_1$  is observable only for small objects ( $A_1 \propto 1/d$ ) experiencing close approaches, which break Keplerian motion around the Sun and thus the correlation between  $A_1$  and  $a$ : 2009 BD (Micheli *et al.*, 2012; Mommert *et al.*, 2014a), 2011 MD (Micheli *et al.*, 2014; Mommert *et al.*, 2014b), and 2012 LA (Micheli *et al.*, 2013).

The Yarkovsky effect is generally more relevant than solar radiation pressure, although solar radiation pressure is larger in magnitude (see Fig. 2b). In fact, the Yarkovsky-related semimajor axis drift causes a run-off in longitude that accumulates quadratically with time. For asteroids (6489) Golevka (Chesley *et al.*, 2003) and (101955) Bennu (Chesley *et al.*, 2014), the availability of three radar apparitions clearly reveals the action of the Yarkovsky effect. For (152563) 1992 BF (Vokrouhlický *et al.*, 2008) the Yarkovsky effect is needed in order to match the precovery observations from 1953. Moreover, there are few tens of objects for which the Yarkovsky-related semimajor axis drift is detected from the orbital fit (Nugent *et al.*, 2012; Farnocchia *et al.*, 2013a) (see the chapter by Vokrouhlický *et al.* in this volume).

Figure 3 shows how important it can be to include non-gravitational perturbations in the model to make reliable predictions. Asteroid (101955) Bennu was observed by radar in 2011 (Chesley *et al.*, 2014). Since the observed arc before the 2011 radar observations can be fit with a gravity-only orbit, it is possible to make two different predictions for the radar delay measurements: either with or without the Yarkovsky effect in the model. By using a gravity-only solution we obtain a prediction with a small uncertainty of 3  $\mu$ s. If the Yarkovsky effect is included in the model, we obtain a significantly different prediction, shifted by 700  $\mu$ s with respect to the gravity-only prediction. Moreover, the prediction uncertainty is much larger, i.e., 150  $\mu$ s, as it accounts for the  $A_2$  uncertainty obtained by fitting the observed arc before the 2011 radar observations. The comparison between the actual delay measurements, whose reported uncertainty is 2  $\mu$ s, and the gravity-only prediction results in a  $170\sigma$  discrepancy. On the other hand, the radar measurements and the prediction obtained including the Yarkovsky effect

**Fig. 3.** Comparison between predictions and 2011 radar delay measurement for asteroid Bennu. Circles represent radar measurements, whose uncertainty is 2  $\mu$ s. Solid lines are prefit predictions with and without Yarkovsky effect in the model. Dashed lines correspond to the  $1\sigma$  prediction uncertainties, 3  $\mu$ s without Yarkovsky, and 150  $\mu$ s with Yarkovsky in the model. The origin of the y-axis corresponds to the gravity-only prediction.

in the model agree at the  $0.6\sigma$  level. The significantly better agreement between prediction and observations is due to both a much better nominal prediction and a larger uncertainty that accounts for the uncertainty in the Yarkovsky effect. This example shows that, although one can fit the available data without nongravitational perturbations, the inclusion of nongravitational perturbations may be important (if not necessary) to provide accurate predictions.

#### 4.3. Nonlinearity in Propagation

The main difficulty in asteroid trajectory estimation is nonlinearity, which restricts the validity of the linear methods of section 2 to local approximations. There are three main causes of nonlinearity.

The first source of nonlinearity is when the confidence region  $\Delta Q \leq \sigma^2$  becomes too large. This situation occurs when the normal and covariance matrices have a large condition number, which results in confidence ellipsoids with a very elongated shape: If  $\lambda_j$  are the eigenvalues of the normal matrix  $C$ , the lengths of the semiaxes of the confidence ellipsoid are  $\sigma_j = 1/\sqrt{\lambda_j}$ , and the ratio of the longest to the shortest is  $\sqrt{\text{cond}(C)}$ . It is common to find ratios  $10^5 \approx 10^6$ , thus some of the points in the confidence ellipsoid are far from the nominal solution.

When the quadratic approximation of  $\Delta Q$  fails, the shape of the actual confidence regions is very different from the ellipsoid given by equation (5). The boundaries of the confidence region are level manifolds of the probability density

function (PDF). Because of the exponential dependence on  $\chi^2$ , the probability estimates from the linearly propagated normal distributions fail. The PDF of the orbital elements cannot be computed from the covariance matrix. This has serious implications in the orbit determination for asteroids with few observations (see section 5).

The second cause of nonlinearity is the propagation of the orbit to some time well separated from the observed arc. This situation occurs even for Keplerian motion and is therefore relevant even for orbits weakly perturbed by planets, e.g., main-belt asteroids. The mean-motion  $n$  is a nonlinear function of the semimajor axis  $a$ ,  $n \propto a^{-3/2}$ . Since  $n(a)$  is a convex function, even a perfectly elliptic confidence region at the initial epoch is converted into a banana-shaped region in Cartesian space (see Fig. 5.2 in Milani and Gronchi, 2010), and the PDF is not normal anymore. The condition number of the normal matrix grows proportionally to the square of the time interval, so that even well-constrained initial conditions have badly conditioned normal matrices when propagated far in time.

The third cause is chaos, i.e., the exponential increase in the largest semimajor axis of the confidence ellipsoid as a function of time. The Lyapunov time is the time interval in which the longest axis increases, on average over long times, by a factor  $\exp(1)$ . For main-belt asteroids Lyapunov times can be on the order of thousands to tens of thousands of years (Holman and Murray, 1996). Because of planetary encounters, for near-Earth asteroids (NEAs) (perihelion smaller than 1.3 AU) Lyapunov times can range from years to decades (Whipple, 1995). As an example, for asteroid 2009 FD (Spoto et al., 2014) the Lyapunov time in the time interval 2009–2185 is about 15 yr: The longest axis of the confidence ellipsoid grows by a factor  $\approx 10^5$ . Although the current uncertainty is well approximated by an ellipsoid, the prediction uncertainty for 2185 has a very long banana shape. Note that the increase of size of the uncertainty region does not occur in all directions (also because the flow is volume preserving in phase space, in the purely gravitational case): The predominant direction in which the uncertainty grows is along-track, as a consequence of changes in the semimajor axis due to close approaches. After a time long with respect to the Lyapounov time, the uncertainty region appears like a wire bending and winding around the orbit and therefore impact monitoring is difficult for chaotic orbits (see section 6).

## 5. SHORT-ARC ORBIT DETERMINATION

When the observed arc is short, perhaps only a few hours or less, the standard technique of iterative differential corrections often fails due to nonconvergence, and even if there is convergence it is hard to rule out the possibility of other local minima of  $Q$  that may actually be closer to the true orbit. Nor is it obvious how to assess the prediction uncertainty when the linear theory presented in section 2 clearly does not apply and indeed some of the elements may be substantially unconstrained.

### 5.1. Bayesian Orbit Determination

To remove the assumption of linearity, one can use the Bayesian inversion theory as described by Muinonen and Bowell (1993). Given the orbital elements  $\mathbf{x}$ , their probability density is proportional to the product of the distribution of the observation residuals and a prior distribution

$$f_{\mathbf{x}}(\mathbf{x}) \propto f_v(v(\mathbf{x}))f_{\text{prior}}(\mathbf{x}) \quad (7)$$

The prior distribution  $f_{\text{prior}}$  can be non-informative, e.g., a uniform distribution in Cartesian coordinates, or informative, e.g., based on asteroid population models such as Grav et al. (2011). See Farnocchia et al. (2015b) for a discussion on the choice of  $f_{\text{prior}}$ .

When the linear approximation fails, the probability distribution of the orbital elements  $\mathbf{x}$  given by equation (7) can be very complicated. Therefore, Monte Carlo methods are suitable to generate orbital samples compatible with the available observations. Since optical observations constrain the angular position and rates, ranging methods are preferred. These methods originate in the plane-of-sky spherical coordinate frame, where the observer is at the origin and the asteroid state is given by the position and rates in right ascension, declination and range  $(\alpha, \delta, \dot{\alpha}, \dot{\delta}, \rho, \dot{\rho})$ , and they sample the space of  $\rho$  and  $\dot{\rho}$  in some way so as to explore a reasonable extent of line-of-sight position and velocity.

**5.1.1. Statistical ranging.** The idea of statistical ranging (Virtanen et al., 2001) is to randomly sample the topocentric range, i.e., the distance  $\rho$  between observer and asteroid. The first step is choosing the interval  $[\rho_{\min}, \rho_{\max}]$  of plausible values of the topocentric range. Then, orbital samples are generated as follows: (1) Noise is added to the observations according to the observational error model (e.g., see section 3). (2) Two observations  $(\alpha_A, \delta_A)$  and  $(\alpha_B, \delta_B)$  are randomly selected. (3) The topocentric distances  $\rho_A$  and  $\rho_B$  are randomly generated in the chosen interval and, coupled with the selected observations, yield two Cartesian states  $\mathbf{r}_A$  and  $\mathbf{r}_B$  at epochs  $t_A$  and  $t_B$ . (4) From  $\mathbf{r}_A$  and  $\mathbf{r}_B$ , one computes an orbit (e.g., see Dubyago, 1961) and the observation residuals. (5) The probability density function for the computed orbit is obtained from equation (7).

**5.1.2. Systematic ranging.** The systematic ranging technique (Chesley, 2005; Farnocchia et al., 2015b) relies on the fact that a series of astrometric positions over a short time interval gives an excellent constraint on the sky-plane position and motion. The range and range-rate are only weakly constrained, if at all, but if one were to fix the values of  $(\rho, \dot{\rho})$  the result would be a complete orbit, with small uncertainty. Thus, the systematic ranging concept scans a suitably dense grid in  $(\rho, \dot{\rho})$ , computing at each grid point the constrained best-fitting orbit. Then, the corresponding observation residuals provide the marginal probability in  $\mathbf{x} = (\rho, \dot{\rho})$  through equation (7).

**5.1.3. Markov-Chain Monte Carlo ranging.** The Markov-Chain Monte Carlo ranging (Oszkiewicz et al., 2009) is based on statistical ranging but allows one to generate an

unbiased sequence of orbital samples distributed according to equation (7). Statistical ranging is used to generate candidate orbits. However, a candidate orbit  $\mathbf{x}'$  is not always accepted. If  $\mathbf{x}_m$  is the last accepted solution, the acceptance of  $\mathbf{x}'$  depends on the ratio

$$\tau = \frac{f_{\mathbf{x}}(\mathbf{x}')}{f_{\mathbf{x}}(\mathbf{x}_m)}$$

The candidate orbit is accepted, i.e.,  $\mathbf{x}_{m+1} = \mathbf{x}'$ , with probability  $\min(1, \tau)$ . If the orbit is rejected, then  $\mathbf{x}_{m+1} = \mathbf{x}_m$ .

## 5.2. Linkage

Modern surveys produce a large number of observations belonging to many different moving objects. In general, one can initially identify only a very short arc of observations, also called tracklet, as belonging to the same physical object. When the arc length is small enough so that the curvature is not significant with respect to the astrometric uncertainties, the information contained in the short arc can be compressed through a linear fit in an attributable (Milani and Knežević, 2005)

$$\mathcal{A} = (\alpha, \delta, \dot{\alpha}, \dot{\delta})$$

which represents the angular position and velocity of the object in the sky. Given an attributable  $\mathcal{A}$ , the radial distance  $\rho$  and the radial velocity  $\dot{\rho}$  between the moving object and the observer are completely undetermined. If  $\rho$  and  $\dot{\rho}$  were known, it would be possible to compute the Cartesian state, and therefore the orbit, of the object

$$\begin{aligned} \mathbf{r} &= \mathbf{q} + \rho \hat{\mathbf{p}}, \\ \mathbf{v} &= \dot{\mathbf{q}} + \dot{\rho} \hat{\mathbf{p}} + \rho \dot{\alpha} \partial \hat{\mathbf{p}} / \partial \alpha + \rho \dot{\delta} \partial \hat{\mathbf{p}} / \partial \delta \end{aligned} \quad (8)$$

where  $\hat{\mathbf{p}} = (\cos \alpha \cos \delta, \sin \alpha \cos \delta, \sin \delta)$  is the line of sight, and  $\mathbf{q}$  and  $\dot{\mathbf{q}}$  are the observer's heliocentric position and velocity, respectively.

As the amount of data that can immediately be assigned to a single object is not enough to compute an orbit, we need to solve the identification problem, i.e., finding among independent observations those belonging to the same physical object. On the other hand, an identification can be considered reliable only if an orbit can be consistently fit to all the data believed to be of the same physical object. Thus, orbit determination and identification have to be solved by a single algorithm. Moreover, the computational complexity of the algorithm is a key consideration: Efficient methods capable of computing preliminary orbits using a low number of observations are desirable.

A comprehensive discussion of the process to solve the identification problem is beyond the scope of this chapter and can be found in chapter 11 of Milani and Gronchi (2010). Here we only discuss the linkage, i.e., joining together two or more short arcs of observations to form an orbit fitting all the data. First, we quickly describe the Kubica

*et al.* (2007) kd-tree algorithm and then we focus on other two methods to perform the linkage: The first method is based on the admissible region theory (Milani *et al.*, 2004), while the second method relies on the prime integrals of Keplerian motion (Gronchi *et al.*, 2010, 2011).

**5.2.1. kd-trees.** Kubica *et al.* (2007) present a technique based on kd-trees that has been successfully used by the Pan-STARRS PS1 Moving Object Pipeline System (MOPS) (Denneau *et al.*, 2013). kd-trees are hierarchical data structures that can be used to efficiently answer a variety of spatial queries (Bentley, 1975) and their structure provides fast and scalable performance. The first step is linking tracklets with a quadratic fit for the plane-of-sky motion, then preliminary orbit determination methods are used to find orbits compatible with the linked tracklets (Milani *et al.*, 2008).

**5.2.2. Admissible region.** Given an attributable  $\mathcal{A}$ , the possible values of  $\rho, \dot{\rho}$  can be constrained by making some hypotheses.

Using equation (8), the heliocentric two-body energy is an explicit function of  $(\rho, \dot{\rho})$

$$\begin{aligned} 2\mathcal{E}(\rho, \dot{\rho}) &= |\mathbf{v}(\rho, \dot{\rho})|^2 - 2GM_{\odot}/|\mathbf{r}(\rho)| \\ &= \dot{\rho}^2 + c_1 \dot{\rho} + W(\rho) - 2GM_{\odot}/\sqrt{S(\rho)} \end{aligned} \quad (9)$$

where  $c_1$  is a constant and  $W$  and  $S$  are quadratic functions of  $\rho$  (Milani *et al.*, 2004).

The first condition defining the admissible region is to select only those values of  $(\rho, \dot{\rho})$  for which the orbit is bounded, i.e.,  $\mathcal{E} < 0$ . The region of the  $(\rho, \dot{\rho})$  plane satisfying this condition has at most two connected components (Milani *et al.*, 2004).

A difficulty in the practical usage of the region defined above is that it is not a compact set, i.e., the observed object could be at an arbitrarily small distance from the observer. Thus, we need to define an inner boundary. A solution to assign a lower limit to the distance is to impose the constraint that the object is not very small and very close to Earth. The size can be controlled by setting a maximum value for the absolute magnitude  $H \leq H_{\max}$ . If an average value  $V$  of the apparent magnitude is available, then  $H$  can be computed as

$$H = V - 5 \log_{10} \rho - g(\rho, \phi)$$

where the correction  $g(\rho, \phi)$  accounts for the distance from the Sun and the phase angle  $\phi$  (owell *et al.*, 1989). For small values of  $\rho$ ,  $g(\rho, \phi)$  can be approximated with a constant  $g_0$ . However, this approximation is also acceptable for larger values of  $\rho$ . Thus, the upper bound on  $H$  yields

$$\log_{10} \rho \geq \frac{V - H_{\max} - g_0}{5} = \log_{10} \rho_H$$

Therefore, given the apparent magnitude  $V$ , we have a minimum distance  $\rho_H = \rho(H_{\max})$  for the object to be of significant size. Other conditions to define the inner boundary can be found in Milani *et al.* (2004).

Figure 4 shows the admissible region for asteroid (60558) Echeclus using the negative heliocentric energy and the upper bound on the magnitude ( $H_{\max} = 30$ ), which results in a lower bound on  $\rho$  of 0.34 AU.

Once the admissible region for a given attributable is computed, one can generate samples  $(\rho_i, \dot{\rho}_i)$  by constructing a Delaunay's triangulation (Bern and Eppstein, 1995) (see Fig. 4). Each node of the admissible region corresponds to an orbit to which we can assign a covariance matrix resulting from the attributable uncertainty. This orbit can be considered as a virtual asteroid (VA), i.e., one of the possible orbits compatible with the given attributable.

Each computed orbit and its covariance can be propagated to the time of a second attributable  $\mathcal{A}_2$  to compute a predicted attributable  $\mathcal{A}_p$  with covariance  $\Gamma_p$ . If  $\Gamma_2$  is the covariance of  $\mathcal{A}_2$  we can compute an attribution penalty (see chapter 7 of Milani and Gronchi, 2010) as

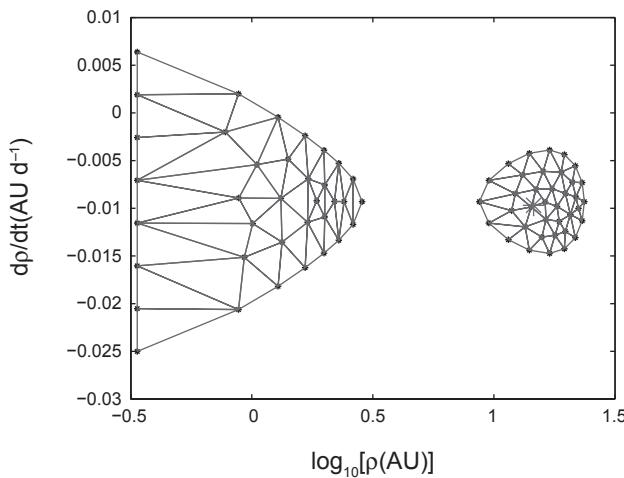

$$K = (\mathcal{A}_p - \mathcal{A}_2)^T (\Gamma_p^{-1} - \Gamma_p^{-1} \Gamma_0 \Gamma_p^{-1}) (\mathcal{A}_p - \mathcal{A}_2)$$

where

$$\Gamma_0 = (\Gamma_p^{-1} + \Gamma_2^{-1})^{-1}$$

If  $K$  is below some maximum value  $K_{\max}$ , the orbit is kept as candidate orbit to be confirmed by adding additional observational data (see chapter 11 of Milani and Gronchi, 2010). The distribution of  $\chi^2$  with 4 degrees of freedom can be used as a reference to select  $K_{\max}$ , although some margin might be necessary to account for nonlinearity.

**5.2.3. Keplerian integrals.** Another method to compute orbital solutions from two attributables  $\mathcal{A}_1$  and  $\mathcal{A}_2$  is based on the use of the conservation of the orbital energy  $\mathcal{E}$  and

**Fig. 4.** An example of admissible region for asteroid (60558) Echeclus. The attributable is computed from the Spacewatch observations of February 5, 2000. The Delaunay's triangulation is indicated by the solid lines and the nodes are marked with dots. The actual solution for  $(\rho, \dot{\rho})$  is marked with an asterisk.

angular momentum  $\mathbf{c}$ .  $\mathcal{E}$  can be expressed as a function of  $(\rho, \dot{\rho})$  (see equation (9)). The same holds for  $\mathbf{c}$

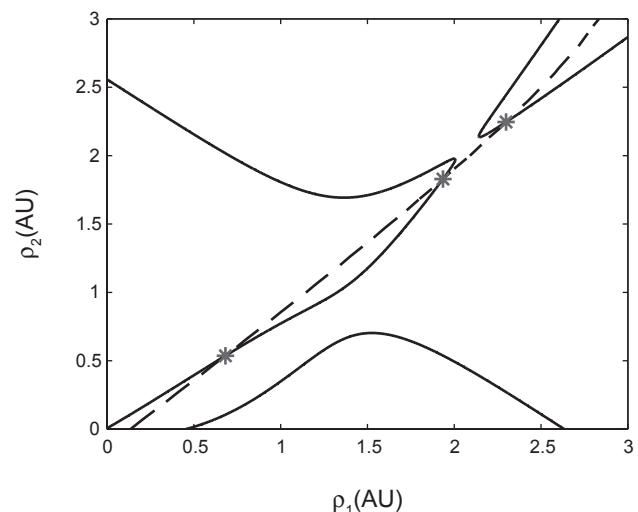

$$\mathbf{c}(\rho, \dot{\rho}) = \mathbf{r} \times \mathbf{v} = \mathbf{D}\dot{\rho} + \mathbf{E}\rho^2 + \mathbf{F}\rho + \mathbf{G}$$

where  $\mathbf{D}$ ,  $\mathbf{E}$ ,  $\mathbf{F}$ , and  $\mathbf{G}$  only depend on the attributable and the observer's position and velocity (Gronchi et al., 2010). By imposing the conservation of  $\mathcal{E}$  and  $\mathbf{c}$  at the time of the two attributables we obtain a system of four equations in four unknowns

$$\begin{cases} \mathcal{E}_1(\rho_1, \dot{\rho}_1) = \mathcal{E}_2(\rho_2, \dot{\rho}_2) \\ \mathbf{c}_1(\rho_1, \dot{\rho}_1) = \mathbf{c}_2(\rho_2, \dot{\rho}_2) \end{cases} \quad (10)$$

By eliminating  $\dot{\rho}_1$  and  $\dot{\rho}_2$ , we are left with two equations  $p_1(\rho_1, \rho_2) = 0$ ,  $p_2(\rho_1, \rho_2) = 0$ . As an example, the corresponding curves are shown for asteroid (243) Ida in Fig. 5. By using the resultant (Cox et al., 2007) and other algebraic manipulations it is possible to obtain a polynomial equation in either  $\rho_1$  or  $\rho_2$  of degree  $\leq 48$  (Gronchi et al., 2010). It is possible to lower the maximal degree of the polynomial equation down to 20 if the conservation of the energy is replaced by the conservation of the eccentricity vector projected on a suitable direction (Gronchi et al., 2011).

Some of the solutions of the polynomial equation are unphysical, e.g.,  $\rho_1 < 0$ . Other solutions are spurious, i.e., they have been introduced by algebraic manipulations. Thus, each solution of the polynomial equation has to be tested to make sure it is a solution of system (10) as well. For the solutions passing the test we obtain  $(\rho_1, \dot{\rho}_1)$  and  $(\rho_2, \dot{\rho}_2)$ , and so the Cartesian states of the orbit at the epochs of the two attributables  $t_1$  and  $t_2$ . Still, one needs to make sure that the

**Fig. 5.** Projection of system (10) on the  $(\rho_1, \rho_2)$  plane for asteroid (243) Ida. The attributables used are from February 17 and March 27, 1993. The asterisks mark the possible solutions for  $(\rho_1, \rho_2)$ . The solution  $(\rho_1, \rho_2) = (1.9, 1.8)$  AU is compatible with the actual orbit of Ida.

corresponding orbits are compatible. The conservation of the energy and the angular momentum ensures that semimajor axis, eccentricity, inclination, and longitude of node are the same. However, argument of perihelion and mean anomaly may well be incompatible.

As described in Gronchi *et al.* (2011), by solving system (10), one can map  $(\mathcal{A}_1, \mathcal{A}_2)$  to  $(\mathcal{A}_1, p_1, \dot{p}_1)$ . Thus, one can map the known covariances  $\Gamma_{\mathcal{A}_1}$  and  $\Gamma_{\mathcal{A}_2}$  of the two attributables to the covariance of the orbit at the epoch of  $\mathcal{A}_1$ . Finally, one can check the compatibility of the orbit and  $\mathcal{A}_2$  as described at the end of section 5.2.2. Again, the orbits passing this test can be used to find additional observations compatible with the computed orbital solution.

## 6. IMPACT MONITORING

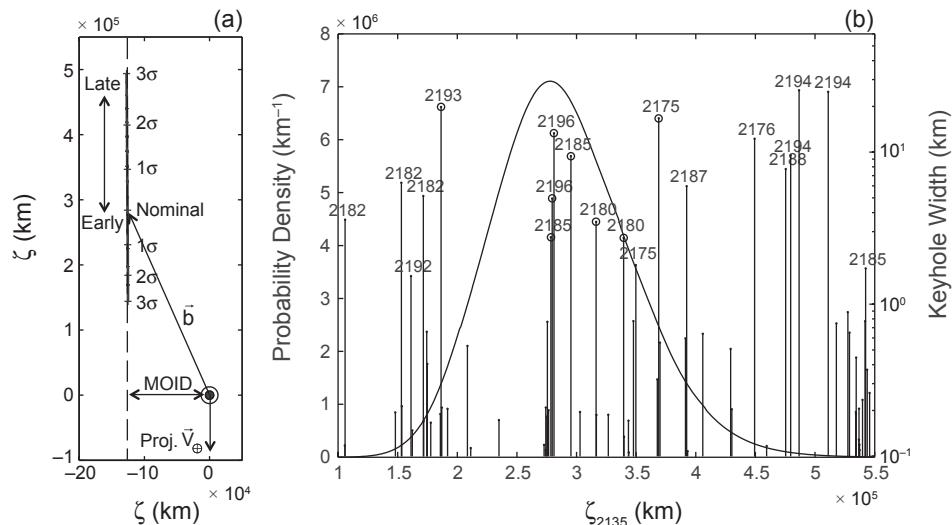

A high-profile application of asteroid orbit estimation and ephemeris prediction is Earth impact monitoring. This area of work has obvious relevance to the public, requiring great care to make sure results are transparent and accurate. Moreover, the imperative to make impact hazard assessments as far in advance as possible — and thereby allowing the maximum time for deflection or other mitigation efforts — leads to severe technical challenges.

The b-plane frame, sometimes also known as the target plane or Öpik plane, is a common and convenient framework for conducting Earth-asteroid impact hazard analyses (Vals-ecchi *et al.*, 2003; Öpik, 1951, 1976). In this formalism, the b-plane includes the geocenter at the origin and is oriented orthogonal to the incoming asymptote of the asteroid's geocentric orbit. For hazard assessment we are interested in the b-plane position  $\mathbf{b}$  of the inbound asymptote. As important is the uncertainty in  $\mathbf{b}$ , which in the simplest case is normally

distributed and can thus be described as an ellipse centered at  $\mathbf{b}$ . For the trajectory unperturbed by Earth,  $\mathbf{b}$  marks the encounter distance; however, due to gravitational focusing, close flyby trajectories can impact even if the asymptote does not intersect the figure of Earth. The b-plane distance of a grazing trajectory is given by  $b_{\oplus} = R_{\oplus}\sqrt{1 + v_e^2/v_{\infty}^2}$ , where  $R_{\oplus}$  is Earth radius,  $v_{\infty}$  is hyperbolic excess velocity, and  $v_e$  is Earth escape velocity ( $v_e^2 = 2GM_{\oplus}/R_{\oplus}$ ). For a spherical Earth, trajectories for which  $b < b_{\oplus}$  will impact.

The classical Öpik formulation of the b-plane establishes coordinate axes  $\mathbf{b} = (\xi, \zeta)$  so that the projection of Earth's heliocentric velocity onto the b-plane defines the negative  $\zeta$ -axis. Thus, the  $\zeta$  coordinate defines how early or late the asteroid is for the minimum orbital intersection distance (MOID) (Gronchi, 2005), which is well approximated by the absolute value of the  $\xi$  coordinate. Because in the most challenging cases the uncertainty in the time of arrival strongly dominates over the uncertainty in the other orbital elements, this decoupling of the miss distance into timing and orbital separation allows an intuitive perspective from which one can analyze encounters. As example, Fig. 6a shows the uncertainty region of (101955) Bennu mapped onto the b-plane of the 2135 Earth encounter. The uncertainty is mostly stretched along  $\zeta_{2135}$  and reflects the time of arrival uncertainty. The inner circle at the origin corresponds to Earth radius, while the outer circle corresponds to Earth capture radius.

The preferred approach to detecting potential impacts and assessing the hazard posed by potential impactors varies depending on the uncertainty in the estimated orbit, the time span of interest, and the intervening dynamics between the time of the observations and that of the potential impact. As we discuss below, linear methods are fast and therefore

**Fig. 6.** (a) Map of the Bennu  $3\sigma$  uncertainty region onto the b-plane of the 2135 Earth encounter. The inner circle at the origin corresponds to the Earth radius, while the outer circle corresponds to the Earth capture radius. (b) Distribution of  $\zeta_{2135}$  for asteroid Bennu. preferred when linear approximations are reliable for both the orbit determination and propagation. In cases where the linear assumption is inappropriate, an array of more computationally intensive nonlinear tools is available, such as Monte Carlo or line of variations (LOV) methods. One can picture this as a sort of cascade of computational tools that apply as the problem becomes progressively more nonlinear and less constrained.

## 6.1. Linear Methods

Linearity is a strong assumption for the impact monitoring problem and must be met in both the mapping from the observation residuals  $v$  to the orbital parameters  $x$  at the time of the observations, and in the mapping of  $x$  to orbital state  $x_{\text{ENC}}$  at the time of potential encounter. Following the notation of section 2 the assumption requires  $\Delta x \approx B\Delta v$  and  $\Delta x_{\text{ENC}} \approx A\Delta x$ . In such cases the observational uncertainty can be mapped directly to the future position uncertainty through the chain rule  $\Delta x_{\text{ENC}} \approx AB\Delta v$ .

The final step is to map the encounter state  $x_{\text{ENC}}$  and its uncertainty to the b-plane according to the linear mapping  $\Delta b = J\Delta x_{\text{ENC}}$ , where  $J = \partial b / \partial x_{\text{ENC}}$ . Here again the question of nonlinearity must be addressed, because for cases with large uncertainty and distant encounters, the curvature of Earth's orbit induces subtle nonlinearities that can corrupt results.

In the event that the linearity assumptions are valid, the uncertainty on the b-plane can be represented by the  $2 \times 2$  b-plane covariance matrix  $\Gamma_b = JABW^{-1}B^T A^T J^T$ , with probability density

$$f_b = \frac{1}{\sqrt{4\pi^2 \det \Gamma_b}} \exp\left(-\frac{1}{2}(\mathbf{b} - \bar{\mathbf{b}})^T \Gamma_b^{-1} (\mathbf{b} - \bar{\mathbf{b}})\right)$$

where  $\bar{\mathbf{b}}$  is the nominal b-plane prediction. From here the impact probability  $\mathcal{P}$  is simply the integral over the impact cross-section of Earth

$$\mathcal{P} = \int_{b < b_{\oplus}} f_b db$$

This is a fast numerical computation, but can only be used in cases where the numerous linearity assumptions hold. As a rough rule of thumb, the linear method is reliable when the impact probability increases above  $\sim 10^{-3}$ ; lower probabilities imply that the uncertainty region is too large to be adequately represented by a normal distribution. An optical data arc that extends over several days or more will generally allow linearity in the orbit determination so that  $\Gamma_x$  can represent the uncertainty. Generalizations are more difficult for the propagation to the prediction epoch, but the state transition matrix  $A$  will often prove adequate if the data arc is at least several days and the propagation time is at most a few years. For multi-apparition datasets propagations up to a century are often linear, though intervening close approaches may introduce nonlinearities far earlier.

## 6.2. Nonlinear Methods

When the foregoing linearity assumptions are invalid, one must resort to more cumbersome and computationally intensive techniques to properly characterize the prediction uncertainty at a potentially threatening close encounter. These techniques can be grouped into three general categories, namely Monte Carlo, ranging, and LOV methods. Each approach has its own advantages and disadvantages, and yet each has a regime where it is best suited to provide accurate and efficient results.

**6.2.1. Monte Carlo methods.** Monte Carlo methods are the most accurate and the most computationally intensive approach. The basic idea is to take randomly distributed orbital samples and for each sample compute the Earth miss distance at the epoch of interest. The estimated impact probability is simply the number of impacts divided by the number of samples  $N$ .

The most robust approach is to sample in the space of observations, i.e., to add normally distributed noise to the observation to model the observational uncertainty. The sampling can be done according to the probability density function  $f_v$  of the residuals (see equation (4)). The sampled  $v$  is added to the observations and these synthetic observations are used in the orbit estimation process to derive a sample least-squares orbit, which is then propagated to the time horizon of interest.

A somewhat more efficient approach can be used if the orbital variations are linear in the observation residuals over the range of uncertainty. In that case one can directly sample the orbit with the covariance  $\Gamma_x$  around the nominal orbital solution  $\bar{x}$ .

The uncertainty  $\sigma_{\mathcal{P}}$  in the impact probability estimate is given by  $\sigma_{\mathcal{P}}^2 = \mathcal{P}(1-\mathcal{P})/N$ . Thus, to find most potential impacts with probabilities greater than  $\mathcal{P}_{\text{lim}}$ , one needs to propagate  $\geq 4/\mathcal{P}_{\text{lim}}$  samples. For instance, for  $\mathcal{P}_{\text{lim}} \approx 10^{-6}$  we require  $N \approx 4 \times 10^6$  samples to obtain a 50% relative precision in our Monte Carlo result. With current computer technology, one can accurately propagate asteroid orbits at the rate of a few million years per hour, and so if we desire to identify all potential impacts with  $\mathcal{P} > 10^{-6}$  for a given asteroid for the next 100 yr we would need to integrate a total of  $4 \times 10^8$  yr, which would require roughly a week of time on a single processor. Reaching  $\mathcal{P} > 10^{-7}$  would require a few months of computing. Even with parallelization this technique can be impractical to implement in the framework of monitoring all NEAs for potential impact and updating the search whenever new observations become available.

Despite these limitations, the technique can be reasonably fast for potential impacts taking place within a few years if the probabilities are not too small. More importantly, the Monte Carlo techniques allow a robust uncertainty propagation where other methods falter or fail, and they can serve as an important validation tool in critical cases that require more careful analyses.

**6.2.2. Ranging methods.** A particularly challenging case arises with the need to provide short-term warning

for newly discovered objects that may impact within a few days of discovery. One might consider using the Monte Carlo approach in observation space if differential corrections converge successfully, but the question of sampling at other (potentially unknown) local minima could compromise the result. Since for newly discovered objects we generally only have a short arc of observations, the ranging methods described in section 5.1 are the most reliable means to perform the hazard assessment. Whichever ranging approach is used, the final result is an assessment of the element-space probability density and an estimate of the impact probability, whose reliability depends on obtaining enough samples to properly cover the orbital element phase-space. Because of the large uncertainty regions and computational cost, ranging techniques are particularly well-suited for single-night datasets and for impact monitoring up to a few weeks into the future.

For example, Fig. 7 shows the application of systematic ranging (see section 5.1.2) to 2014 AA, a small 2–4-m-sized asteroid. 2014 AA was discovered 21 h before striking Earth and only seven optical observations over 69 min were collected prior to the impact (<http://neo.jpl.nasa.gov/news-news182.html>). Despite the limited amount of data available, the astrometric RMS level curves bound the possible orbits and clearly suggest that 2014 AA is on a collision course.

**6.2.3. Line of variations methods.** The LOV method takes advantage of the fact that the orbital uncertainty grows with time in a peculiar way, by stretching into a long slender ellipsoid in Cartesian space. Small variations in most of the elements lead to periodic variations in the future position prediction, and by the same token, modest uncertainties in these elements lead to prediction uncertainties that do not grow with time. However, the uncertainty in semimajor

axis  $a$  is unique in this context because small variations in  $a$  produce variations in orbital period that cause the orbital anomaly to drift steadily away from the nominal orbit, a process referred to as Keplerian shear. The effect is to steadily stretch the uncertainty region along the orbit track, and so even for modest uncertainties in semimajor axis the uncertainty region can grow to cover the entire orbit. As an example, for an asteroid with semimajor axis  $1 \pm 0.05$  AU the mean anomaly uncertainty can increase to  $\pm 180^\circ$  in less than 7 yr, meaning that the asteroid could be anywhere along, although probably not far from, its nominal orbit.

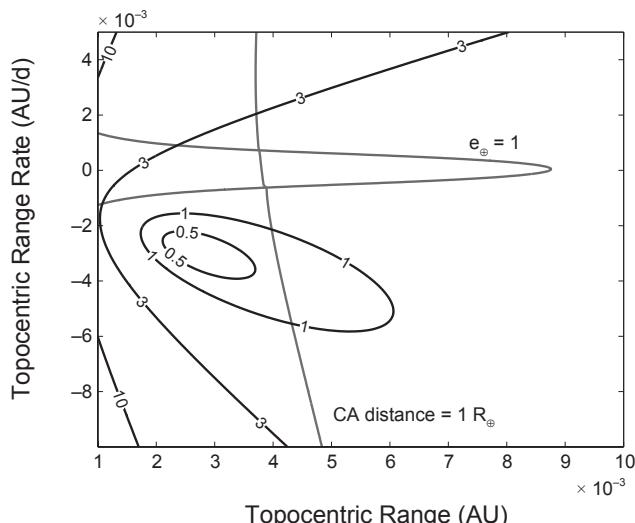

The tendency of the uncertainty region to grow long and slender as time passes suggests the possibility of a one-dimensional parameterization of the orbital uncertainty region. In the LOV method we only sample the spine, or LOV, of the confidence region, and if all orbits are sufficiently close to the LOV, then we obtain tremendous computational savings over higher-dimensional sampling methods without sacrificing reliability. The LOV method begins by computing the orbit at intervals along the LOV, forming a set of ordered multiple solutions (Milani *et al.*, 2005a), each of which is propagated to a time horizon of interest while recording all close approaches within a selected distance, which may be, say, 0.1 AU. By sorting and collating the recorded close approaches, while preserving the order implied from the multiple solutions, one can identify simply connected loci of points on the b-plane of a given encounter and perform an impact hazard assessment for every identified route to impact.

The LOV method is unmatched in its ability to reliably detect low probability events deep in the nonlinear regime with a minimum of computational effort. Milani *et al.* (2005b) define the generic completion level of the search as the greatest impact probability that can escape detection if the LOV is reasonably well behaved on the target plane. The finding is that generic completion levels of  $10^{-7}$  can be readily obtained with the propagation of only  $\sim 10^4$  multiple solutions, leading to compute times 3–4 orders of magnitude below those required for similar completeness in Monte Carlo simulations. Such speeds are clearly a tremendous advantage; however, the disadvantage of the method is that the LOV analysis can grow quite complex after it has been stretched and folded by multiple close planetary encounters, leaving open the possibility of missing pathological cases, which is a lower risk for Monte Carlo methods.

A more complete discussion of LOV methods is presented by Milani *et al.* (2002), while a complete implementation of the LOV method, which can be fairly involved, is described in detail by Milani *et al.* (2005b).

### 6.3. Keyholes and Hazard Assessment

The trajectory of a potential impactor will have by definition a very small MOID relative to Earth's orbit. Given enough time, asteroids on such trajectories will therefore likely experience multiple close approaches to our planet. Consider the case in which an asteroid misses Earth during one close approach, but the gravitational perturbation of the

**Fig. 7.** Contour levels of the astrometric RMS ("") for asteroid 2014 AA based on the seven optical observations obtained before the impact. The labeled curves show the limits for bounded geocentric orbits ( $e_\oplus = 1$ ) and impacting orbits (CA distance =  $1 R_\oplus$ ).

encounter places the object on a near-resonant trajectory that causes it to impact during a later encounter. The term keyhole was introduced by Chodas (1999) to describe the small region in the b-plane of the initial encounter encompassing the trajectories that impact at the later encounter.

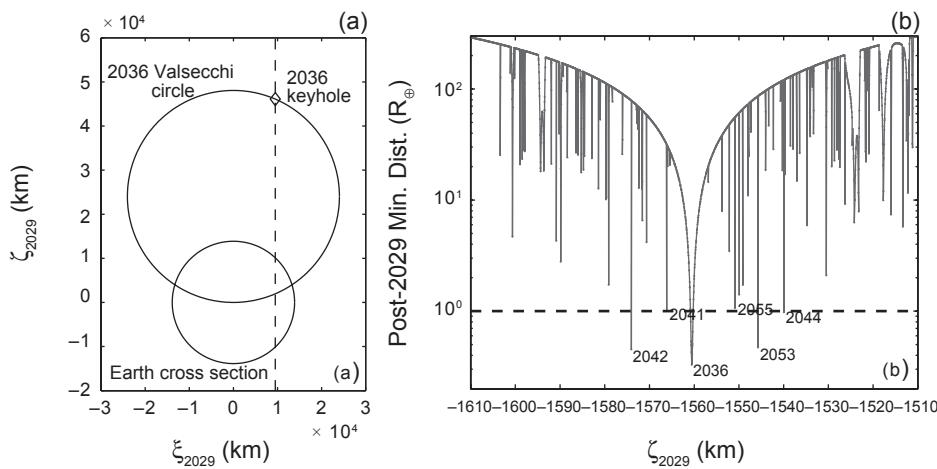

Early Monte Carlo explorations of uncertainty regions in a b-plane revealed keyholes as long narrow gateways that led to later impacts. All trajectories that pass through a keyhole will impact the planet at a subsequent encounter. Each keyhole is generally associated with an orbital resonance: The keyhole for a 7:6 resonance, for example, would place an object on an orbit that makes six complete revolutions about the Sun while Earth makes seven. Since there are many possible resonances, there can be many keyholes created by a close approach. Valsecchi *et al.* (2003) outline the mathematical theory behind keyholes and describe how their approximate locations can be predicted as a function of the heliocentric orbit and the particular keyhole resonances. As a first approximation, the coordinates on the b-plane corresponding to a given resonant return form a circle. The intersection between this circle and the uncertainty region gives the keyhole. As an example, Fig. 8a shows the 2029 b-plane for asteroid (99942) Apophis and the Valsecchi circle corresponding to the 2036 resonant return. The intersection between the LOV and the Valsecchi circle corresponds to the 2036 keyhole. It should be noted that nonresonant returns are also possible (Milani *et al.*, 1999) and that some resonances will not have associated keyholes because of perturbations from other planets.

Keyhole widths range from less than a kilometer to hundreds of kilometers or more. The 2036 keyhole in the 2029 b-plane of Apophis, for example, is very narrow, only about 600 m wide (Chesley, 2006). The narrow width is due to the fact that close approaches tend to scatter initially neighboring trajectories, because of the differential gravita-

tional perturbation. Slight differences in the close approach distance produce differences in the post-encounter semimajor axis, leading to a secular spreading apart of the different trajectories along the orbit path. A sequence of initially close neighboring points can be stretched apart by the close approach, and the points can become widely separated by the time of a potential impact. Keyholes can be thought of as pre-images of Earth mapped back to the pre-impact b-plane: When the stretching is reversed, the Earth disk at impact compresses down to the width of the keyhole in the pre-impact plane. Note that closer pre-impact encounters with Earth will lead to larger rates of spreading, and therefore to narrower keyholes. As a matter of fact, the 2036 keyhole for Apophis is narrow because of the small Earth encounter distance in 2029 of about 38,000 km.

Statistical studies have shown that about 15% of potential impactors will pass through a keyhole of several hundred kilometers or less in the 50-yr period before impact (Chodas, 2012). These studies also address the question of how close an object needs to approach Earth to form a keyhole: For a close approach within 50 yr of impact, the close approach distance must be less than about 0.10 AU in order to form a keyhole. Interestingly, distant pre-impact close approaches can have an effect opposite to that of keyhole encounters: Instead of spreading neighboring trajectories apart, encounters at distances of roughly 0.10 AU to 0.15 AU can actually focus neighboring trajectories (Chodas, 2012).

A systematic analysis of keyhole locations and widths along the length of the uncertainty region in a pre-impact b-plane forms the basis of another approach for estimating the impact hazard. A key step in this analysis is the creation of what we call a keyhole map. The map is formed using an LOV method very similar to that described in section 6.2.3, but with more finely spaced steps: Typically, hundreds of

**Fig. 8.** (a) The 2029 b-plane for asteroid Apophis. The two circles are the cross section of the Earth and the Valsecchi circle corresponding to a resonant return in 2036. The dashed line represents the LOV direction and the diamond the 2036 keyhole. (b) A segment of the Apophis keyhole map, i.e., the minimum post-2029 Earth distance as a function of  $\zeta_{2029}$ . Encounters distances smaller than  $1.1 R_\oplus$  are labeled with the corresponding year. The  $\zeta_{2029}$ -axis origin is set to 47677 km to match Fig. 9.

thousands of samples are used along the LOV. The trajectories are all propagated forward in time, first to the primary encounter where the keyholes will be mapped, and then forward to a time horizon of interest, while recording the close approach distances of the subsequent, secondary Earth encounters, within a threshold distance such as 0.15 AU. The Öpik coordinates are also computed in the secondary b-planes. The keyhole map is formed by plotting the minimum secondary close approach distance for each trajectory against the  $\zeta$ -component in the primary b-plane.

Figure 8b shows a close-up of the keyhole map for Apophis in the region surrounding the 2036 keyhole in the 2029 b-plane. Each downward spike represents a close approach sometime between the years 2029 and 2100. The dashed horizontal line marks the radius of Earth, and points below it indicate trajectories that impact, with the year of the impact noted. The 600-m width of the 2036 keyhole can be clearly seen as the horizontal width of the portion of the curve below the dashed line. The downward spikes on either side of the main keyhole are secondary returns spawned by the 2036 encounter. Just as the Earth capture disk in a b-plane is surrounded by primary keyholes, primary keyholes are in turn surrounded by secondary keyholes. And since they are produced by two consecutive close approaches, there are two levels of trajectory stretching, and the secondary keyholes are therefore even narrower than primary keyholes, often only meters or tens of meters across.

Special efforts are made to interpolate between points in the often sparsely populated secondary b-planes, and the closest approach point of the LOV from the origin is computed; the corresponding minimum close approach distance is then included in the keyhole map. If the LOV happens to cut across the Earth capture cross section in the secondary b-plane, there must be a keyhole in the primary b-plane. To get the width of the keyhole, the first step is to compute the chord length of the LOV intersection in the secondary b-plane, and then scale it down by the stretching factor between the b-planes. The stretching is computed by examining the trajectories that bracket the keyhole and taking the ratio of separation between the trajectories in the two b-planes.

The impact probability associated with each keyhole is estimated by integrating the  $\zeta$  PDF in the primary b-plane across the keyhole. Keyholes are usually narrow enough that one can assume a constant probability density across the keyhole. For instance, Fig. 6b shows an alternative representation of a keyhole map, with the probability distribution of  $\zeta$  in 2135 for Bennu as well as the locations and width of the keyholes corresponding to potential later impacts. The impact probability for each of these impacts can be easily computed as the product of the PDF at the keyhole center and the keyhole width.

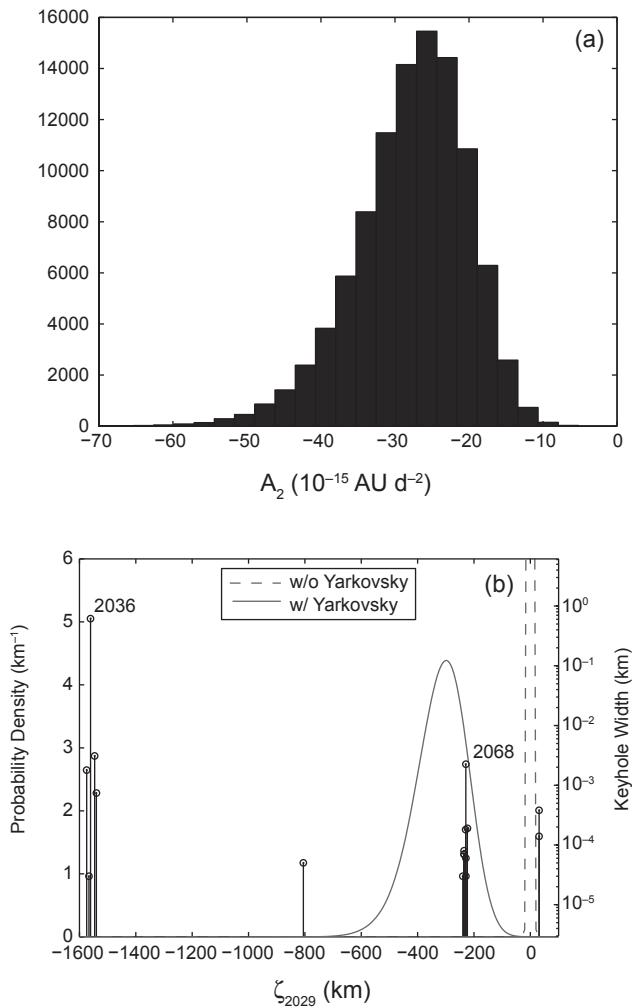

#### 6.4. Yarkovsky-Driven Impact Monitoring

The impact monitoring discussion so far has implicitly assumed gravity-only orbital dynamics and that an asteroid orbit only requires six estimable parameters. And yet, as

discussed in section 4.2, we know that asteroids can be significantly perturbed by nongravitational accelerations. In particular, the Yarkovsky effect can be a crucial part of an asteroid's impact hazard assessment, although this generally applies only to well-observed asteroids with precise orbits. The reason is that the Yarkovsky effect is such a slight perturbation to the orbit that it cannot rise above the overwhelming uncertainty seen in a new discovery, or even a typical multi-apparition orbit. The semimajor axis drift  $da/dt$  of a typical half-kilometer NEA may be only on the order of  $10^{-9}$  AU yr $^{-1}$ , i.e., 100 m yr $^{-1}$  or less, far below the uncertainties in most NEA orbits, where the uncertainty is completely dominated by astrometric uncertainties. As a result, the Yarkovsky effect generally remains unimportant for uncertainty propagation until decades of observations are available, although radar astrometry can require Yarkovsky consideration far sooner.

The generic case of a Yarkovsky-driven impact hazard assessment is centered upon a scattering encounter where the b-plane uncertainty is significantly enhanced by uncertainties in the Yarkovsky acceleration. Consider for instance the 2029 encounter of Apophis, which is nominally at a geocentric distance of 38,000 km. By neglecting the Yarkovsky effect and assuming gravity-only dynamics we find a b-plane uncertainty of only a few kilometers (see dashed line in Fig. 9b) and no meaningful probability of impact. However, the available physical characterization of Apophis (Binzel *et al.*, 2009; Pravec *et al.*, 2014; Müller *et al.*, 2014) suggests a reasonable range of the Yarkovsky effect. Specifically,  $A_2$  could be between  $-6 \times 10^{-14}$  AU d $^{-2}$  and  $-1 \times 10^{-14}$  AU d $^{-2}$  (see Fig. 9a), which corresponds to  $da/dt$  between  $-400$  m yr $^{-1}$  and  $-70$  m yr $^{-1}$  (Vokrouhlický *et al.*, 2015). Thus, the Yarkovsky effect leads to b-plane dispersions of several hundred kilometers and numerous keyholes fall within the b-plane uncertainty footprint. Figure 9b shows a keyhole map of the 2029 encounter where the large difference between the gravity-only and Yarkovsky uncertainty regions is apparent. After the scattering encounter, the Yarkovsky effect may again be negligible because the range of scattered orbits dominates over post-scattering Yarkovsky drift. The only effect of the post-scattering drift is a slight shift of the keyhole locations, typically by a distance that is similar to the actual size of the keyhole. Similarly, there is the possibility that the scattering encounter could induce a change in the spin state, for instance, by exciting a non-principal axis rotation state that could change the Yarkovsky drift rate. Again, this has only a small effect of shifting the keyhole locations on the b-plane, but does not appreciably alter the hazard assessment.

Most detected potential impacts are associated with recently discovered objects with large orbital uncertainties for which the impact probabilities are correspondingly low. The best approach to resolving these cases lies with obtaining more astrometric data to extend the data arc and eliminate the possibility of impact. For Yarkovsky-driven cases the situation is much different because the uncertainty at the scattering encounter is dominated by Yarkovsky dispersions,

**Fig. 9.** (a) Distribution of the Yarkovsky parameter  $A_2$  for Apophis. (b) Apophis distribution on the 2029 b-plane and keyhole map. Both the distribution without the Yarkovsky effect (gravity-only) and the one with the Yarkovsky effect are shown. The  $\zeta_{2029}$ -axis origin is arbitrarily set to 47,677 km, i.e., the nominal  $\zeta_{2029}$  value of the gravity-only solution.

and gathering additional astrometry will have a small or negligible effect on the hazard analysis.

When the Yarkovsky effect is relevant to the hazard assessment, there are two distinct approaches: either modeling or estimating the Yarkovsky effect. The most widely applicable technique is to model the range of the Yarkovsky effect by considering the thermophysical characteristics that drive it. We can model the Yarkovsky effect (Bottke et al., 2006; see the chapter by Vokrouhlický et al. in this volume) as

$$A_2 \propto \frac{\cos \gamma}{\rho d} f(I, \omega, A)$$

where  $\gamma$  is the obliquity of the asteroid equator,  $\rho$  is the bulk density,  $I$  is the surface thermal inertia,  $\omega$  is the rotation rate, and  $A$  is the Bond albedo. All these quantities can be con-

strained to some extent depending on what is known about the specific asteroid, or the asteroid population in general, and from that a distribution of  $A_2$  can be derived. Farnocchia et al. (2013b) and Farnocchia and Chesley (2014) provide a more detailed description of this approach, while Fig. 9a shows the example of Apophis where its nonprincipal axis rotation is accounted for (Vokrouhlický et al., 2015). This  $A_2$  distribution can be used as a basis of a Monte Carlo method to perform the hazard assessment: We randomly select  $A_2$  from its distribution, we compute a best-fit orbital solution corresponding to that value of  $A_2$ , we sample the orbital elements within the uncertainty region, and we propagate the orbit to the desired epoch. For instance, by doing so we obtain the  $\zeta_{2029}$  distribution for Apophis as shown in Fig. 9b. Finally, the  $\zeta_{2029}$  distribution can be compared to the keyholes to compute the impact probabilities by multiplying the  $\zeta_{2029}$  PDF and the keyhole widths.

With this technique the best way to resolve the impact hazard situation is to reduce the Yarkovsky dispersions by refining the asteroid physical model through direct observations of albedo, spin state, thermal inertia and shape, etc. Any new information on these characteristics feeds further refinements to the Yarkovsky model and reductions in the b-plane uncertainty.

When the signal for the Yarkovsky drift is visible in the astrometric dataset, often due to the availability of radar astrometry, we can work in the other direction, i.e., direct estimation. The usual strategy is to estimate  $A_2$  as a part of the orbit-determination process and use that directly to reduce the uncertainty at the encounter. In this case the orbit determination is a straightforward seven-parameter estimation process with a  $7 \times 7$  covariance matrix. The prediction problem still requires mapping to the b-plane, but now with seven parameters. This mapping may not be linear due to two-body dynamics and N-body perturbations, but Monte Carlo or LOV methods are readily extended to the seven-parameter case. Direct estimation of the Yarkovsky effect is preferred when available because there is less reliance on inference of sometimes poorly known physical properties. In this scenario, resolving Yarkovsky-driven impact problems calls for additional astrometry that can help to constrain the Yarkovsky effect, irrespective of thermophysical modeling. For instance, the mapping of the uncertainty region of Bennu on the 2135 b-plane (see Fig. 6b) was obtained by using a seven-dimensional orbital solution where  $A_2$  is determined with 0.5% precision (Chesley et al., 2014).

## 7. FUTURE WORK

Computing asteroid trajectories is a 200-yr-old problem. Despite the work that has been done so far, the quality and amount of observational data still call for continuous research and ever more accurate models.

While the star catalog debiasing and weighting schemes presented in section 3 represent a significant step forward in the statistical treatment of astrometric observations, there is still plenty of room for improvement. The Gaia star catalog

(Perryman *et al.*, 2001) will be released in the near future with its unprecedented accuracy for star positions and proper motions. Therefore, the Gaia catalog will allow better astrometric solutions for asteroid observations as well as a better reference to remove biases due to systematic errors in the other star catalogs. For the astrometric weights we plan a more indepth analysis to account not only for observation type and observatory code but also for specific observers, timing errors, correlations between right ascension and declination, angular rates, and observational signal-to-noise ratio.

The force model discussed in section 4 is accurate enough for most asteroids. We have seen how minor perturbations such as planetary relativistic accelerations, second-order spherical harmonics of Earth, and nongravitational forces can be critical to fit observational data and to make accurate predictions. In the near future, with more and more accurate astrometric data collected, we might find that other terms need to be added to the force model. In particular, the Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) mission (Lauretta *et al.*, 2012) will push the presented dynamical model to its limits. For instance, OSIRIS-REx will provide an independent measurement of the Yarkovsky effect acting on (101955) Bennu, thus serving as a validation for the current  $200\sigma$  detection (Chesley *et al.*, 2014). Moreover, OSIRIS-REx's ranging, together with the three radar apparitions already available, will put exceptional constraints on Bennu's orbit and reveal possible inaccuracies in the observation and force models.

The rapid increase of the quantity of asteroid astrometry could result in an excessive accumulation of unidentified single-night observations. Therefore, the short-arc orbit determination methods described in section 5 are important for present and future asteroid surveys. For instance, Bayesian-inversion orbit determination is planned for the asteroid observations obtained by Gaia (Mignard *et al.*, 2007). The linkage methods presented in section 5.2 and their improvement will be useful to efficiently compute orbits for surveys producing a large amount of data, such as the survey foreseen as part of ESA's Space Situational Awareness program (Drolshagen *et al.*, 2012), the Asteroid Terrestrial-Impact Last Alert System [ATLAS (Tonry, 2011)], and the Large Synoptic Survey Telescope (LSST) survey (LSST Science Collaboration and LSST Project, 2009).

In section 6 we described the current techniques to compute the probabilities of potential asteroid impacts. Whereas for most objects the impact monitoring is handled with methods that have been in use for the last 15 yr, there are nonstandard cases for which additional effort is required. In these cases we need to estimate the dispersion due to nongravitational perturbations, explore beyond scattering planetary encounters, and extend the impact-prediction horizon. Although we described methods to successfully compute impact probabilities for these cases, we are still far from having a fully automated procedure.

Another field of future work is the hazard assessment for short-term impactors. When a potential NEA is observed for the first time, the MPC places the corresponding informa-

tion on the NEO Confirmation Page (NEOCP) (<http://www.minorplanetcenter.net/iau/NEO/ToConfirm.html>) so that other astronomers can collect additional observations and confirm that it is indeed a NEA. When an object is on the NEOCP the orbit is only weakly constrained by the observations and the theory of least squares does not always apply. Still, we would like to be able to identify those objects that not only are potential NEAs but also potential short-term impactors. This way, astronomers would give priority to potentially hazardous objects on the NEOCP and provide additional astrometry to refine the trajectory before a possible impact occurs. While the ranging methods described in section 5.1 are suitable to identify hazardous asteroids, their implementation for automated short-term impact monitoring of all new detections is an ongoing project.

---

We are now approaching the level of technical expertise necessary to deflect a near-Earth asteroid (NEA) capable of destroying a large urban area, if not a small country. The current level of activity in the field, including search programs, physical characterization, and international initiatives to assess mitigation strategies, is unprecedented. However, we have only just started to explore the relevant properties of the small end of the NEA population (diameter <300 m), of which the next major impactor is most likely to be a member. The Chelyabinsk event has reminded us that objects as small as 20 m, about which we know very little, impact frequently and are a serious threat to life and property. Political awareness and international response efforts are still at a very primitive stage. For a global guarantee of protection, advances in scientific and technical competence must be matched by improvements in international coordination, as well as preparedness at the political level.

## 1. INTRODUCTION

The planets of the solar system started out as clumps of material, so-called planetesimals, with diameters of around 1–100 km, which grew by accreting particles and small bodies from the cloud of gas and dust that surrounded the newly formed Sun. Some planetesimals enjoyed rapid growth and quickly developed significant gravitational fields, thereby attracting and absorbing more and more small bodies to become fully fledged planets. Others were destroyed in violent collisions that produced clouds of fragments. A large fraction of the asteroids present in the solar system today are collisional fragments, orbiting the Sun in the main asteroid belt between the orbits of Mars and Jupiter. As a result of gradual orbital evolution due to the recoil effect of thermal radiation emission (the Yarkovsky effect; see the chapter

by Vokrouhlický et al. in this volume) and perturbations by large planets, primarily Jupiter, there is a continual leakage of asteroids from the main belt into the inner solar system. The resulting populations of so-called Mars crossers and near-Earth asteroids (NEAs) have orbits that give rise to occasional collisions with the terrestrial planets. The orbits of periodic comets can also evolve to cross Earth's orbit. The population of near-Earth objects (NEOs, a term embracing both asteroids and comets) contains a wide variety of bodies with diverse physical and dynamical properties (see the chapter by Jedicke et al. in this volume), and presents a permanent threat to our civilization and a serious challenge to those involved in developing mitigation strategies. While the term "NEO" is often used in texts on the impact hazard, comets are much less numerous than asteroids in Earth's neighborhood and represent only a minor fraction of potential

impactors. In this chapter we use the term “NEA” when referring primarily to the asteroid component of the NEO population (e.g., in discussions of population statistics and deflection techniques).

Awareness of the threat presented by NEOs has grown rapidly during the past few decades as a result of, for example, the first observation in real time of a large-scale impact on a planet, i.e., the impact of Comet Shoemaker-Levy 9 on Jupiter in 1994 (e.g., see *Noll et al.*, 1996); observations of fresh craters appearing on the Moon and Mars (e.g., *Buratti and Johnson*, 2003; *Malin et al.*, 2006); the discovery, with search programs of ever-increasing sophistication, of thousands of NEOs, some of which make uncomfortably close approaches to Earth; and the realization that the Tunguska event of 1908 was not a freak phenomenon after the blast waves from the Chelyabinsk superbolide of February 15, 2013, injured some 1500 people and damaged thousands of buildings (*Popova et al.*, 2013) (see section 2). The rather unsettling coincidence of the anticipated close approach at an altitude of only 28,000 km *on that very same day* of (367943) Duende (known at the time by its provisional designation of 2012 DA<sub>14</sub>), an asteroid with an extent of about 20 × 40 m unrelated to the Chelyabinsk object, ensured that asteroids made the headlines in most major news media at the time.

While this chapter concentrates on developments since the publication of *Asteroids III*, readers interested in earlier developments in this field are referred to, e.g., *Chapman and Morrison* (1994), *Toon et al.* (1997), and the books edited by *Gehrels* (1994), *Belton et al.* (2004), and *Bobrowsky and Rickman* (2007). In nearly all aspects of the impact hazard there have been major advances since the publication of the predecessor chapter to this one (*Morrison et al.*, 2002) in *Asteroids III*. In terms of our knowledge of the threat, the number of NEAs of all sizes discovered has risen from around 2000 at the end of 2002 to some 11,000 at the time of this writing (section 3). Surveys carried out by spacebased infrared telescopes, such as the Wide-Field Infrared Survey Explorer (WISE) (*Wright et al.*, 2010) and the Spitzer Space Telescope (*Werner et al.*, 2004), have provided diameters and albedos for many hundreds of NEAs, in contrast to the few tens of NEAs for which this information was available in 2002 (see section 5 and the chapter by *Mainzer et al.* in this volume). There has been a significant increase in efforts by observers and modelers to physically characterize the NEA population in terms of spin vectors, taxonomy, thermal properties, binarity, shape, surface structure, etc., and investigate properties particularly relevant to deflection considerations, such as porosity and internal structure, although these efforts have not kept pace with the dramatic increase in the discovery rate. Three NEAs have been visited by spacecraft, revealing very different small worlds, despite similarities in taxonomic type. The NASA Near Earth Asteroid Rendezvous (NEAR)-Shoemaker spacecraft visited the second largest NEA, (433) Eros, for one year starting in February 2000, revealing a peanut-shaped body with rich geological features such as large craters but a lack of small ones, boulders, “ponds,” and a fine regolith-covered surface (*Cheng*, 2002). The Japan

Aerospace Exploration Agency’s (JAXA) Hayabusa spacecraft visited the small NEA (25143) Itokawa and returned a surface sample to Earth (*Nakamura et al.*, 2011). Images of Itokawa suggest that even a body of just a few hundred meters in size can have a rubble-pile structure and be covered with large boulders and coarse regolith (*Fujiwara et al.*, 2006; see also the chapter by *Yoshikawa et al.* in this volume). The Chinese Chang’e-2 lunar mission flew by (4179) Toutatis just 800 m above its surface when Toutatis came within 18 lunar distances of Earth in December 2012. The images obtained show a contact binary NEA of 4.75 × 1.95 km and details of the distribution of boulders and regolith (*Huang et al.*, 2013). Radar observations have provided information on the shapes of some NEAs passing close to Earth (see the chapter by *Benner et al.* in this volume), including small binary NEAs, which constitute about 15% of the NEA population.

The Chelyabinsk event (Fig. 1 and section 2) taught us that an Earth-bound object large enough to cause considerable destruction of property, if not life, can be small enough to escape detection, especially if its final approach is in the daylit sky. While new wide-field, rapid-scan telescopes are currently planned to detect small impactors, the days to weeks of warning time they might provide would be inadequate for any mitigation action, apart from advising the relevant communities, who might organize evacuation if considered appropriate and feasible. The size of the threatening NEO that will trigger the first spaceborne deflection attempt is a matter of debate. Due to the steep size distribution of NEOs there are many more small objects than large ones, and consequently many more sightings of fireballs than crater-forming impacts. However, in this respect it is informative to compare the airburst of a stony object, such as the Tunguska event, which flattened 2000 km<sup>2</sup> of forest but left no other obvious trace on the ground, with the impact of a similarly sized metallic object, which produced the 1.2-km-diameter Barringer Crater in Arizona. In both cases the diameter of the impactor is estimated to be 30–50 m. Clearly the potential of a threatening NEO to cause damage depends not only

**Fig. 1.** The trail left by the Chelyabinsk bolide. The left part of the image shows two contrarotating vortices formed by heating and buoyancy effects in the horizontal cylinder of air in which kinetic energy of the asteroid was deposited. Credit: Wikimedia Commons.

on its size but also on its composition, density, and ability to survive passage through the atmosphere. The asteroid 2008 TC<sub>3</sub> lost 99.9% of its mass during its passage through the atmosphere, which suggests that this meter-sized body probably consisted of fragile material, as well as more solid but weakly aggregated pieces. Nevertheless, a few hundred fragments with a surprising range of lithologies were recovered in Sudan (see, for example, the chapters by DeMeo et al. and Borovička et al. in this volume). It seems that the lower size threshold for considering spaceborne deflection action should be around 30–50 m (see the discussion in section 6), although with current and foreseeable search programs it is highly unlikely that an object of this size would be detected far enough in advance for any deflection action to be feasible. At the other end of the size scale, it would seem difficult to justify spending taxpayers' money at present investigating how to deal with an object of more than 300 m in diameter, given that the impact probability per year of such objects is estimated to be around one in 70,000. In any case, given the size-frequency distribution of NEOs, it is probable that we will gain some experience in deflecting smaller ones before being confronted by a large potential impactor.

Serious effort is now being spent on investigating realistic asteroid deflection techniques (section 4). The main contenders at present are impulsive techniques, such as kinetic and explosive methods, and so-called "slow-push" techniques, such as those based on laser or ion-beam devices. The gravity tractor is a viable contender as a "slow-pull" technique. An interesting concept is the use of a slow technique directly after an impulsive deflection has taken place, in order to make fine corrections to the new orbit of the deflected NEA and provide some insurance against malfunction of the impulse transfer.

In recent years not only have the scientific and space-technology communities begun to pay more attention to impact-hazard issues, but some national space agencies and international organizations are now investing significant funding in various endeavors, motivated by the increased awareness of the problem.

NASA now funds the International Astronomical Union's Minor Planet Center and has recently significantly increased its funding of NEO search programs such as Lincoln Near Earth Asteroid Research (LINEAR), the Catalina Sky Survey, and the Panoramic Survey Telescope and Rapid Response System (Pan-STARRS) (see the chapter by Jedicke et al. in this volume). NASA also funds several groups to carry out research into aspects of NEA deflection options, such as those at Iowa State University's Asteroid Deflection Research Center. In total NASA allocated about 3% of its 2013 NEO funding to mitigation studies. The European Space Agency (ESA) is currently developing a program devoted to NEO defense in the framework of its Space Situational Awareness (SSA) initiative, including establishing a European NEO Coordination Centre. A collaborative mission concept currently under study in the U.S. and Europe is the Asteroid Impact and Deflection Assessment (AIDA) mission, the goal of which is to demonstrate the kinetic impactor concept by impacting the moon of a binary NEA (see section 4).

The European Commission's Seventh Framework Programme for Research and Technological Development (FP7) issued a call for proposals in 2010 entitled "Prevention of impacts from near-Earth objects on our planet." A consortium of 13 partners from 6 countries, including Russia and the U.S., responded with a proposal for the project NEOShield (<http://www.neoshield.net>), which succeeded in gaining 5.8 million euros of funding from January 2012 to May 2015. The NEOShield partners are investigating mitigation-relevant NEO physical properties and potential mitigation techniques (Harris et al., 2013). A further call for proposals for similar research projects was issued by the Commission in 2013; funding for a second phase of NEOShield, until 2017, was granted while this chapter was in preparation.

In a complementary initiative to those mentioned above, the United Nations (UN) has authorized the establishment of two new bodies (see section 7), the International Asteroid Warning Network (IAWN) and the Space Mission Planning Advisory Group (SMPAG).

While it seems the stage is now set for coordinated international activities in pursuit of solutions to the NEO impact threat, it remains to be seen if the momentum built up over the past few years can be maintained. The activities to be overseen by the IAWN and SMPAG will require significant and continuous funding, which will have to be made available by the participating countries. The recent Chelyabinsk event has served to focus attention on the impact hazard, but it is a fact of life that political interest in an area of public concern tends to wane if not regularly stimulated. Furthermore, we are still far removed from having an international agreement on who would do what, who would pay for what, and who would take responsibility for failure, in the event of a deflection action becoming necessary.

## 2. THE CHELYABINSK EXPERIENCE

On February 15, 2013, at the crack of dawn, a glowing object appeared in the clear southeastern sky seen from the industrial Russian city of Chelyabinsk. As it streaked nearly sideways across the sky, it grew brighter until it was a blinding white light that cast eerie moving shadows. It radiated high-intensity light for several seconds as it elongated and grew into a larger source, then gradually slowed, dimmed, and changed color from white to yellow, orange, and then a dull red. The sources of light continued along the original path as the main body stopped, forming the roiling head, rising like thunderclouds from a long, puffy trail that traced its entire path across the heavens. As residents looked on in wonder, the trail split neatly into two parts that seemed like mirror images of one another with a sharp line between them (Fig. 1). The columns silently drifted apart and grew upward, attracting early morning office workers and students to windows to observe and snap photos with their smart phones.

Suddenly, just under a minute and a half after the brightness of the fireball peaked, an unexpected blast wave ripped through the city, blowing out windows and showering spectators with high-speed shards of glass and falling ceiling

tiles. Nobody anticipated a blast following so long after the spectacle in the sky, the delay being due to the time it took the blast wave to travel at the speed of sound some 29 km down to the city. Fifteen hundred people would have to be treated for their injuries. Out on the streets, startled residents screamed and shouted expletives as the concussion hit them and set off car alarms. After the main boom, smaller explosions continued in rapid succession like artillery fire. The blasts lofted years of accumulated dust from old factories, creating a thick black pall over parts of the city as the booms continued. Power lines and mobile phone towers bounced and shook from the succession of blasts, leading to outages. To the south of the city, small black rocks rained down on villages and snow-covered fields.

Across the city and surrounding countryside, dashboard-mounted digital cameras captured the event from every angle. Within minutes, computer-savvy Russians were uploading images and videos to the internet. The Russian media initially reported the event as an unidentified flying object (UFO), and these reports were forwarded across the world by users of social media. Scientists at the Jet Propulsion Laboratory (JPL) in Pasadena first learned of the event from Twitter, and only because a dedicated JPL media specialist monitors her feed after hours. Others found out from Facebook because a late-night chess-playing Canadian shared a story posted by his early morning Russian counterparts.

U.S. government satellites with instruments designed to detect nuclear explosions recorded the bright flash as it happened, but did not automatically report it because it did not have the characteristics of a weapon. Seismometers in Russia recorded the shaking ground, which resembled an earthquake. Slower-moving low-frequency sound waves in the air (infrasound), which carried the first atmospheric news of the event, had not yet reached the western border of Russia by the time the international wire services picked up the story, albeit with sketchy anecdotal descriptions.

In the western hemisphere, most relevant experts were blissfully asleep, either on the U.S. east coast, where it was after midnight, or in pre-dawn Europe. Ironically, many were prepared for what was expected to be the big news event of the day, the close passage of asteroid (367943) Duende. With interviews and press conferences scheduled, they had no way of knowing that the Chelyabinsk event had just occurred. NASA does not have a system to detect atmospheric explosions, and the International Monitoring System only puts out alerts when explosions are nuclear, so nobody's pager went off. Without fortuitous social media connections, it is possible that officials would have been caught entirely off guard when asked by reporters if the Chelyabinsk event was related to (367943) Duende, or if NASA's calculations were wrong.

Those who had already seen the YouTube videos knew immediately that this was pure coincidence. The Chelyabinsk asteroid came from the direction of the Sun in the northern hemisphere, and Duende was arriving from the southern nightside. Nevertheless, if a few scientists in western time zones hadn't had their attention drawn to it and alerted their colleagues to the east, it could have created an unfortunate

embarrassment (even though it was not NASA's job to know about it, the public, media, and politicians may have perceived it differently).

Embarrassment, however, is not the worst-case scenario. If it had been cloudy in Chelyabinsk that morning, it may not have been immediately apparent to locals or outsiders that this was a cosmic airburst. The bright flash and huge blast, followed by the sound of heavy artillery, and parts of the city shrouded in dark smoke, could have been misperceived as an act of aggression. Snezhinsk, to the north, is the Russian equivalent of Lawrence Livermore National Laboratory in the U.S., and the region is of nuclear strategic importance. Russia, unlike its neighbor Kazakhstan in the direction from which the asteroid came, is still a nuclear-armed state. It is hard to know what would happen in the heat of the moment when there is great uncertainty about the cause of a half-megaton explosion over a Russian city.

If the same asteroid had come from a different direction it may have had far worse consequences on the ground. It was lucky that it arrived on a near-grazing trajectory, because its energy was spread out over a large distance, and was deposited high enough in the atmosphere to diverge and disperse before it reached the ground. A steeply descending asteroid would explode much lower and its downward momentum would carry it closer to the ground, causing much more severe damage (Kring and Boslough, 2014). It is almost certain that there would have been massive casualties under just slightly different conditions.

Thanks to the plethora of data collected from the dashboard cameras, seismometers, infrasound detectors, and satellites, we have a very good understanding of what happened. The best estimate of the kinetic yield (explosive energy) is 400–500 kt, making Chelyabinsk the most powerful such event observed since the 1908 Tunguska explosion [3–5 Mt (Boslough and Crawford, 2008)]. Analysis of video combined with subsequent onsite stellar calibrations enable reliable estimates of entry velocity ( $19 \text{ km s}^{-1}$ ), angle ( $17^\circ$  elevation), and altitude of peak brightness (29 km). This implies a preentry diameter of  $\sim 20 \text{ m}$  and mass of  $\sim 12,000 \text{ t}$ . Satellite sensors recorded the emission peak at 03:20:33 UT, with a total radiated energy of  $3.75 \times 10^{14} \text{ J}$  ( $\sim 90 \text{ kt}$ ). A typical bolide luminous efficiency of 20% implies a total energy of  $\sim 450 \text{ kt}$ , consistent with infrasound and other observations. The maximum radiant intensity was  $2.7 \times 10^{13} \text{ W sr}^{-1}$ , corresponding to an absolute magnitude (referenced to a distance of 100 km) of  $-28$ , or more than  $30\times$  brighter than the Sun as seen by an observer located directly below (Brown *et al.*, 2013).

The shallow entry angle led to a long bolide duration (16.5 s) and energy was deposited over hundreds of kilometers, leading to an extended, near-horizontal, linear explosion. The blast was distributed over a large area, and was much weaker than it would have been in the case of a steep entry and a more concentrated explosion closer to the surface. The orientation also led to different phenomena than expected for a more vertical entry. There was no ballistic plume as observed in the case of the Shoemaker-Levy 9 impacts into Jupiter ( $45^\circ$ ), or calculated for Tunguska [ $\sim 35^\circ$ ] (Boslough

and Crawford, 1997)]. Instead, buoyant instabilities grew into mushroom clouds and bifurcated the trail into two counterrotating vortices (Kring and Boslough, 2014).

Hydrodynamic models can now be initialized with extremely accurate energy depositions at correct locations, and results can be compared with observations (such as timing and distribution of blast energy at the surface, and evolution of the trail) to validate the models and better understand the physical phenomena associated with airbursts. Models suggest that airbursts are more damaging than nuclear explosions of the same yield (traditionally used to estimate impact risk, although nuclear radiation is not produced by the impact of a NEO). On the basis of recent observation-based size-frequency data, Chelyabinsk was estimated to be a once-per-century event while Tunguska was about once-per-millennium. These two events suggested that the size-frequency data underestimated the frequency of large airbursts. However, one of us (Harris of MoreData! Inc.) has updated the size-frequency estimates and determined that Chelyabinsk is a 50-year event. Chelyabinsk can no longer be considered an outlier as it is the only observed event of its size in the last 50 years. On the other hand, Tunguska is now estimated to be a 500-year event, so its occurrence just over 100 years ago can still be considered a statistical outlier. The new size-frequency data are presented and discussed in section 3 (see also Table 1). The risk from airbursts is greater than previously thought, but still highly uncertain.

There are several approaches that can be employed to reduce the uncertainty in the risk, and also to reduce the risk itself. One way to reduce uncertainty is to improve the monitoring and quantification of bolides. There are extensive records of past bolides seen by U.S. government satellites, and these data have been used by Brown *et al.* (2002, 2013) to estimate the flux of 1-m- to 10-m-diameter asteroids (permission has now been granted for the scientific community to access more recent data; see <http://neo.jpl.nasa.gov/fireball>). Another approach would be to launch dedicated satellites with missions optimized to observe and quantify bolides. Such a system would also provide immediate notice and location of an airburst event, which would aid in communication to the public as well as recovery of meteorites.

The best way to reduce the risk from Chelyabinsk-class asteroids would be to implement a short-warning survey, with groundbased telescopes optimized to search the entire night sky on a roughly daily basis, which would find even asteroids and meteoroids much smaller than Chelyabinsk as they brighten during the last days or weeks of their final encounters with Earth (see section 5). An alternative or complementary measure could be an infrared space telescope with a position and cadence optimized to find small objects within days or weeks of impacts. Such systems would also find smaller objects that are not a threat, but that would be a potential boon to science, and could even be commercialized with costs recouped by the recovery of meteorites and high-end adventure tourism (Boslough, 2014). If such a system had existed in 2013, the storyline of Chelyabinsk might read differently:

*On February 15, 2013, at the crack of dawn, a glowing object appeared as expected in the clear southeastern sky seen from the industrial Russian city of Chelyabinsk. As it streaked nearly sideways across the sky it was tracked with scientific instruments, including telescopes, spectrometers, high-definition cameras, radar, and calibrated radiometers. Optical pyrometers determined the temperature of the fireball as it cooled and changed color. As the spark-like fragments continued to fade out and fall in dark flight, they were still glowing in the thermal infrared and were tracked all the way to the ground, where they were immediately recovered and taken to meteorite laboratories that had been prepared for them.*

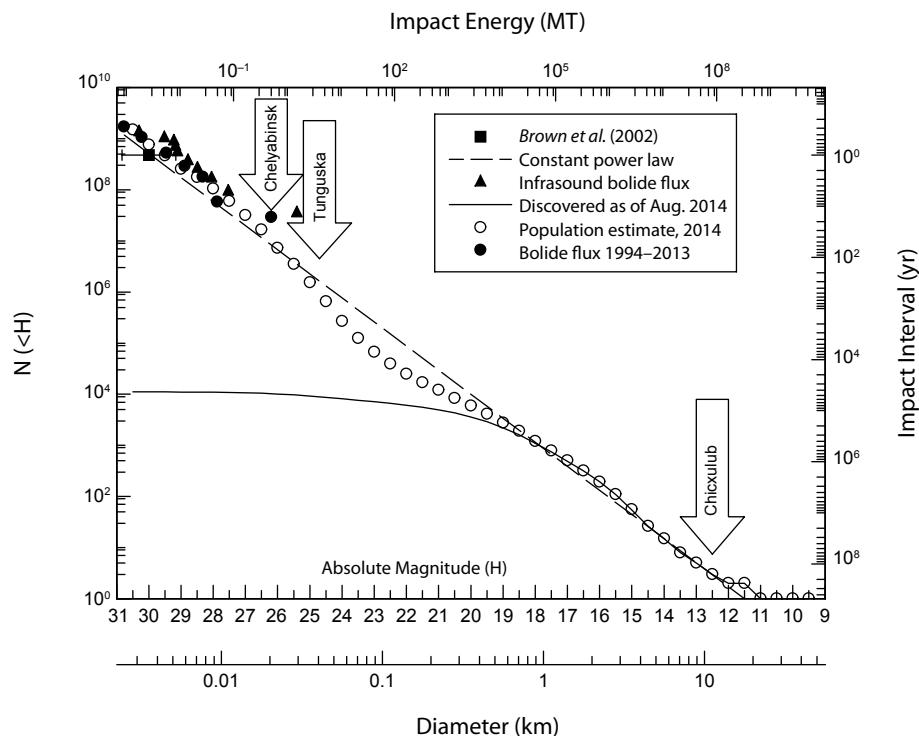

*Residents who had been warned to stay away from windows and to watch from a safe distance looked on in wonder. Hotels in outlying areas were filled with adventure tourists who had come from all over the world to see this once-in-a-lifetime spectacle. Some had volunteered to join scientific expeditions to scour the fall area for meteorites.*

*Researchers were able to use the wealth of high-quality, calibrated data to improve models of ablation, fragmentation, breakup, and explosion, improving their understanding of the high deformation-rate processes that will ultimately improve risk assessment, as well as facilitate the design of more effective impulsive deflection methods if a larger hazardous asteroid is discovered with sufficient advance warning.*

### 3. CURRENT UNDERSTANDING OF THE IMPACT HAZARD

Although the impact frequencies for NEAs with diameters, D, larger than 100 m are known quite well, and about 90% of NEAs with D > 1 km have been discovered, smaller NEAs are less well characterized. Relative to astronomical surveys of NEAs, actual impact events like Chelyabinsk (although small in number), and recalibration of infrasonic airwave data (Silber *et al.*, 2009), suggest that the frequencies of impacts by bodies tens of meters in diameter may be several times higher than those estimated earlier from optical survey data.

Our present understanding of the numbers of NEAs and impact probabilities is summarized in Fig. 2, in which the curve traced by the circles represents current best estimates of the cumulative number of NEAs larger than a given diameter. For a given H-value interval, optical survey population estimates are derived by counting the number of redetections of previously discovered objects compared to the total number of detections (new discoveries plus redetections) in the most recent survey period of two years. As the ratio of redetections to all detections approaches 100%, so does the survey completion. However, since some asteroids are easier to find than others, and the easy ones are discovered first, the estimated completion is actually always less than the redetection ratio. A correction to the completion estimate is derived using a realistic model of the NEA population and

**Fig. 2.** Estimated number of NEAs larger than a given diameter/brighter than a given absolute magnitude. The continuous curve represents discoveries as of August 2014; the curve traced by the circles represents the estimated total number of objects in the NEA population, derived from computer modeling of discovery and redetection rates by optical telescope surveys over the two-year period to August 2014. The population estimated in this way appears to be in excellent agreement with population estimates from bolide and infrasound data. The estimated mean interval between impacts of objects larger than a given diameter can be read off on the righthand scale using the curve traced by the circles. The conversion from H to diameter assumes an albedo of  $p_V = 0.14$ . The uncertainty in the estimated population curve in the range  $D = \sim 10$  to  $\sim 100$  m from all errors, observational, model, and the albedo assumption is probably less than a factor of 3. At larger sizes, the uncertainty is even less, diminishing to only a few percent for  $D \sim 1$  km and larger.

a computer simulation of a hypothetical optical telescope survey over the same time period, in this case 20 years.

The latest update of the NEA population, presented in Fig. 2, appears to largely resolve the above-mentioned discrepancy in population estimates between astronomical surveys and bolide frequencies (Brown *et al.*, 2013; Silber *et al.*, 2009). Earlier population estimates from astronomical surveys obtained a population in the tens of meters size range about a factor of 3–4 lower than estimated from bolide and infrasound data (see, e.g., Harris, 2014). However, the most recent population estimate falls within the scatter over the size range of the bolide estimates.

To the best of our knowledge there is no current threat from any NEA larger than about 4 km in diameter, since they have probably all been found and none are on a threatening trajectory during the next century. There remains a very small but uncertain threat from large comets. Objects originating in the Oort cloud are discovered typically only about two years prior to perihelion, precluding any effective spaceborne de-

flection action in these cases. For example, Comet C/2013 A1 (Siding Spring) was discovered in January 2013 on its way into the inner solar system from the Oort cloud. Early orbit calculations revealed a small probability that the comet would impact Mars on October 19, 2014, with a velocity of some 56 km s<sup>-1</sup>. Even with a diameter of around 500 m, at the lower end of initial size estimates, an impact of the comet on Mars would have had dramatic, possibly global, effects, not to mention the potentially disastrous consequences for the valuable scientific assets on its surface and in orbit around it. Later refinements of the orbit of C/2013 A1 ruled out an impact but showed it would pass within around 20 martian diameters of the planet (Farnocchia *et al.*, 2014).

Apart from the frequency of impacts by cosmic bodies of various sizes, a major question concerns the scale of damage such an impact might cause. The Chicxulub (K-Pg boundary) impact at 66 Ma presents a qualitative example of how very infrequent impacts by large NEOs can greatly change the global ecosphere and biosphere of Earth. Near-

Earth objects with  $D = 2\text{--}3 \text{ km}$ , and possibly as small as 1 km, could destroy civilization as we know it, although the degree to which that civilization is robust or vulnerable to the multiple environmental effects of such impacts remains speculative. Impacts of bodies only 500 m in diameter could, for example, severely damage or destroy the ozone layer (Birks et al., 2007). Near-Earth objects of such sizes impacting in the ocean could also produce very destructive tsunami, although a number of studies (e.g., Gisler et al., 2011; Wünnemann et al., 2007; Korycansky and Lynett, 2005; and references therein) suggest that such waves would largely disperse before reaching coastlines, unless the impact were rather close to the coastline. The environmental consequences of damage from a ground explosion are simulated in the online program Impact Earth [<http://www.purdue.edu/impactearth/> — for details, including assumptions and uncertainties, see Collins et al. (2005)]; how much infrastructure would be destroyed or how many lives would be lost would depend on proximity to the impact (see, e.g., Garbolino and Michel, 2011) and how much advance warning there was to strengthen infrastructure or evacuate the region.

Recently there has been emphasis on the effects of the smaller but much more frequent impacts of NEOs several tens of meters in diameter and smaller. A big issue has been, what is the smallest NEO that would be damaging? The NASA NEO Science Definition Team study (NASA SDT) (Stokes et al., 2003) concluded that NEOs with  $D < 40 \text{ m}$  would explode rather harmlessly in the upper atmosphere, but that conclusion has been undercut for several reasons. First, Boslough and Crawford (2008) realized that downward momentum of a NEO through the atmosphere would be more damaging than a stationary explosion, and concluded that the great damage at Tunguska could have been produced by a body only  $\sim 40 \text{ m}$  in diameter (a few megatons of equivalent energy). Second, we have learned that some types of smaller projectiles can be more damaging than the average, such as nickel-iron objects, which are relatively dense, and objects that can reach the ground by virtue of unusual aerodynamic shapes. Low cosmic velocities ( $12\text{--}14 \text{ km s}^{-1}$ ) and shallow entry angles also contribute to reducing aerodynamic stress and may allow meter-sized stony meteoroids to reach the ground, such as the object that caused the 13-m-diameter impact crater near the Peruvian village of Carancas in 2007 (Kenkmann, et al., 2009; Tancredi et al., 2009). The Chelyabinsk event (section 2) could have been even more destructive at ground zero if it had entered the atmosphere at a less shallow angle. On the other hand, the impact was unfortunately close to a major city, which would not usually be the case. One factor that needs to be recognized is that any nominal estimate of size (and associated damage potential) has uncertainties that could be very great for a body discovered only shortly before impact. Asteroids have diverse compositions and shapes, wide ranges of albedo and bulk density, and other uncertain attributes, which could be difficult or impossible to assess before impact but conceivably could result in the nominal estimate of destructive energy being in error by an order of magnitude in either direction.

Thus, even if a body just 10 m in diameter or smaller were predicted to strike a locality, a prudent civil defense official might well warn people to evacuate, or at least stay indoors in structurally sound buildings well clear of windows (to avoid flying glass), to cover their ears (to avoid eardrum rupture), and, where possible, to open all windows and doors (to minimize damage by the overpressure of the blast waves).

The general approach to dealing with the NEO hazard is to (1) search the skies for NEOs that may strike Earth; (2) plan and carry out a deflection spacecraft mission if there is sufficient time and the threat is sufficiently great (high probability of damaging impact); and/or (3) evacuate or otherwise prepare to mitigate the effects of an impact.

Telescopic searches for NEOs are of several kinds (see the chapter by Jedicke et al. in this volume). The Spaceguard Survey was designed to find  $>90\%$  of NEOs  $>1 \text{ km}$  in size, and it has accomplished that task, although taking some years longer than the mandated decade. As a byproduct, the Survey has found many NEOs down to hundreds of meters in diameter, and a statistical sample of those down to  $\sim 10 \text{ m}$  in diameter. The Survey continues, although with modifications. The NASA NEO Science Definition Team report and the subsequently passed law by the U.S. Congress (George E. Brown, Jr. NEO Survey) recommend finding 90% of NEOs with diameters larger than 140 m within the near term. Various groundbased, e.g., the Large Synoptic Survey Telescope (LSST), and spacebased, e.g., the NEOCam and Sentinel, projects are designed to meet this goal, although the timeframe for the surveys keeps slipping into the future. Yet another approach is to use dispersed small telescopes to cover the sky on a nightly basis and find NEOs as they approach Earth for the last time before striking. The Catalina Sky Survey, for example, found the tiny asteroid/meteoroid 2008 TC<sub>3</sub> just over 20 hours before it struck in the Sudanese desert. Several systems are under development [e.g., the University of Hawaii's Asteroid Terrestrial-impact Last Alert System (ATLAS) or ESA's Fly-Eye concepts — see section 5] that could find up to half of potential impactors during the days to months before impact — those coming from the night sky rather than from the daylit sky — providing adequate time for evacuation warnings.

If a sizeable NEA is discovered to be on a possible impact trajectory years or a decade or two before impact, then a spacecraft mission designed to deflect the asteroid is technically feasible. Direct deflection of a hazardous NEA so that it passes several Earth radii away from Earth instead of striking Earth may be necessary in the worst case. However, an asteroid may closely approach Earth on a previous apparition so that the perturbation by Earth's gravitational field is just the right amount to cause its orbit to enter a resonance condition with Earth's orbit and impact Earth on a later approach. The small region of space through which the NEA has to pass to enter a resonance is called a gravitational (or resonance) "keyhole" (see the chapter by Farnocchia et al. in this volume). A recent prominent example was the prediction of a keyhole only about 600 m wide in the case of the 2029 approach to within 35,000 km of Earth's surface of

(99942) Apophis, a NEA with a diameter of some 325 m. If Apophis were to pass through the keyhole an impact with Earth would follow in the year 2036 (see, e.g., *Yeomans et al.*, 2009). Fortunately, recent observations have ruled out a possible passage of Apophis through the keyhole. Accurate knowledge of an asteroid's orbit allows the existence of keyholes for the object to be predicted well in advance. It is much easier to deflect the asteroid from passing through a small keyhole than having to deflect it by several Earth radii.

Studies of deflection missions are in their infancy (see section 4) but there appear to be no fundamental issues preventing existing technology from being put together rapidly to build a deflection mission, should the need arise. Similarly, the disaster response community has little familiarity with asteroid impact as a natural disaster, but the kinds of environmental effects arising from the atmospheric explosion or ground impact of a NEO are similar to those of more common natural disasters (*Garshnek et al.*, 2000) so that, provided a predicted impact is properly communicated to relevant officials in the relevant nations or localities, it seems likely that appropriate responses to a predicted impact would result in most cases. There will always be, though diminishing with time as surveys advance, the chance that an unpredicted impact will occur, as in the case of Chelyabinsk.

#### 4. NEAR-EARTH ASTEROID DEFLECTION TECHNIQUES

Many ideas have been proposed to deflect an asteroid from an Earth-bound trajectory or to disrupt it. However, to date none has been tested in space and the feasibility of proposed techniques given present technology differs greatly.

Three apparently realistic methods have emerged from the numerous studies devoted to this topic, namely the kinetic impactor, the gravity tractor, and blast deflection, which are described below. Other suggested techniques include directing a laser beam at the asteroid's surface to expel (ablate) material from it, thereby creating a force that moves the object so as to conserve linear momentum (*Gibbins et al.*, 2013). Similarly, the use of large mirrors or lenses to concentrate the Sun's energy onto an asteroid using single or multiple spacecraft has been advocated. Another idea would be to exploit the momentum transmitted by a collimated beam of ions impacting the asteroid surface (*Bombardelli et al.*, 2013). Ion thrusters attached to a hovering spacecraft could be used for this purpose. The spacecraft, placed at a distance of a few asteroid diameters, would also need an ion thruster pointed in the opposite direction of the asteroid to balance the spacecraft's reaction to the deflecting thrust and keep a constant distance between the asteroid and the shepherd spacecraft. A more speculative idea is to paint the surface of an asteroid to increase its albedo, thereby enhancing the solar radiation pressure acting upon it (*Paek*, 2012). These methods require much *a priori* knowledge of the asteroid and/or they involve technologies that require significant further development. In particular, providing adequate power for deploying beams of light or ions to deflect a threatening NEA to a safe

trajectory, developing systems that can operate continuously and reliably over periods of years, and the requirement for autonomous guidance and control of the deflecting spacecraft are all major technical challenges.

Most recent studies (e.g., *Shapiro et al.*, 2010) find that the most reasonable approach in the vast majority of cases, especially for NEAs with diameters above about 100 m (see section 6), is deflection by hypervelocity kinetic impact by a massive spacecraft, while an observer spacecraft (preferably with a slow push or pull capability, such as a gravity tractor, as discussed below) looks on to assess the success and magnitude of the deflection. The impact of the artificial projectile (spacecraft) transfers momentum to the NEA, causing a small change in velocity. If a large amount of ejecta is produced by the impact event then the momentum transferred can be greatly enhanced, as dictated by the law of conservation of momentum, resulting in a larger deflection of the object's course. The production of ejecta increases the effectiveness of impulsive deflection techniques but the amount of ejecta produced depends strongly on the subsurface properties of the asteroid. A series of kinetic impactors should suffice for threatening NEAs possibly up to 1 km in size.

The NASA Deep Impact mission (*A'Hearn et al.*, 2005) successfully caused an impactor to collide with the nucleus of Comet 9P/Tempel 1 on July 4, 2005. Due to the large mass of the 6-km-diameter nucleus, and nongravitational forces acting on it, it was not possible to measure a change in the comet's trajectory resulting from the impact, so the experiment did not provide a measurement of momentum transfer to the comet. Nevertheless, the mission successfully impacted its target and highlighted the complex autonomous guidance necessary to do so.

The kinetic impactor technique has been the subject of a number of studies carried out by major space agencies. In 2006 the European Space Agency funded and coordinated detailed studies of a kinetic impactor concept called Don Quijote, which consisted of an orbiter and a small impactor spacecraft arriving several months later than the orbiter (e.g., see *Wolters et al.*, 2011, and references therein). The orbiter would first characterize the target and measure the deflection due to the impact of the second spacecraft. While the Don Quijote concept as such has not been funded to date, it has served as the inspiration for aspects of the NEOShield program and European participation in the AIDA concept. In early 2010, ESA, Johns Hopkins University's Applied Physics Laboratory, NASA, the Côte d'Azur Observatory, and the German Aerospace Center initiated a study of AIDA, the aim of which is to deflect the small secondary of a binary asteroid, chosen so that the perturbation to the orbit of the secondary can be observed from groundbased facilities in 2022. The target is the binary asteroid (65803) Didymos. The mission (*Cheng et al.*, 2015; *Michel et al.*, 2015) has two independent components: the projectile spacecraft, "Double Asteroid Redirection Test" (DART), which would be developed in the U.S., and the European rendezvous spacecraft Asteroid Impact Mission (AIM). DART would serve as a test of our ability to impact a small (150-m-diameter) object, while

AIM would allow it to be characterized in detail by observing the target before, during, and after the impact event. The advantage of the AIDA concept, compared to a mission to deflect a normal NEA, lies in the relative ease with which the orbit of a small binary moon around the primary can be changed to a measurable extent, and the fact that in the case of Didymos, due to the favorable observation geometry, the change can be measured by groundbased telescopes monitoring the variability of reflected sunlight caused by eclipses and occultations in the binary system. While groundbased observations would complement the observations made by AIM and provide a vital backup, AIM would measure the resulting change in orbit of the moon with greater accuracy, and would provide detailed *in situ* reconnaissance of the system's physical characteristics. The results of the AIDA mission would allow the detailed verification of impact models on a realistic size scale. At the time of this writing AIDA is the only deflection mission concept that is actively under study by major space agencies. If funded for launch, the impact would occur in October 2022.

An alternative, relatively inexpensive, test of the kinetic impactor concept, under consideration in ongoing NEOShield work, would be to impact a NEA far from its rotation axis, thus causing a change in its rotation rate, which, depending on the choice of the target, could be measurable with ground-based telescopes (NEOTwIST, Drube et al., in preparation). The change in rotation rate would provide insight into the same near-surface structural characteristics on which the efficiency of the kinetic impactor deflection concept depends. A possible target for such a test would be the NEA (25143) Itokawa, which has been well studied by the Japanese Hayabusa mission. The payload of the impactor spacecraft could include an ejectable science package to allow the impact to be observed and provide information on the crater formation, and ejecta mass and velocity distributions. While any type of deflection test would be very instructive, given the diverse properties of NEAs we should bear in mind that the responses to impacts could be very different for other NEAs.

In the case of the gravity tractor (*Lu and Love*, 2005), a spacecraft under power hovers near an asteroid and uses the gravitational attraction between it and the asteroid to tow the asteroid off course. Multiple spacecraft flying in formation could be deployed to expedite the gravity tractor maneuver and/or provide redundancy (*Foster et al.*, 2013). Given the very small tractor/asteroid mass ratio, this technique is only useful for small objects, but since small NEAs are more numerous than larger ones, a gravity tractor might suffice for the most likely scenarios in which deflection seems to be warranted, depending on the available time before the predicted impact. How small is still a matter of debate, but the current practical upper diameter limit suggested by recent (as yet unpublished) NEOShield results is around 50 m for a direct impact trajectory [*Shapiro et al.* (2010) give roughly 100 m for the same limit]. The main difficulty is developing reliable autonomous control systems able to keep the tractor at a fixed distance from a small, rotating, irregularly shaped asteroid, possibly for a period of many

years. If time is insufficient for the use of a gravity tractor as sole deflector, a currently realistic scenario is deployment of the gravity tractor as a secondary deflection technique to an impulsive primary strike. For example, an appropriately designed and instrumented spacecraft could first act in a reconnaissance capacity and study the NEA in advance of the impact, subsequently remain in place to monitor the deflection, and have the capability to finally act as a gravity tractor to adjust the post-impact trajectory of the NEA, if necessary. Alternatively, if the threatening object were due to pass through a keyhole, then a relatively small deflection, which could be performed by a gravity tractor alone, would suffice to cause the object to miss the keyhole. In fact, in the case of keyhole avoidance, the gravity tractor alone may suffice to deflect much larger asteroids.

While the gravity tractor appears to be feasible with current technology, the slow-push alternatives, such as the ion-beam shepherd and laser ablation mentioned above, may in time prove to be more practical and effective per kilogram of launch mass in many cases, depending on future developments of the relevant technologies and the details of the hazard scenario. An important advantage of the gravity tractor is that few characteristics of the NEA need to be known in advance. However, gravity tractors and the alternative slow-push techniques are weak, so depending on the time available and the circumstances of the NEA's orbit (presence of keyholes), the much more powerful capability of a kinetic impactor may be desirable or necessary.

In the very unlikely case of a very large hazardous asteroid and/or inadequate time for the deployment of other deflection techniques, "blast deflection" with a nuclear device may offer the only technically feasible solution: This technique requires the use of an explosive close to, on the surface of, or buried beneath the surface of the NEA. Complete disruption of the threatening object would be an option if it were small enough so that the largest pieces of debris would not present a hazard on impact. Otherwise, the blast should be designed to deflect the asteroid, not break it up. The blast from a nuclear device would cause the outer layers of the NEA to evaporate and be expelled from the surface. The effect would be similar to rocket propulsion, thus altering the asteroid's trajectory. Burying an explosive on the asteroid before setting it off, or delivering the device by means of a surface penetrator, would probably be most effective at ejecting surface material, but this method would require prior knowledge of the material properties and subsurface structure of the object. A deflection mission concept study supported by NASA's Innovative Advanced Concepts Program combines a kinetic impactor mission with a nuclear device for deflection of large asteroids, or for cases in which there is very little warning time. In the very unlikely case of a large comet, deflection would be very challenging at best due to the likely short lead time and nongravitational forces affecting the comet's trajectory. In any case, political and legal objections, not to mention technical issues, would have to be overcome before nuclear explosive devices could be used for NEA deflection.

## 5. CURRENT PRIORITIES AND INITIATIVES

At the time of this writing there are a number of ground-based telescopes under development with the goal of discovering very small NEOs to provide advance warning of about one week for objects with diameters in the range 30–50 m, and longer times for larger objects. Examples of such wide-field, rapid-scan search programs currently under development are ESA's Fly-Eye (*Farnocchia et al.*, 2012) and NASA's ATLAS (*Tonry*, 2011). Plans for ATLAS include up to eight small telescopes, each fitted with cameras of up to 100 megapixels. According to the ATLAS team, the system should offer a warning of about 1 week in the case of a 50-m-diameter asteroid or “city killer,” and 3 weeks for a 150-m “small country killer.” Such wide-field survey systems will complement the established surveys, such as the Catalina Sky Survey and Pan-STARRS, in being able to provide warning of small objects in the final phase of their plunge to Earth, thereby enabling measures on the ground, such as evacuation, to be carried out.

Apart from the work to discover and track NEOs, there is much ongoing groundbased effort to investigate their physical properties. Observations in the visible and infrared spectral regions of light reflected from asteroid surfaces are a powerful means of studying their compositions and assigning them to taxonomic classes. For reviews of earlier work the reader is referred to *Binzel et al.* (2002), and for more recent developments, to the chapters in this volume, such as those by Binzel et al. and DeMeo et al. Efforts to derive information on the physical properties of asteroids by observing absorption features in reflected sunlight are complemented by observations of thermally emitted infrared radiation and radar investigations. The latter two approaches, briefly discussed here, have brought major advances relevant to the impact hazard since the publication of *Asteroids III*.

A survey of the sizes and albedos of more than 100,000 asteroids has been carried out by the NASA WISE space telescope (*Wright et al.*, 2010). WISE was launched to Earth orbit in December 2009 carrying a 40-cm-diameter telescope and infrared detectors. WISE surveyed the sky for 12 months and the objects observed included a total of at least 584 NEOs, of which more than 130 were new discoveries (*Mainzer et al.*, 2011). The specially funded Near-Earth Object Wide-field Infrared Survey Explorer (NEOWISE) program analyzed images collected by the WISE spacecraft to derive information on the NEOs detected. The fact that the cryogenic phase of the WISE mission measured asteroid thermal emission in up to four infrared bands, centered on 3.4, 4.6, 12, and 22  $\mu\text{m}$ , allowed reliable values of diameter, albedo, and other parameters to be derived for many of the asteroids observed. *Mainzer et al.* (2011) report that after debiasing with a synthetic NEO population, the NEOWISE results imply a total of some 980 for the number of NEOs larger than 1 km. These results mean that the Spaceguard goal of detecting 90% of all NEOs with diameters larger than 1 km has now been met (see the chapter by Mainzer et al. in this volume). A complementary program to NEOWISE,

“ExploreNEOs” (*Trilling et al.*, 2010; see also the chapter by Mainzer et al. in this volume), has used the Spitzer Space Telescope to observe some 600 previously detected NEOs to study the size and albedo distributions of the NEO population, and identify NEOs that may have a cometary origin or that could serve as accessible and scientifically interesting targets for future robotic or manned space missions.

Following in the footsteps of the successful Infrared Astronomical Satellite (IRAS) mission in 1983, the WISE and Spitzer missions have highlighted the value of spacebased infrared telescopes for basic physical characterization of the asteroid population. In addition to size and albedo information, application of thermal models to thermal-infrared observations has revealed their potential to provide information on thermal inertia and mineralogy, including the presence of metal on the surfaces of asteroids (*Harris and Drube*, 2014). A threatening NEA containing a large amount of metal would presumably be relatively robust and massive, depending on its internal structure, factors that would require careful consideration by deflection-mission planners and/or those mandated to manage mitigation, e.g., evacuation and other activities on the ground in advance of a possible impact. Moreover, the identification of NEAs with high metal content is an important task for endeavors in the field of planetary resources. Metal-rich asteroids could provide a vast reservoir of vital materials for future interplanetary space activities and perhaps eventually for use on Earth.

The success of NEOWISE suggests that future missions with more sensitive spacebased infrared telescopes, designed specifically for NEO detection, would bring major advances in our knowledge of the mitigation-relevant small end of the NEO size distribution, and may even provide a useful guide for interplanetary prospectors. Examples of such spacebased infrared telescopes currently under study are the Near-Earth Object Camera (NEOCam) and Sentinel (see the chapter by Jedicke et al. in this volume). In particular, a spacebased infrared telescope on a heliocentric orbit inside that of Earth, such as the Sentinel spacecraft, would have an advantage over Earth-based telescopes in detecting Aten asteroids and inner-Earth objects (Atiras), which spend much of their time in the daylit sky as seen from Earth.

Radar is a crucial means of obtaining very accurate astrometric data for NEOs. Radar observations can provide enormous improvements in the precision of a NEO's orbit and allow the position of the object to be projected much further into the future than allowed by optical monitoring alone. The uncertainty in the prediction of a future impact can be dramatically reduced with the help of radar data or, much more likely, a possible impact can be ruled out (*Ostro and Giorgini*, 2004). Radar is also a powerful method for the characterization of NEOs, especially their sizes, shapes, and surface structure. A radar echo contains information not only on the position and velocity of a NEO, but also on a number of mitigation-relevant physical parameters. Radiation transmitted at a single frequency is returned from a rotating asteroid with a spread of (Doppler-shifted) frequencies, each component frequency being associated with a particular time

delay depending on the distance to the reflecting surface element. The “delay-Doppler” distribution of echo power is determined by the size, spin rate, orientation, and shape of the target asteroid, and radar reflectivity of the surface material. Given a suitable transmission coding, the information in a radar echo can be processed to provide resolved radar “images” of asteroids. The strength of the echo, normalized to the size and distance of the target (“radar albedo”), can provide information on the mineralogy of the asteroid surface, in particular its metal content. A circularly polarized transmission will give rise to a mix of “opposite sense” (OC) and “same sense” (SC) polarized radiation in the echo, depending on the number of reflections taking place at the surface. The ratio of SC/OC polarization in the echo is an indicator of the roughness of the surface at the scale of the radar wavelength (typically 3–13 cm). In particular, radar observations have observed a large number of binary NEAs, and have taught us that small asteroids can have very irregular shapes but also that some NEAs are surprisingly round, with equatorial bulges, suggestive of loose agglomerates of boulders and gravel that change shape as the spin rate exceeds a critical value, presumably preceding the spinning off of material that may then accumulate to form a moon (see the chapter by Walsh and Jacobson in this volume). For an overview of radar observations of asteroids, see the chapter by Benner et al. in this volume.

Rendezvous missions are a valuable source of mitigation-relevant physical information on particular NEAs. A concept under study by NASA at the time of writing is the Asteroid Redirect Mission (ARM), in which either an asteroid with a diameter of less than 10 m is captured whole, or a 2–3-m boulder from a larger NEA is collected, and brought into lunar orbit (see the chapter by Abell et al. in this volume). For the second option, NASA is considering a test of the gravity-tractor concept by using the combined mass of the spacecraft and the boulder to slightly change the orbit of the mother NEA. In general, regardless of which option is chosen, experience gained with ARM in the rendezvous and approach phases, and in capturing and maneuvering large masses with a solar-electric powered spacecraft, will be of direct benefit to mission planning for planetary defense.

While their primary aim is to contribute to our understanding of solar system history, sample-return missions to asteroids also provide valuable information for planetary defense. The Japanese Hayabusa mission was the first mission to return samples of an asteroid to Earth. The micrometer-sized grains returned by Hayabusa from the NEA (25143) Itokawa allowed a direct link to be demonstrated between asteroids of S taxonomic type and the LL class of meteorites (Nakamura et al., 2011). JAXA launched the Hayabusa-2 mission (see, e.g., Tsuda et al., 2013) on December 3, 2014, with the aim of returning a sample from the primitive (i.e., relatively unprocessed) C-class NEA (162173) Ryugu (1999 JU<sub>3</sub>), which has a diameter of about 750 m. The payload includes a small copper projectile designed to impact the surface of the NEA at about 2 km s<sup>-1</sup>, and a small camera to observe the event. Observations in real time of the production of a crater

would provide data of direct relevance to deflection studies. In addition, a small European lander, the Mobile Asteroid Surface Scout (MASCOT), will perform *in situ* compositional measurements. NASA is also developing a sample-return mission called the Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) (Lauretta et al., 2012). Launch is currently scheduled for September 2016. The sample mechanism is designed to collect between 60 g and a few kilograms, depending on the surface properties of the target, namely the primitive B-type NEA (101955) Bennu, which has a diameter of ~450 m.

It is important not only to improve our understanding of the mitigation-relevant physical properties of small NEAs, but also to develop technically and financially realistic test missions to enable deflection concepts to be tried out on real NEA targets, representative of the sort of objects that could threaten Earth in the not-too-distant future. Given the diverse observed shapes and mineralogies, and strong evidence for relatively low bulk densities, high porosities, and loose rubble-pile structures among NEAs, demonstrating that we can actually measurably change the orbit of a NEA is a vital step in building confidence that we can defend our civilization from a natural hazard that will otherwise cause serious loss of life and property in the future, if not threaten our long-term survival on planet Earth. The NEOShield project has performed industrial studies of test missions for the kinetic impactor, gravity tractor, and blast deflection concepts, as well as studies of the future evolution of NEA orbits after deflection attempts. While an actual deflection demonstration mission was financially beyond the scope of the NEOShield project, the aim was to provide the first designs of appropriate demonstration missions, sufficiently detailed to facilitate the rapid development of such a mission in subsequent rounds of project funding in a European/international frame.

Results from the type of studies carried out by NEOShield and similar programs obviously also serve to reduce the scientific and technical preparatory work required to bring an appropriate and viable deflection mission to the launch pad in an emergency situation.

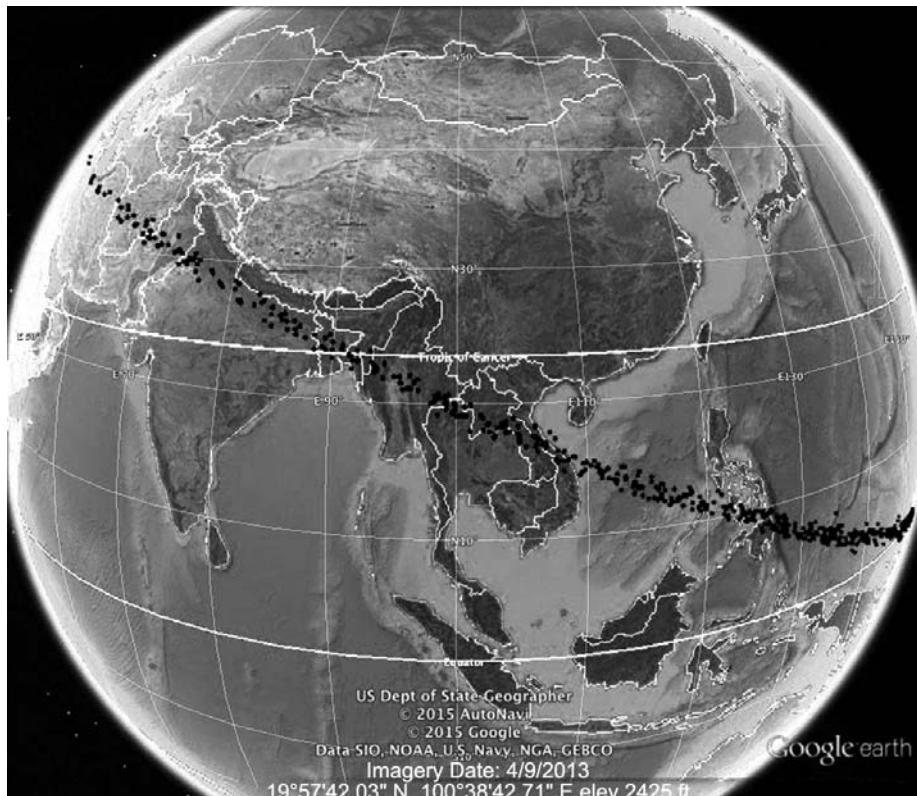

## 6. WHAT WE DO NOT KNOW: PRESSING AREAS OF CONCERN

Although it will happen one day, the likelihood of any generation being confronted with a threatening object with a diameter, D, of around 300 m or larger is extremely small. In any case, NEO survey programs may provide several decades of warning time in which to prepare a response, although at present an estimated 40% of such objects remain to be discovered. Therefore, in the case of large objects, we should normally have sufficient time between hazard identification and the predicted time of impact to physically characterize the NEO using Earth-based telescopes and rendezvous missions, and prepare and test an appropriate deflection mission. The lower size threshold below which we could safely ignore an approaching object is subject to debate (see below). Even a NEO with a diameter of just 20 m can

cause serious damage, impacting on average about once or twice per century. It would therefore seem prudent to take precautionary measures well in advance, and not wait until a threatening object is identified. Apart from civil defense planning in case a late detection precludes a deflection attempt, appropriate measures include investigations of the mitigation-relevant physical properties of small NEOs, such as composition, density, porosity, internal structure, spin rate, and shape, and the development and testing of appropriate and reliable deflection techniques. Unfortunately, our current knowledge of the NEO population is very biased toward the large end of the size range, since large NEOs are brighter and more readily detected and observed. Relatively little is known about the small members of the population and much work remains to be done in exploring their deflection-relevant physical properties.

At present we have no clear idea of how the international community would respond to the announcement of a credible threat from a NEO identified as significantly hazardous. After discovery of the NEO in question and initial orbit refinement, the threat could be expressed only as a probability for those parts of Earth lying on the “risk corridor” (the track of possible impact points allowed by imperfect knowledge of the object’s trajectory; see Fig. 3). We would not know for sure whether the object would impact or not

due to the observational uncertainties in the orbit and factors influencing its evolution, and we would only have a poor idea of what damage it would cause if it did. If, for example, the probability of impact somewhere on Earth in 15 years’ time were to be estimated at 5%, politicians could argue that with a 95% probability of a miss there is hardly any justification for action to be taken (depending, perhaps, on whether their part of the world were in the risk corridor!). Indeed, one would normally expect the impact probability to suddenly drop, after initially rising, as further observations reduce the uncertainty region so that Earth is no longer within it (see, e.g., Chesley and Spahr, 2004). However, if Earth were to remain within the uncertainty region as more observational data are gathered, the probability might rise to levels at which an international consensus for action builds, regardless of other circumstances, and valuable time would have been lost for characterizing the object and preparing a spaceborne deflection mission. One of the most difficult challenges faced by astronomers and scientists involved in impact-hazard assessment is ensuring that politicians and decision makers are adequately informed of, and understand, the level of the risk at each stage and how it might develop with time, i.e., how to interpret evolving impact probabilities based on uncertain observational data and incomplete knowledge of factors influencing a NEO’s orbit. Critical decisions

**Fig. 3.** Example of a hypothetical impact-risk corridor, traced by the black dots extending from the eastern Pacific Ocean, through the Philippines, Southeast Asia, India, to Turkey. In the event the fictional asteroid were to impact Earth, it would do so somewhere within the region traced by the dots. Credit: P. Chodas, NASA/JPL [emergency response exercise conducted during the International Academy of Astronautics (IAA) 2015 Planetary Defense Conference in Frascati, Italy, April 13–17, 2015].

would have to be made as a threatening impact scenario evolves concerning what type(s) of mitigation or deflection measure(s) need to be implemented, depending on the size, hence potential destructive power, of the threatening NEO. The answers necessarily depend on some other aspects of the specific scenario, such as duration of advance warning, whether the predicted impact will be in or over an ocean or instead will involve a populated land region, or the availability of heavy-lift launch vehicles.

From a politician's point of view the consequences of "getting it wrong" would be a prime consideration in the decision-making process. Spending the equivalent of hundreds of millions, or billions, of dollars on a deflection campaign, only to learn at a later stage that new observational data imply that the hazardous object will in fact just miss Earth, or that its potential for damage had been grossly overestimated, could lead to serious loss of credibility in the eyes of the public, not only for the politicians involved but also for the scientific community. On the other hand, ignoring a threat that turns out to have more serious consequences than nominally assumed from the available observational data and estimated probabilities would be a far worse outcome. In any case, civil defense planning should always be considered when a threatening object is identified, not only in the case of small objects, e.g., on the scale of Chelyabinsk, but also for larger objects as a back-up measure in case a deflection mission fails. At least in the next couple of decades, it is most likely that predicted impacts by small NEAs will involve days to weeks, or possibly months, of warning, because in general small NEAs would be detected during their final plunges to Earth (see section 5). Such warning times are typical of, or longer than, warning times for evacuation of cities or coastlines in the cases of other natural disasters, such as hurricanes/typhoons. But in most cases, such as those resembling, or smaller than, Chelyabinsk, sheltering in place and staying away from windows is preferable to evacuation. As a precaution against unusual circumstances or early uncertainties about the mass of a recently discovered NEA, such warnings might even be given for predicted impacts by bodies estimated to be as small as a few meters in diameter.

Above what size of impactor would a deflection mission be called for? Since development and execution of such a mission takes years to perhaps a decade, the question of whether or not to seriously embark on such an endeavor will most likely arise well before the magnitude of the threat is well known. In particular, how large an impactor can be allowed to strike without a deflection? And does a spacefaring nation start spending money on such a mission when the probability of striking Earth is just 1%, or must it be 50% or greater? If the probability of striking Earth were only a few percent, it seems unlikely that society would fund such an ambitious project. Perhaps 10% or 30% is a more appropriate threshold for action, although it would certainly depend on the specifics of the threat, and it would be influenced by public attitudes and political and economic considerations. In almost all cases, the risk corridor will be known soon after discovery of the threat, even though the probability of

actually impacting may be very low. Assuming, as is probable, that the risk corridor does cross populated regions, it is unlikely (despite the Chelyabinsk example) that it will threaten a major population area or truly critical infrastructure, in which case allowing a Tunguska-sized object to enter the atmosphere, and employing civil defense measures only, should be a reasonable response (unless it is known in advance that the object has a metallic composition; see section 5). It is more problematic to allow a 50–100-m-diameter NEA strike without a deflection attempt, but surely above 100 m diameter a deflection would seem to be mandatory, if feasible.

In terms of the development of appropriate deflection techniques, we have only just started to consider realistic possibilities; indeed, the choice of deflection technique will depend on knowledge of the physical properties of the threatening object (see, e.g., Michel, 2013). There are many schools of thought on how asteroids could be deflected (section 4). The kinetic impactor appears to offer a realistic approach for objects in the size range 100–500 m. Sending a spacecraft to collide with an asteroid at high relative velocity appears to be feasible, although this method and its associated technology remain to be verified in a test mission. Studies, such as those of the Don Quijote and AIDA concepts (see section 4), imply that the technique could provide an impulse of sufficient magnitude to deflect an object in the aforementioned size range (the secondary of a binary object in the case of AIDA), given some years of warning time, depending on the size and orbit of the asteroid. However, there are many outstanding questions associated with the kinetic impactor technique: How much impactor kinetic energy may be wasted in compaction and restructuring, rather than excavating momentum-enhancing ejecta? How does the target NEA's momentum change depend on parameters such as its bulk density, porosity, mineralogy, and subsurface/internal structure, and the velocity vector of the impactor relative to the NEA (see the chapter by Jutzi et al. in this volume)? Can ejecta production be characterized in terms of mineralogy and taxonomic type? If so, such knowledge would greatly increase the value of groundbased observations for deflection mission planning. Preliminary work carried out within the European-funded NEOShield project suggests that the momentum transferred by an artificial projectile to a nonporous body is significantly greater (by up to 10× the momentum of the projectile) than to a porous body (Jutzi and Michel, 2014), a result that is consistent with laboratory impact experiments using scaling laws to extrapolate the results to asteroid scales (e.g., Holsapple and Housen, 2012). However, much work remains to be done to enable reliable predictions to be made as to how a NEA with a particular set of physical parameters would respond to an impacting spacecraft.

Furthermore, there are a number of important issues relating to the targeting accuracy achievable with current technology. The efficiency of momentum transfer from the impactor to the hazardous NEA depends crucially on the impact accuracy. While linear momentum is conserved, a

spacecraft impacting near the end of an elongated object would waste kinetic energy in changing the spin state of the object rather than producing momentum-enhancing ejecta. The most effective collision trajectory would be aimed at the center of mass of the asteroid. How would the necessary camera resolution and autonomous control-loop response time depend on the approach velocity, target size, thruster sizing, and required accuracy of the impact location? What is the trade-off between impactor approach trajectory, impact accuracy, and potentially unfavorable illumination conditions (e.g., approach from a high solar phase angle)? These are examples of questions that need to be addressed before we could be confident that a kinetic-impactor mission would have the desired effect. It is clear from the above discussion that not only does the kinetic impactor technique have an upper size limit on its applicability due to current limitations on launch mass, but also a lower size limit given by the targeting accuracy achievable with current autonomous guidance, navigation, and control systems.

Other currently favored deflection techniques that may be more suited to smaller bodies, or cases in which only a small deflection is required (such as avoidance of a “keyhole” — see section 3), include the so-called slow-push (or -pull) techniques, such as those involving the use of lasers or ion beams and the gravity tractor (see section 4). Such techniques differ considerably in terms of their maturity. The gravity tractor concept has the advantage of relative simplicity and, given current technology (but as yet without the benefit of practical experience), is considered to be the most reliable option in the class of non-impulsive techniques.

If the discovery of a threatening NEA leads to the decision to develop a deflection mission, which kind of deflection technique would be most appropriate? Here we assume currently available launch vehicle capabilities, a few decades of warning, a NEA bulk density of  $2 \text{ g cm}^{-3}$ , and that populated regions are near ground zero or near the risk corridor. We assume that the purpose of deflection is to miss Earth by a comfortable margin ( $2.5 R_{\oplus}$  from Earth’s center), although there will be cases where the much easier task of deflection — to miss a small keyhole — is all that is required. These issues were evaluated by *Shapiro et al.* (2010). It is anticipated that one or a series of kinetic impactors could reasonably deflect an NEA of 500 m to  $\leq 1 \text{ km}$  in diameter. For most scenarios involving larger bodies, a nuclear device is the only sufficiently energetic approach for deflection. A gravity tractor acting for a decade could deflect a NEA of up to  $\sim 50 \text{ m}$  in diameter. So the kinetic impactor approach to deflection would be appropriate for most of the truly dangerous scenarios for which deflection is mandatory in order to prevent a regional catastrophe (e.g., an impact that could lay waste to land areas the size of a country or a U.S. state). Such an approach, for NEAs mainly in the diameter range of 100 to 500 m, would necessarily require a high degree of reliability, which could be assured by appropriate physical characterization of the threatening body by precursor investigation, supplemented by an observer spacecraft to witness the deflection operation and assess its success, and

finally, if necessary, function as a gravity tractor. It would, of course, be desirable to have backup kinetic impactors and gravity tractors in case the first ones fail.

One can question whether a deflection technique with excessive capability might be used on a smaller NEA. For example, a nuclear device could surely deflect or even destroy a NEA much smaller than 0.5–1 km. We suggest that such possible use is not realistic because of the serious ancillary political issues involving development of such a capability, legal issues concerning practicing such a capability in outer space, and expected widespread public objection to using such a technique, except perhaps as a measure of last resort. On the other hand, there is the concern that procrastination in approving and implementing feasible nonnuclear deflection missions might leave nuclear as the only last-minute option, which would pose a serious geopolitical dilemma.

Should kinetic impactors be used even for NEAs smaller than 100 m, where a slow-push/pull method could be sufficient? Here, the answer may be “yes.” Of course, the kinetic impactor approach is inherently less precise because it involves direct interaction with the possibly heterogeneous surface of the NEA for which the momentum enhancement factor may be very uncertain. However, a kinetic impactor can accomplish its task with an instantaneous strike rather than having to operate reliably for many years.

In Table 1 we give an overview of our current state of knowledge (or perhaps ignorance!) of the impact hazard for different sizes of impactor and appropriate mitigation strategies given current technology. Some knowledge of the physical properties of a threatening NEA is necessary to ensure the successful outcome of a deflection attempt. The type of knowledge required depends on the deflection technique in question (see, e.g., *Michel*, 2013): A gravity tractor has to operate for long periods of time in close vicinity to the NEA, but does not physically interact with the surface; in this case, therefore, accurate information on the mass, shape, and rotation vector of the object are required, which can be obtained by the spacecraft after it arrives at the object, but other physical properties are largely irrelevant. On the other hand, in the case of a kinetic impactor, knowledge of density, porosity, and internal structure would also be important for a predictable outcome. In the case of a deflection mission based on a laser, ion-beam, or explosive device, knowledge of the mineralogical composition of the surface material would also be relevant.

The NEOShield consortium, among others, has performed studies of observational data on NEAs (see, e.g., *Harris and Drube*, 2014) and laboratory experiments, including hypervelocity impacts on asteroid surface analog materials, and carried out related computer simulations (see, e.g., *Jutzi and Michel*, 2014). While our knowledge of NEA properties has grown significantly over the past decade, our knowledge of the deflection-relevant internal structures of NEAs is still seriously lacking. Available data on the distribution of lightcurve amplitudes and spin rates (Fig. 4) suggest that many fast-spinning objects take on more symmetrical shapes, presumably due to restructuring caused by spin-induced movement and relocation

TABLE 1. Estimated near-Earth asteroid numbers, impact intervals, impact consequences, and mitigation possibilities.

NEA Diameter, D (m)	Estimated Total Number* with Diameter $\geq D$ in the NEA Population	Indicative Impact Interval (yr)* for NEAs with Diameter $\geq D$	Possible Consequences of Impact Near Populated Region†	Appropriate Mitigation/Deflection Strategy Assuming Current Technology
10	100 million	5	Meteorite falls; crater unlikely	Civil defense only
30	3 million	150	Chelyabinsk/Tunguska-type airburst; crater, depending on composition; some injuries and deaths	Civil defense only
50	500,000	1000	Violent Tunguska-type airburst; crater, depending on composition; potentially many injuries and deaths	Slow push/pull (e.g., gravity tractor) or kinetic impactor, if feasible, civil defense only if not
100	50,000	10,000	Crater 1–2 km in diameter; local destruction; tsunami risk from near-shore impacts; many deaths likely	Civil defense; slow push/pull or kinetic impactor — slow push/pull combination
300	7000	70,000	Crater several kilometers in diameter; regional/national destruction; tsunami risk; potentially millions of deaths	Kinetic impactor — slow push/pull combination if feasible, explosive impulse if not, plus civil defense if practical
500	3500	140,000	Crater some 10 km in diameter; international catastrophe; tsunami risk; potentially millions of deaths	Kinetic impactor — slow push/pull combination if feasible; several kinetic impactors may be necessary. Explosive impulse if no alternative
1000	1000	500,000	Global effects; partial disruption of civilization	Series of kinetic impactors or large explosive impulse
10,000	3‡	100 million	End of present civilization	Series of large explosive impulses; deflection may not be feasible with current technology

\* Estimated from current detections (see Fig. 2).

† The effects listed are rough estimates based on incomplete knowledge of NEA physical characteristics and impact processes in the atmosphere and on the ground. The actual outcome of an impact could differ considerably, depending on parameters such as composition and density of the impactor, impact velocity, impact angle, and the nature of the surface impacted.

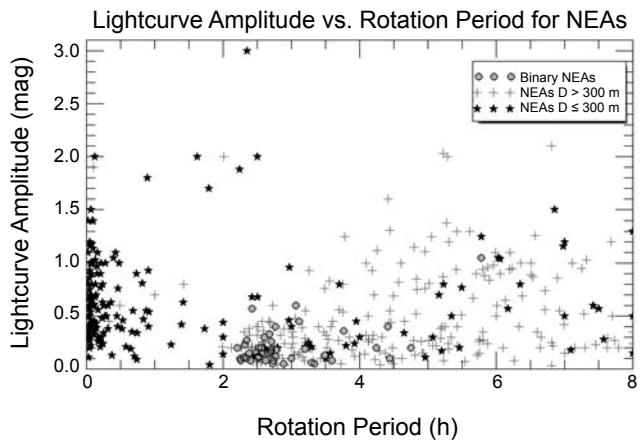

‡ The remaining risk is dominated by long-period comets; deflection would not be possible with any foreseeable technology (see section 3).

of material in a rubble-pile-like structure with little cohesion. The fact that binary objects cluster just below the spin barrier for gravity-dominated bodies with diameters larger than about 300 m (spin period  $\sim 2$  h) also suggests that many objects in this size category have insufficient cohesion or strength to withstand faster rotation (Figs. 4 and 5); on the other hand, many of the asteroids smaller than 300 m rotate much faster, implying they must have a cohesive structure, even if just a small amount of cohesion appears to be sufficient for them to survive (Holsapple, 2007). Sánchez and Scheeres (2014) hypothesize that van der Waals forces acting between small dust grains in a rubble pile can give rise to cohesion: Boulders and pebbles of diverse sizes could be held in place by a surrounding matrix of finer material. In this picture even very small objects with large lightcurve amplitudes (and therefore probably elongated shapes) could exist as rubble piles but spin more rapidly than the spin barrier for gravity-dominated objects. For example, work by Rozitis *et al.* (2014) implies that

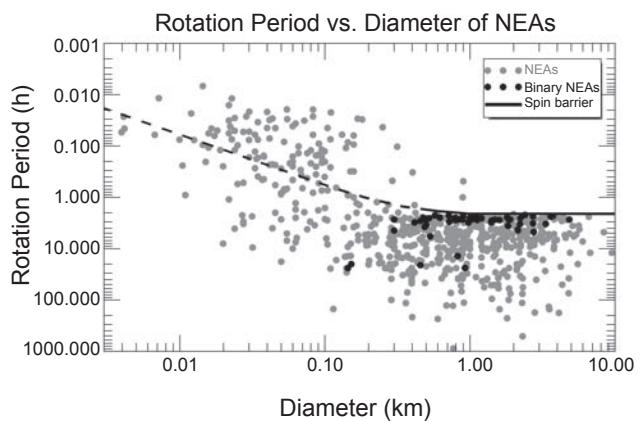

the fast-spinning kilometer-sized NEA (29075) 1950 DA is a rubble pile held together by weak cohesive forces comparable to, or less than, the forces between grains in lunar regolith. However, if the spin rate of a rubble pile is increased, as a result of the Yarkovsky-O’Keefe-Radzievskii-Paddack (YORP) effect or a close planetary encounter, then the object could disintegrate, giving rise to small monolithic bodies. While observational data and modeling results are consistent with rubble-pile structures being common among NEAs, the fact that numerous small objects spin at rates above the Sánchez and Scheeres (2014) disruption limit (Fig. 5) suggests the possible existence of monolithic asteroids at the small end of the size distribution.

In any case, the fact that small asteroids can have very high rotation rates (some measurements exceed 1 rev/min) is an important consideration for a deflection mission. In the case of a kinetic impactor, fast rotation, combined with imperfect knowledge of the target’s shape, and rapid approach from a

high solar phase angle could significantly increase the risk of a navigation error and failure to impact at the required position. In the case of a gravity tractor, maneuvering and station keeping close to the surface of an irregularly shaped

**Fig. 4.** Lightcurve amplitude vs. spin period for NEAs. Data are from the European Asteroid Research Node (EARN) database (<http://earn.dlr.de/>). The data suggest that many fast-spinning objects with diameters larger than 300 m take on more symmetrical shapes (and thus have smaller lightcurve amplitudes), presumably due to restructuring caused by spin-induced movement and relocation of material in a rubble-pile-like structure with little cohesion. On the other hand, many of the asteroids smaller than 300 m rotate much faster, implying they must have a somewhat cohesive structure.

**Fig. 5.** Rotation period vs. size for NEAs. Data are from the EARN database (<http://earn.dlr.de/>). The “spin barrier” for gravity-dominated bodies (spin period ~2 h, diameters larger than about 300 m) is shown merging into the disruption limit (dashed line) of Sánchez and Scheeres (2014) for smaller bodies. The plotted disruption limit corresponds to a cohesion strength of 25 Pa, which is consistent with available data according to Sánchez and Scheeres (2014). It should be noted, however, that a higher strength is required to enclose the super-fast rotators among smaller (<100-m-diameter) objects. Thus, the internal strength of many smaller NEOs must be greater than that of the larger ones.

asteroid with an irregular gravity field become more difficult at high rotation rates. Since fast-rotating NEAs appear to be common, and deflecting a fast-rotating target is likely to be technically challenging, a deflection demonstration mission targeting a representative relatively fast rotator would provide a revealing test of current NEA deflection capabilities.

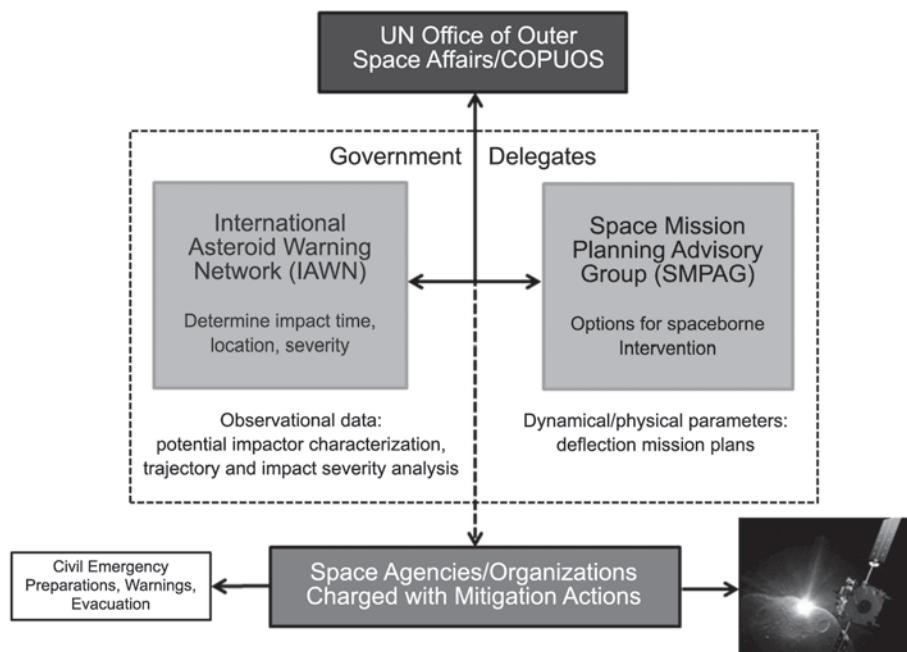

Studies of NEA physical properties, including laboratory work, numerical modeling, and computer simulations, are essential aspects of a program to develop deflection technology, but they are not sufficient to enable robust predictions to be made of the outcome of a deflection attempt. We may one day be faced with having to decide on a risky deflection mission without having time to acquire adequate information on the physical properties of the threatening object. We would obviously obtain the best knowledge of the body possible using available astronomical facilities, but that might still result in uncertainties of a factor of a few in the body’s mass and ignorance of other relevant characteristics. A “bang and hope” mission with an uncertain outcome would be our only option, although we could improve our chances by preparing back-up missions and taking civil defense action. In any case, to minimize the uncertainties in the outcome of a deflection mission, it would seem prudent to test our concepts and assumptions in experimental missions to deflect suitable representative NEA targets *before* we are forced to apply deflection technology in a hurry in a real impact-prevention scenario.

## 7. INTERNATIONAL COORDINATION EFFORTS AND THE POLITICAL DIMENSION

Protecting Earth from NEO impacts is a global problem and, as such, any deflection strategy should involve at least the most scientifically and technologically capable nations. However, all nations, especially those with large geographical areas or regions of high population density, should be encouraged to take part in discussions and decision-making concerning mitigation planning in general. Impact-hazard-related activities at the UN were prompted by the recommendations of the Third United Nations Conference on the Exploration and Peaceful Uses of Outer Space (UNISPACE III) held in Vienna in July 1999. Following the UNISPACE III recommendations the Action Team on Near-Earth Objects (AT-14) was established by the UN’s Committee on the Peaceful Uses of Outer Space (COPUOS), an intergovernmental body set up in 1959 to “encourage continued research and the dissemination of information on outer space matters and to study legal problems arising from the exploration of outer space.” Action Team 14, which is composed of both government and nongovernment experts, was charged with reviewing the ongoing efforts in the field of NEOs, identifying fields in which further effort is required, or where other countries/organizations could contribute, and proposing steps for the improvement of international coordination. The work of AT-14 continued until 2008 when the team presented a summary of the recommendations contained in the report *Asteroid Threats: A Call for Global Response*, prepared by the Association of Space Explorers (ASE) (<http://www.space-explorers.org>).

To accelerate the formal processing of the ASE report within the UN, the Scientific and Technical Subcommittee of COPUOS established a working group at the government level for the purposes of formally receiving and assessing the recommendations of the report. Subsequently, in the light of the ASE/AT-14 recommendations, the focus of AT-14 changed to reviewing policies and proposing procedures for handling the NEO threat on the international stage. As a direct result of the work of AT-14 and the ASE, the establishment of two new groups (Fig. 6) was endorsed by the sixty-eighth session of the UN General Assembly in December 2013: the IAWN and the SMPAG. The purpose of the IAWN is to link together institutions carrying out discovery, monitoring, and physical characterization of potentially hazardous NEOs with other relevant organizations, and promote an internationally recognized clearinghouse to manage NEO observations and impact predictions. While some of these functions are already covered by existing bodies, such as the Minor Planet Center at the Smithsonian Astrophysical Observatory, which operates under the auspices of the International Astronomical Union, the IAWN is intended to enhance cooperation between relevant organizations and to be the *UN-mandated international portal* for accurate and validated information on the NEO population, as well as to provide recommendations for communication strategies for governments and other relevant bodies in the event of an emerging impact threat. NASA has agreed to be the initial coordinator of the IAWN.

The IAWN is also charged with establishing collaboration with international disaster response agencies in order to develop emergency plans in response to an impact threat in a populated area. NASA sponsored a tabletop exercise in April 2013 to simulate an impact on Earth for the U.S. Federal Emergency Management Agency (FEMA). A further impact simulation exercise was held during the Planetary Defense Conference in Flagstaff, Arizona, also in 2013 (Carnelli et al., 2014), at which FEMA participated. A scenario in which the probability of impact of a 200–300-m NEA increased over a period of 15 years was simulated. More than 200 exercise participants were allocated to groups to take charge of different aspects of mitigation planning (e.g., NEO discovery and follow-up, mitigation techniques and missions, impact effects, media and risk communication, launch capability of space agencies, etc.). FEMA and NASA have recently established a NEO Impact Working Group, to be responsible for reviewing disaster response and recommend future exercises. In 2014, ESA also held an information meeting and similar tabletop exercise for representatives of the European emergency response community. Further information meetings involving emergency coordination agencies, including those of the UN, are planned and will help to establish a dialog between the scientific and technical impact hazard community and those that would be responsible for disaster management in the event of an impact emergency.

**Fig. 6.** Draft scheme of the organization of NEO impact hazard activities under the auspices of the United Nations. Details of the tasks, responsibilities, and funding of the IAWN and SMPAG, and the assignment of mandates to take action in an emergency situation, are under discussion at the present time. The vertical dashed arrow represents channels that have yet to be formally established. Contacts with civil defense organizations are currently being developed. Present membership of the SMPAG includes space agencies that would be capable of contributing to a spaceborne deflection attempt. Kinetic impactor illustration courtesy of ESA-AOES Medialab.

The SMPAG was established to promote opportunities for international collaboration on research and development work relating to NEO deflection and to develop a framework, timeline, and options for initiating and executing space-mission-response activities. The SMPAG should also develop a set of reference missions, addressing a variety of potential NEO impact scenarios and deflection/disruption possibilities, to facilitate realistic technical and resource planning. Whenever a credible impact threat is established by the IAWN, the SMPAG is charged with proposing options for spaceborne intervention to divert the threatening object. Membership in the SMPAG is open to all national space agencies or governmental or intergovernmental entities that coordinate and fund space activities and are capable of carrying out, or contributing to, a spaceborne NEO deflection campaign. The first chair of the SMPAG is ESA; the chairmanship will rotate around the members at intervals of two years.

Information on the history, development, and status of UN activities relating to NEOs and the impact threat is available from <http://www.oosa.unvienna.org/oosa/en/COPUOS/stsc/wgneo/index.html>.

The IAWN and SMPAG are asked to work together on recommendations for criteria and thresholds for mitigation action, such as notification of a significant impact risk or the initiation of observation/mitigation campaigns. Both groups are currently still in their infancy and questions regarding such details as their ultimate tasks and responsibilities, schedule of activities, etc., are still open at the time of this writing. A pressing current concern with regard to the initiatives of the UN is financial provision for the tasks involved. The work of both the IAWN and SMPAG has to be carried out at no cost to the UN budget. Consequently, the states and organizations making up the membership of the two UN groups have to fund their involvement from their own resources. A model for the support of the activities of the groups might be the current funding of the NEOShield project by the European Commission. While 11 of NEOShield's 13 partner organizations are from European Union countries, two are from non-EU countries, namely Russia and the U.S., but they also receive funding from the European Union. Therefore NEOShield is a truly international project. Taking the SMPAG, for example, statements or "white papers" on future research and development requirements in the field could be issued by the SMPAG on a regular basis, carrying the authority of the UN. Calls for proposals from funding agencies, such as the European Commission or national agencies, could refer to the SMPAG statements, and proposers could orient their work plans accordingly. A plausible vision for the future would be coordinated calls for mitigation-related proposals from a combination of international and national funding bodies, based on the recommendations of the UN-backed groups.

## 8. SUMMARY AND CONCLUSIONS

The period since the publication of *Asteroids III* has seen rapid progress in many fields related to impact hazards. Optical search programs benefiting from advances in detector

technology and sophisticated automated detection routines are currently enjoying increased funding from NASA. The rate of discovery of NEOs has increased to an average of some 3 per day and the number of NEOs discovered of all sizes has risen from around 2000 at the end of 2002 to some 11,000 at the time of this writing. While endeavors in the field of physical characterization have not kept up with the rate of new discoveries, the NEOWISE and ExploreNEO projects have provided size and albedo data for many hundreds of NEOs and demonstrated the value of spacebased telescopes sensitive in the thermal infrared for NEO risk assessment.

Unfortunately, the unanticipated Chelyabinsk event on February 15, 2013, has demonstrated that the blast waves from even relatively small (diameter ~20 m) asteroids exploding in the atmosphere can cause serious injuries and damage to property. Chelyabinsk has also taught us that a potentially serious impact can occur with no prior warning if the orbit of the NEO happens to be unfavorable for detection from the ground.

A number of initiatives suggest that the NEO impact threat is attracting increasing attention in political circles not only in the U.S. The European Commission funded the NEO-Shield project from 2012 to 2015, enabling 13 academic and industrial organizations from 6 countries, including the U.S. and Russia, to collaborate on investigating NEO physical characteristics and deflection options. European activities also include the NEO segment of ESA's Space Situational Awareness program, which is currently under development and includes plans to build the "Fly-Eye" telescope system with the aim of providing sufficient warning of small impactors to allow civil defense measures to be taken. A U.S. project with similar aims is the ATLAS system. New groups have been established under the auspices of the UN to help to coordinate astronomical NEO survey and characterization activities (IAWN) and to advise on deflection-related space mission planning (SMPAG). The UN initiatives demonstrate that concern about the NEO impact hazard is increasing worldwide.

Despite the encouraging progress made during the past decade or so, there is still much to be done before we can be confident of our ability to deflect a threatening NEO. Evidence from observations, laboratory impact experiments, and theoretical work suggest that NEOs differ widely in the nature of their near-surface structure, and the outcome of impulsive techniques, such as the kinetic impactor, would be difficult to predict in the absence of information on bulk density, porosity, tensile strength, etc. While alternative slow-push or -pull techniques, such as the gravity tractor, may be suitable in certain circumstances, such as keyhole avoidance, it seems at present that the most likely scenario in which a deflection mission is called for would involve an impulsive technique, perhaps together with a combination observer/gravity tractor spacecraft to provide reconnaissance data and the opportunity to adjust the post-impulse trajectory of the target.

While studies of a number of deflection techniques have been carried out, no technique has yet been tested in space on a real NEA. In order to minimize the uncertainties in the outcome of a deflection mission, it would certainly be

prudent to test our concepts and assumptions in experimental missions to deflect suitable representative NEA targets before we are forced to apply deflection technology in a hurry in a real impact-prevention scenario.

**Acknowledgments.** We thank L. Johnson, Program Executive for NASA's NEO Observations Program, for information on the status of NASA NEO initiatives. We thank our referees, D. Morrison and D. Yeomans, for their thorough reviews, which have led to significant improvements in the presentation of this work. Some of the research described in this article has received funding from the European Union's Seventh Framework Program (FP7/2007–2013) under grant agreement No. 282703 (NEOShield).

---

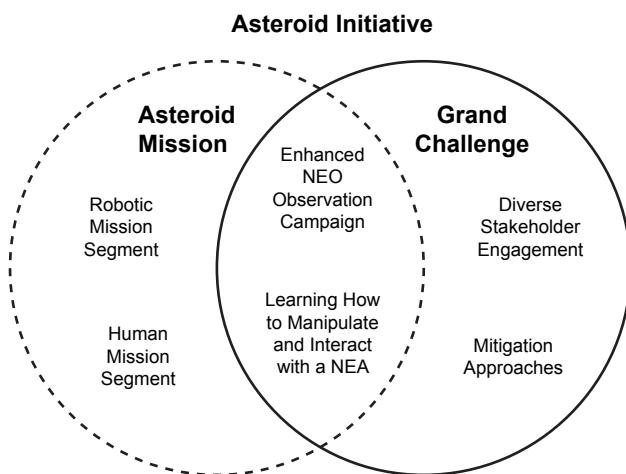

Due to a number of factors, including a recent U.S. presidential directive, the successful return of an asteroid sample by the Japanese spacecraft Hayabusa in 2010, and the high-visibility airburst impact event over Chelyabinsk, Russia, in 2013, scientific and exploration interest in near-Earth asteroids (NEAs) has never been greater. In particular, NASA and the Japanese and European space agencies have begun expending serious effort to discover and identify appropriate NEA targets for a wide variety of spaceflight activities, including both robotic and human missions. These missions are particularly attractive as they will yield an unprecedented amount of knowledge about the formation of the solar system, provide a stepping-stone approach for future human exploration missions to Mars and beyond, identify materials for *in situ* resource utilization (ISRU), and test techniques for deflecting potentially hazardous objects that threaten Earth.

## 1. INTRODUCTION

Asteroids have generated significant worldwide interest in recent years as a result of flyby, rendezvous, and sample return missions. Robotic missions to near-Earth asteroids (NEAs) have already been completed by several space agencies, and subsequent robotic missions to these bodies are under development or consideration. In addition, human-led exploration missions to these destinations are now also being seriously considered. In 2009, the Review of the United States Human Spaceflight Plans Committee, also known as the Augustine Commission, identified NEAs as high-profile destinations for human exploration missions beyond the Earth-Moon system as part of the “Flexible Path” approach ([http://www.nasa.gov/pdf/384767main\\_SUMMARY%20REPORT%20-%20FINAL.pdf](http://www.nasa.gov/pdf/384767main_SUMMARY%20REPORT%20-%20FINAL.pdf),

pdf, accessed July 19, 2015). In response to these findings, President Barack Obama directed NASA to include NEAs as destinations for future human exploration with the goal of sending astronauts to an NEA in the mid to late 2020s. This directive became part of the official *National Space Policy of the United States of America* as of June 28, 2010. More recently, on June 18, 2013, President Obama gave NASA a Grand Challenge to “find all asteroid threats to human populations and know what to do about them.” This Grand Challenge, combined with the directive for a human NEA mission, forms the basis of NASA’s Asteroid Initiative (<http://www.nasa.gov/asteroidinitiative>, accessed June 10, 2015) (Fig. 1).

Near-Earth asteroid targets suitable as destinations for human exploration tend to have orbits very similar to Earth’s, and also have a statistically greater chance of impacting our

**Fig. 1.** NASA's Asteroid Initiative.

planet. Therefore, one of the major goals for NASA's human spaceflight program and the Asteroid Initiative is to identify these NEAs both from the standpoint of human exploration and planetary defense. Ideally, once suitable targets have been identified, NASA would send astronauts beyond the Earth-Moon system to NEAs within the coming decades. These missions, and the activities required to identify and characterize suitable targets, would pave the way for exploration of the martian system, and would have the added benefit of finding potentially threatening objects and increasing our knowledge about the physical characteristics that will be necessary to develop future NEA hazard mitigation techniques.

Human-led missions to NEAs will undoubtedly provide a great deal of technical and engineering data on spacecraft operations for future human deep-space exploration and planetary defense while simultaneously conducting in-depth scientific examinations of these primitive objects. Information obtained during a human mission to an NEA, combined with ground- and spacebased observations and robotic spacecraft investigations of asteroids and comets, will also provide a real measure of ground truth to data obtained from samples within the worldwide extraterrestrial material collections (e.g., meteorites and cosmic dust) and those collected directly from spacecraft sample-return missions [e.g., Stardust, Hayabusa, Hayabusa2, and the Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx)]. Major advances in the areas of geochemistry, impact history, thermal history, isotope analyses, mineralogy, space weathering, formation ages, thermal inertias, volatile content, source regions, solar system formation, etc., can be expected from human NEA missions. Samples directly returned from a primitive body would lead to the same kind of breakthroughs for understanding NEAs that the Apollo samples provided for understanding the Earth-Moon system and its formation history.

Prior to sending human explorers to NEAs, however, robotic investigations of these bodies will be required in

order to maximize operational efficiency and reduce mission risk. These precursor missions will help fill crucial strategic knowledge gaps (SKGs) (see section 6.1.2) concerning the physical characteristics of NEAs that are relevant for human exploration of these relatively unknown destinations.

One such SKG that is considered critical for future human spaceflight is the identification of resources that could be utilized *in situ*. Some NEAs have been identified via spectroscopic observations as having affinities with volatile- and organic-rich carbonaceous chondrite mineralogies, which contain significant amounts of OH and other volatiles bound within their geologic structures (Brearley, 2006; Pizzarello *et al.*, 2006; Weisberg *et al.*, 2006; Burton *et al.*, 2012). Successful identification of these types of materials and the subsequent extraction and utilization of the resources contained within them will enable human missions to leverage these resources and essentially "live off the land." This will reduce mission risk and allow more aggressive approaches for conducting exploration missions beyond low-Earth orbit (LEO). Such missions would not have to carry all the necessary supplies that would normally be used in a round-trip mission, thus freeing up extra mass that could be used for additional payloads and systems. This could eventually aid in the development of alternative mission architectures to Mars and other solar system destinations.

In addition, robotic precursor and human exploration missions to NEAs would allow NASA and its international partners to gain operational experience in performing complex tasks (e.g., sample collection, deployment of payloads, retrieval of payloads, etc.) with crew, robots, and spacecraft under low-gravity or microgravity conditions at or near the surface of a small body. This would provide an important synergy between the worldwide science and exploration communities, which will be crucial for development of future international deep-space exploration architectures and has potential benefits for future exploration of other destinations beyond LEO. This experience would be directly applicable to the moons of Mars, Phobos and Deimos, and could be leveraged to enable an eventual landing on Mars itself.

Among all human spaceflight destinations currently under consideration, only NEAs encompass all the following critical themes: exploration, science, resource utilization, and planetary defense. The scientific, *in situ* resource utilization (ISRU), and hazard mitigation benefits, along with the operational benefits of a human venture into deep space, make a human mission to an NEA a compelling prospect that has the potential to inspire future generations of scientists, engineers, and explorers on an international level for decades to come.

## 2. HISTORICAL BACKGROUND

The impetus for asteroid exploration is scientific, political, and pragmatic, and the idea of sending human explorers to asteroids is not new. Piloted missions to these primitive bodies were first discussed in the 1960s, pairing Saturn V rockets with enhanced Apollo spacecraft to explore what were then called "Earth-approaching asteroids" (Cole, 1963;

(*Cole and Cox*, 1964; *Smith*, 1966). The difference today, compared to nearly a half-century ago, is that the science and engineering communities are now much more aware of the small bodies in the vicinity of Earth. Prerequisite steps must be taken before mounting a robotic precursor mission, let alone piloted missions. The first such step, and the lynchpin of such an architecture, is a spacebased near-Earth object (NEO) survey (see section 6.1.1).

## 2.1. Apollo Applications Program/Post-Apollo

Arguably, the first realistic notions of human missions to asteroids were imagined in the 1960s by *Cole* (1963), *Cole and Cox* (1964), and *Smith* (1966). While Cole was a futurist, he was also an aerospace engineer who suggested a number of innovative scenarios for exploring the inner solar system by utilizing Apollo hardware to reach NEAs. For the most part, however, these ideas were general rather than specific. *Smith* (1966) examined the technical feasibility of implementing a human flyby mission to (433) Eros. Smith suggested that the 1975 close approach of (433) Eros (within 0.15 AU of Earth), coupled with the descending node of the asteroid's orbit, would enable an opportunity for a relatively low-energy interplanetary mission (post-Earth escape  $\Delta v = 4.2 \text{ km s}^{-1}$ ). In the 1960s, Mars and even Venus were considered primary targets for initial human missions. Smith pointed out that missions to asteroids would complement the as-yet only conceptual missions to Mars and beyond, and that a flyby mission of (433) Eros could be accomplished by a single, upgraded Saturn V along with derivatives of the Manned Orbital Research Laboratory (MORL) and the Apollo capsule. The MORL was a concept for a 5-metric-ton space station lofted by a Saturn 1B, with Gemini or Apollo capsules utilized for crew transport. For the Eros mission concept, Smith surmised that an adapted MORL could serve as a habitation module, while the Apollo capsule would be used as a launch and Earth reentry vehicle for the crew. MORL was never launched, as NASA had more ambitious plans with the Apollo Applications Orbital Workshop, which later became Skylab.

The mission architecture considered by *Smith* (1966) in his analysis began with injecting an S-IVB/Interstage Unit (with the crew and habitation module) into a two-day geocentric elliptical orbit. The S-IVB evolved from the upper stage of the Saturn 1, and was the third stage of the Saturn V rocket, which for lunar missions was ignited twice: once to place the combined Apollo Command and Service Modules and Lunar Lander (the Apollo "stack") into LEO after second-stage cutoff, and again for translunar injection (TLI). Upon completing spacecraft and systems checkout, the spacecraft "stack" would depart with a second impulse on a 270-day journey outbound toward Eros. Then, 257 days after the closest approach to the asteroid, the crew would return to Earth. A 500+-day round-trip mission with upgraded Apollo and Saturn V hardware was an audacious concept at best. However, this was the first feasibility study of its kind that examined what might be possible for missions beyond the

Moon. This was before NASA Headquarters established the Apollo Applications Program (AAP) in 1968; its intent was to develop a detailed planning guideline for the Manned Spacecraft Center [now the Johnson Space Center (JSC)] and Marshall Space Flight Center (MSFC) for piloted missions utilizing the hardware developed for the Moon. The proposed flight schedule was ambitious, calling for 13 Saturn 1B and 16 Saturn V missions, but none of these concepts imagined NEA missions. NEA human mission feasibility concepts using Apollo hardware were analyzed in more detail in 1971, but none of these concepts matured beyond the study phase (*Hall*, 1971).

## 2.2. Space Exploration Initiative

*O'Leary* (1977) discussed mining asteroids in the late 1970s, but it would be more than a decade later before NASA examined the idea of visiting NEAs as part of the Space Exploration Initiative (SEI) (*Nash et al.*, 1989). *Davis et al.* (1993) pointed out that given the large investment, as part of the SEI, in a Mars landing mission, a program of robotic and human exploration missions to NEAs would result in additional return by (1) providing a precursor to a Mars mission (with flight testing of hardware and mission operations); (2) providing a highly visible program milestone and thus sustaining momentum for the SEI in the interval between a return to the Moon and a Mars mission; (3) providing a large science return via *in situ* observations and macroscopic sample return; and (4) carrying out an assessment of the resources available in the NEA population.

None of the ancillary SEI studies on asteroids and asteroid exploration specified or even suggested a particular architecture toward achieving the human exploration of these primitive bodies. However, the variety of overview studies did begin to search the asteroid database for potential low propulsive change in velocity (low  $\Delta v$ ) targets in order to develop preliminary "suggestive" lists of possible targets, including but not limited to 1989 ML, 1989 UQ, 1991 VG, and 1991 JW (*Davis et al.*, 1993; *Jones et al.*, 1994).

By 1992, SEI had largely faded from view, suffering from a flawed, defective decision-making process (*Hogan*, 2007). As NASA acknowledged budgetary realities, notions of human exploration beyond LEO were abandoned. A new emphasis was placed on "faster, better, cheaper" robotic missions while maintaining the status quo on human spaceflight activities; this mantra referred to the Discovery program, begun in 1992, that was intended to spur proposals, subject to a competitive peer-review process, for low-cost, high-impact robotic science missions to explore the solar system. The Near Earth Asteroid Rendezvous (NEAR) mission to (433) Eros (later renamed NEAR-Shoemaker in honor of the late Eugene "Gene" Shoemaker) was the first Discovery mission launched. In addition, by 1996, the National Space Policy had removed human spaceflight exploration from the U.S. national agenda. As a result, it would be 15 years before NASA would again consider piloted missions to asteroids.

### 2.3. NASA Near-Earth Object Observations Program

In 1998, NASA established a goal to discover 90% of the NEAs larger than 1 km in diameter and in 2005, Congress extended that goal to include 90% of the NEAs larger than 140 m. There are thought to be approximately 1000 NEAs larger than 1 km and roughly 15,000 larger than 140 m. The progress toward meeting these goals can be monitored on the NEO Discovery page at <http://neo.jpl.nasa.gov/stats/> (accessed October 6, 2015). The NEO Observations program has functioned as a key foundational source for the asteroid identification and characterization activities of NASA.

Since NASA's initiation of the NEO Observations program in 1998, NEO surveys have been extremely successful, reaching the goal of finding more than 90% of the estimated NEAs larger than 1 km and a significant fraction of the estimated NEAs larger than 140 m. The vast majority of these discoveries have been made by NASA-supported groundbased telescopic surveys, including the Catalina Sky Survey (CSS) and Spacewatch near Tucson, Arizona (<http://www.lpl.arizona.edu/css/> and <http://spacewatch.lpl.arizona.edu/>, both accessed October 6, 2015); the Lincoln Near Earth Asteroid Research (LINEAR) project near Socorro, New Mexico (<http://www.ll.mit.edu/mission/space/linear/>, accessed October 6, 2015); the Panoramic Survey Telescope and Rapid Response System (Pans-STARRS) 1 on Haleakala, Maui, Hawai'i (<http://pan-starrs.ifa.hawaii.edu/public/>, accessed October 6, 2015); Lowell Observatory Near-Earth-Object Search (LONEOS) near Flagstaff, Arizona (<http://asteroid.lowell.edu/asteroid/loneos/loneos.html>, accessed October 6, 2015); and the Near-Earth Asteroid Tracking (NEAT) project run by NASA's Jet Propulsion Laboratory (JPL) (<http://neo.jpl.nasa.gov/programs/neat.html>, accessed October 6, 2015). The Near-Earth Object Wide-field Infrared Survey Explorer (NEOWISE), a near-infrared space telescope in an Earth polar orbit, discovered and characterized NEOs for 10 months in 2010 before its cryogens were exhausted, and is operating now in a post-cryogenic mission (<http://neowise.ipac.caltech.edu/>, accessed October 6, 2015). The LINEAR survey has transitioned to a new facility, LONEOS and NEAT have been discontinued, and Spacewatch now operates primarily in a follow-up capacity.

### 2.4. Constellation Program

NASA's Constellation Program (CxP) was formulated as a response to the goals laid out in the Vision for Space Exploration (VSE) ([http://www.nasa.gov/pdf/55583main\\_vision\\_space\\_exploration2.pdf](http://www.nasa.gov/pdf/55583main_vision_space_exploration2.pdf), accessed October 6, 2015). The milestones for the CxP were to (1) complete the International Space Station (ISS); (2) return to the Moon by 2020; and (3) place humans on Mars as the end goal. During the CxP's existence from 2005 to 2009, two studies examined the feasibility of reaching a number of NEAs utilizing CxP hardware elements (i.e., Ares 5 and Ares 4 launch vehicles; Ares 4 with an Atlas V and Centaur upper stage; Ares 5 with a modified Altair lunar lander as a habitation module; etc.).

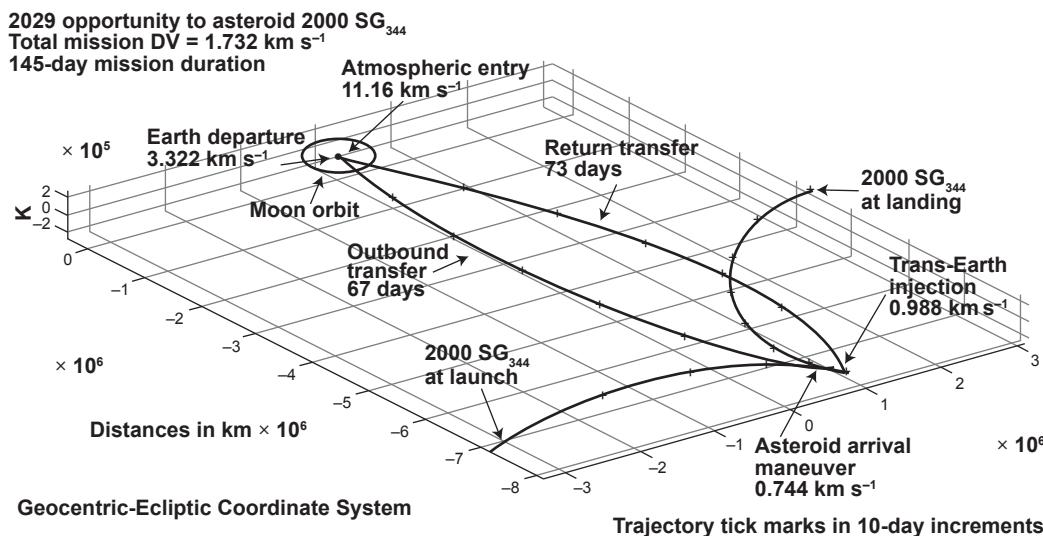

In the first CxP study related to NEAs, *Mazanek et al.* (2005) looked at relatively short round-trip missions (45–90 days) and the hardware that might enable such missions. This study conducted a top-level mission analysis of a “2.5 launch Earth-orbit rendezvous architecture,” which required two Ares 5 upper-stage Earth-departure stages (EDS) for Earth departure and arrival at the asteroid, and one Ares 1 vehicle for the crew. As CxP was rolled out, the nominal architecture for the return to the Moon was the “1.5 launch” scenario, or one Ares 5 and the Ares 1 vehicle for the crew. The 1.5 launch architecture was intended to initially place its payload into LEO (parking orbit) and to be reignited to depart Earth on a translunar trajectory, very much akin to the S-IVB stage of the Saturn V. The *Mazanek et al.* (2005) concept involved a double rendezvous in LEO with the first EDS providing the departure  $\Delta v$  from the Earth-Moon system, while the second EDS, along with the lunar lander's descent stage, would provide the braking  $\Delta v$  for rendezvous, proximity, and surface operations at the asteroid. Following surface exploration operations, including collection of samples, the Orion service module would perform the  $\Delta v$  maneuver (trans-Earth injection) to return to Earth.

The second CxP study also focused on utilizing hardware developed for the return to the Moon, but with a slight difference. It examined the feasibility of adapting that hardware within the then-planned launch vehicle infrastructure with minimal modifications to the Orion vehicle [e.g., only flying two or three astronauts, inclusion of a science instrument module (SIM) bay on the service module section of the Orion, etc.]. Four launch options were assessed: (1) Ares 1/Orion and an evolved expendable launch vehicle (EELV) such as the Atlas V and Delta IV rockets; (2) Orion atop an Ares 4 rocket; (3) Orion atop an Ares 5 rocket; and (4) Ares 1/Orion and Ares 5 (with a modified Altair lunar lander).

These feasibility studies were based upon anticipated CxP hardware performance and primarily addressed the orbital mechanics (i.e., based on low  $\Delta v$  targets and their accessibility). Coincident to and following the CxP studies, a more exhaustive examination of asteroid exploration via the Orion spacecraft was led by *Hopkins* (2009) and *Hopkins and Dissel* (2010) at Lockheed Martin Space Systems; the latter study was called “Plymouth Rock.”

Based on the expected launch vehicle development schedules (ca. 2009) and the assumption of a long-duration test flight, the Plymouth Rock concept looked at several candidate NEA targets before settling on 2008 EA<sub>9</sub> and 2000 SG<sub>344</sub> for possible missions in the 2019–2030 timeframe (Fig. 2).

The Plymouth Rock concept went to greater depth than previous studies. It proposed utilization of Orion capsules; mission durations of 4–7 months; sufficient habitable volume and life support consumables for at least two and preferably three crew members over this time span; a spacecraft propulsion system with at least 1.5 km s<sup>-1</sup> of  $\Delta v$  capability for major course maneuvers in deep space; extravehicular activities (EVAs) or at least minimal telerobotic capability to collect macroscopic samples in geological context; and a

**Fig. 2.** Plymouth Rock mission to 2000 SG<sub>344</sub> (*Hopkins and Dissel, 2010*).

reentry thermal protection system to withstand  $\sim 12 \text{ km s}^{-1}$  (*Hopkins and Dissel, 2010*).

Plymouth Rock considered a dual-Orion launch by an unmanned Ares 5 with the supplemental Orion “deep-space vehicle” and EDS on a Delta IV heavy (or Ares 1) rocket with the crew. After rendezvous in LEO, the EDS would place the combined “stack” on an Earth departure trajectory to the asteroid. *Hopkins and Dissel* (2010) evaluated life support consumables (i.e., food, water, CO<sub>2</sub> removal, O<sub>2</sub> generation, etc.) and acknowledged that even with the quasi-dual Orion (a standard Orion crew cabin capable of reentry and the enhanced Orion deep-space vehicle, not capable of reentry, with a stretched cabin), this would be a minimalistic mission.

The majority of the mission concept studies that have been conducted to date [i.e., CXP, NASA’s “Human Exploration Framework Team” (HEFT)] have not considered the benefit that NEO surveys would provide by finding more accessible targets to enable mission durations on par with ISS expeditions (i.e.,  $\sim 180$  days). The current low discovery level of viable candidate NEAs as potential human destinations is largely due to the fact that the world’s NEO observing assets are currently confined to the vicinity of Earth. Analyses of past trajectory opportunities to known NEOs have shown that some were highly accessible during the timeframes of their discovery, because they had to closely approach Earth in order to be detected. Many of these have synodic periods of several decades and longer, and would be more easily detected by a deep-space telescopic NEO infrared (IR) survey mission at, for instance, the Sun-Earth Lagrange L<sub>1</sub> point (SEL<sub>1</sub>), where such a telescope could focus on the so-called “sweet spots” in order to find human-accessible NEOs leading and trailing Earth’s orbit (*Mainzer et al., 2015*).

### 3. TARGET POPULATION DYNAMICS

The population of NEAs that may be accessible for human space flight missions is defined by the Near-Earth Object

Human Space Flight Accessible Targets Study (NHATS). NHATS is an automated system designed to monitor the accessibility of, and particular mission opportunities offered by, the NEA population. This is analogous to systems that automatically monitor the impact risk posed to Earth by the NEA population. The NHATS system identifies NEAs that are potentially accessible for future round-trip human space flight missions and provides rapid notification to asteroid observers so that crucial follow-up observations can be obtained following discovery of accessible NEAs. NHATS was developed in 2010 and was automated by early 2012. NHATS data are provided via an interactive website (<http://neo.jpl.nasa.gov/nhats/>, accessed June 9, 2015), and daily NHATS notification emails are transmitted to a mailing list (<https://lists.nasa.gov/mailman/listinfo/nhats>, accessed June 9, 2015); both resources are available to the public.

Automation of the NHATS processing was motivated by the fact that newly discovered NEAs are often only detectable for several days or weeks surrounding their discovery epochs because of their faintness in the night sky and tendency to both approach and depart Earth’s vicinity relatively quickly. The brief window of time surrounding discovery is therefore critical to obtain follow-up observations that can provide information about the NEA’s physical characteristics and improve estimates of its orbit. The automated NHATS system supports those efforts by rapidly identifying those NEAs that are particularly accessible and quickly notifying observers.

An NEA is classified as NHATS-compliant if there exists at least one round-trip trajectory solution to the NEA that satisfies NHATS key analysis constraints: (1) the total propulsive change in velocity ( $\Delta v$ ) required for the round-trip mission must be  $\leq 12 \text{ km s}^{-1}$ ; (2) the total round-trip mission duration must be  $\leq 450$  days; (3) the stay time at the NEA must be  $\geq 8$  days; and (4) Earth departure must occur sometime during the years 2015 through 2040. These constraints are discussed in greater detail later in section 3.4.

The discussions presented hereinafter regarding NEA population estimates and dynamical considerations are largely driven and framed by NHATS data, because NHATS provides a comprehensive accessibility assessment for the entire NEA population.

### 3.1. Astrodynamics Background

The accessibility of an NEA is largely framed in terms of the total  $\Delta v$  and round-trip mission duration required to visit it. The other related consideration is what range of Earth departure dates offer feasible (e.g., low  $\Delta v$ /low mission duration) missions to the NEA. Mission  $\Delta v$  is largely influenced by whether the NEA will approach Earth with low relative heliocentric velocity, while mission duration is largely influenced by how closely the NEA will approach Earth. Thus, the most favorable mission opportunities occur when an NEA approaches Earth at close distance with low relative speed. For reference, in this context “close distance” is generally  $<0.1$  AU and “low relative speed” is generally  $<2$  km s $^{-1}$ .

NEAs that will approach Earth at relatively close distances and with slow relative speeds generally have so-called “Earth-like orbits,” meaning that the NEA’s heliocentric orbit has a semimajor axis near 1 AU, eccentricity near zero, and inclination near zero. Efforts have been made to construct analytical formulations based on these fundamental considerations, for the purpose of identifying accessible NEAs based on their osculating heliocentric Keplerian orbital elements (e.g., Adamo *et al.*, 2010). However, the subtle complexities of astrodynamics, especially with regard to constrained optimization of round-trip trajectories, limit the utility of analytical formulations based on NEA orbital elements. Such approaches are not capable of identifying all members of the NEA population that meet specific mission design criteria. The empirical approach taken by the aforementioned NHATS system, on the other hand, provides complete identification of those observed NEAs that meet specific mission design constraints.

One challenging aspect of observing NEAs with very Earth-like orbits is that, much like two cars traveling at nearly the same speed around a race track, NEAs with heliocentric orbit semimajor axis near that of Earth ( $\sim 1$  AU) will be traveling around the Sun at nearly the same rate as Earth and, therefore, have very long synodic periods relative to Earth (decades or, in some cases, centuries). The synodic period is the amount of time required for the orbital geometry between Earth and the NEA to repeat. Thus, while an NEA with a very Earth-like orbit may spend substantial time loitering in Earth’s vicinity, it will then spend much more time slowly pulling ahead of or falling behind Earth as both objects orbit the Sun. Such an NEA will then spend a long period of time very far from Earth, during which it is neither observable via Earth-based telescopes nor readily accessible for spacecraft missions. Thus, one of the factors that makes an NEA very accessible (semimajor axis near 1 AU) during certain favorable time windows (when the NEA is near Earth) also makes that NEA unobservable and inaccessible for long

periods of time between the comparatively brief seasons of observability and mission accessibility.

### 3.2. Near-Earth Asteroid Population Estimates

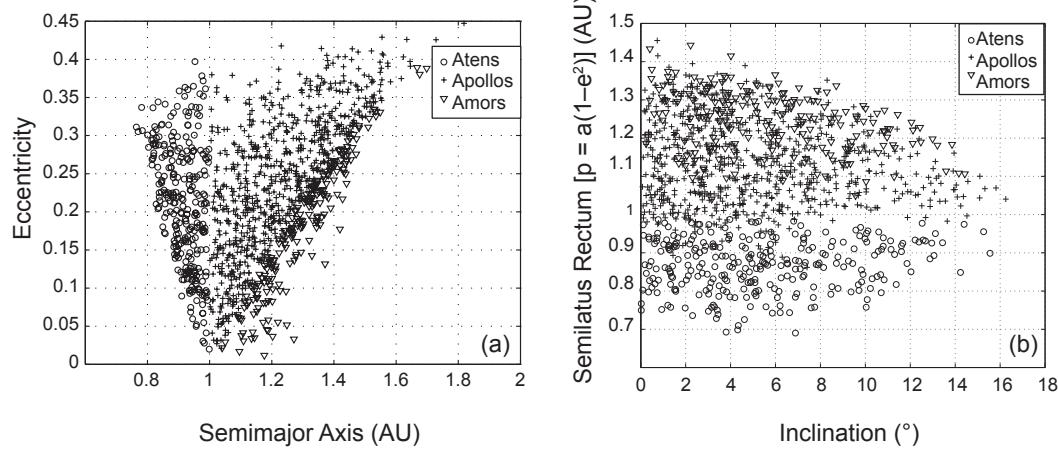

As of June 9, 2015, the number of known NEAs is 12,697, and the current rate of NEA discovery is approximately 1000 to 1500 per year. NEAs are further classified according to both composition and orbit (see the chapters by Binzel *et al.* and Mainzer *et al.* in this volume). The four NEA orbital groups are Amors (exterior to Earth’s orbit), Apollos (Earth-crossing, semimajor axis  $>1$  AU), Atens (Earth-crossing, semimajor axis  $<1$  AU), and Atiras (interior to Earth’s orbit). Some NEAs are also classified as “potentially hazardous” based on minimum orbit intersection distance (MOID) to Earth of  $\leq 0.05$  AU and their estimated diameters (see the chapters by Binzel *et al.* and Farnocchia *et al.* in this volume). The number of known potentially hazardous asteroids (PHAs) as of June 9, 2015, is 1592.

Current estimates for the NEO population survey completeness are based on work published by Mainzer *et al.* (2011), wherein the NEOWISE results lead to debiased NEO population estimates. Based on those results (see the chapter by Jedicke *et al.* in this volume), the total number of NEAs  $>1$  km in diameter is  $\sim 1000$ , of which  $\sim 70$  remain undiscovered, and the total number of NEAs 100 to 1000 m in diameter is  $\sim 19,500$ , of which  $\sim 15,000$  remain undiscovered. Insufficient data are available to precisely estimate the total number of NEAs  $<100$  m in diameter. However, previous modeling suggests that there are on the order of  $10^6$ – $10^8$  undiscovered NEAs  $<100$  m in diameter.

The subpopulation of potential NEA exploration targets may be considered in relation to the entire NEA population by examining the set of NHATS-compliant NEAs and its relationship to the overall population. There are currently 1245 known NHATS-compliant NEAs (11% of known NEAs). Table 1 presents their distribution among the four NEA orbit groups, while Fig. 3 shows the relationships between orbit semimajor axis, eccentricity, and inclination for the NHATS-compliant NEAs according to orbit group. Note that the term semilatus rectum,  $p$ , represents a property of the elliptical path followed by an orbit. It is a function of the orbit semimajor axis,  $a$ , and eccentricity,  $e$ , as follows:  $p = a(1-e^2)$ . In terms of the ellipse geometry, the semilatus rectum is half the length of the chord passing through the

TABLE 1. Currently known NHATS-compliant NEAs by orbit group.

NEA Orbit Group	All NEAs	NHATS NEAs	NHATS Portion of Orbit Group	Orbit Group Portion of NHATS
Atiras	14	0	0	0
Atens	864	289	23%	33%
Apollos	6112	742	60%	12%
Amors	4370	214	17%	5%

**Fig. 3.** Semimajor axis vs. eccentricity and inclination vs. semilatus rectum for the NHATS-compliant NEAs by orbit group.

ellipse focus, running perpendicular to the line of apsides. Because it is a function of semimajor axis and eccentricity, the semilatus rectum also describes the energy of the orbit. Note that asteroids with Earth-like orbits will have a value of  $p$  near 1 AU.

The majority of the currently known NHATS-compliant NEAs (60%) are Apollos, yet only 12% of the currently known Apollos are NHATS-compliant. Furthermore, 33% of Atens are NHATS-compliant, yet Atens are currently a minority among NEAs at ~8% of the known NEA population. This phenomenon is investigated in *Adamo and Barbee* (2011) and may lead to an improved understanding of where the most accessible NEAs tend to reside in orbital element space.

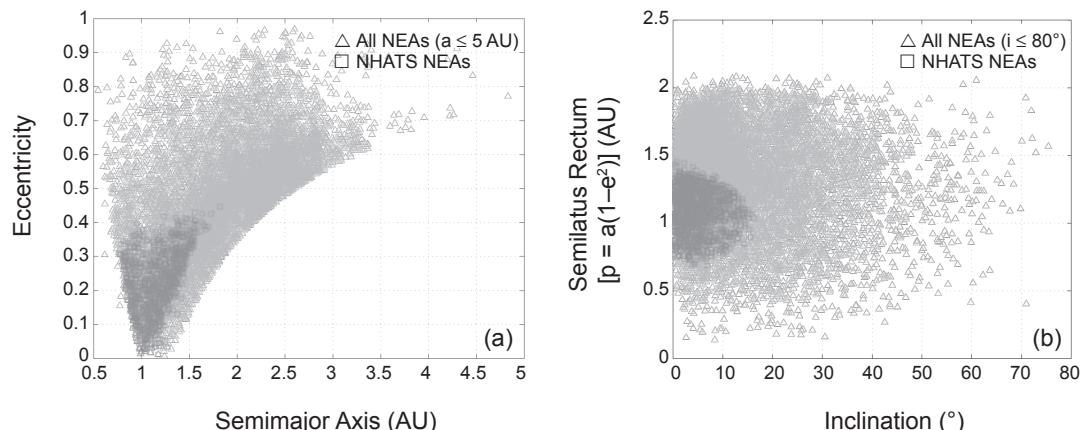

Figure 4 presents the relationships between semimajor axis, eccentricity, and inclination for the NHATS-compliant NEAs in comparison to all known NEAs. Note that seven NEAs are excluded from Figs. 4a,b because their orbit semimajor axis is  $>5$  AU, and/or their orbit inclination is  $>80^\circ$ , which would adversely affect the scales of the plots. While the NHATS-compliant NEAs have more Earth-like orbits

TABLE 2. Uncorrelated statistics for NHATS-compliant NEA orbital elements.

Orbital Element	Minimum	Mean	Maximum
Semimajor axis (AU)	0.764	1.163	1.819
Eccentricity	0.012	0.224	0.447
Inclination	0.021°	5.180°	16.253°

than other NEAs, as expected, the extent to which NHATS-compliant NEA orbits can deviate from being Earth-like is notable. Table 2 summarizes the uncorrelated minimum, mean, and maximum values for NHATS-compliant NEA orbit semimajor axes, eccentricities, and inclinations.

Table 2 clearly indicates that the mean NHATS-compliant NEA orbit is rather Earth-like, although the mean orbital inclination of  $5.180^\circ$  is displaced from the ecliptic plane where Earth's mean orbit plane resides. Orbit inclination is a significant driver of the total  $\Delta v$  required for a spacecraft to visit an NEA, so the maximum NHATS-compliant NEA

**Fig. 4.** Semimajor axis vs. eccentricity and inclination vs. semilatus rectum for the NHATS-compliant NEAs and all known NEAs.

inclination of  $16.253^\circ$  is noteworthy. However, this must be considered in the context of Figs. 3b and 4b, which show that NHATS-compliant NEAs with high inclination have semilatus rectum values near 1 AU; this value is commensurate with the energy level of Earth's orbit (as determined by semimajor axis and eccentricity). Thus, the higher NEA orbit inclinations can only be tolerated by the  $\Delta v$  budget when the NEA's semimajor axis and eccentricity are quite Earth-like.

Figure 5 presents histograms showing the distributions of orbit semimajor axis, orbit eccentricity, orbit inclination, and absolute magnitude for the known NHATS-compliant NEAs and all known NEAs; these distributions add context to the abbreviated statistics presented in Table 2.

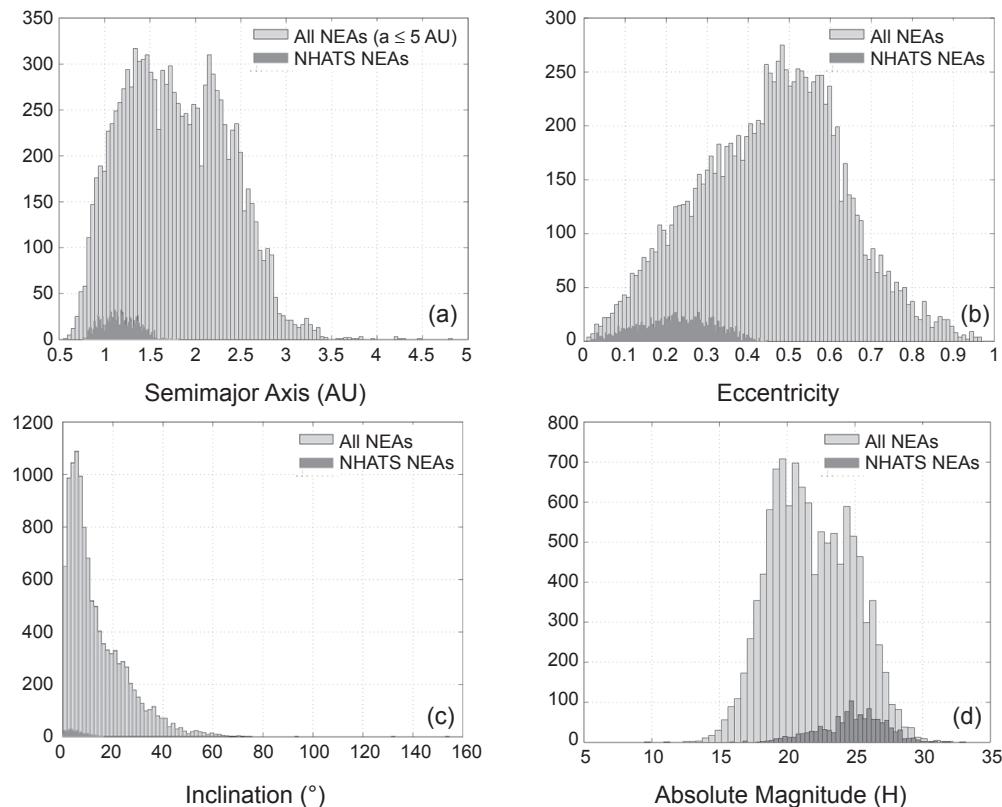

Figure 5d shows the distribution of absolute magnitudes,  $H$ , of the known NHATS-compliant NEAs vs. that for all known NEAs. The mean value of  $H$  is 21.823 for all known NEAs and 24.796 for the known NHATS-compliant NEAs. Since  $H$  can be used as a proxy for asteroid size, the known NHATS-compliant NEAs tend to be smaller, on average, than the overall known NEA population, assuming that the distribution of geometric albedo is similar in the two populations. If the geometric albedo is assumed to be 0.14 (considered representative for the average NEA), the mean diameter of the known NHATS-compliant population is 39 m, while that of all known NEAs is 153 m. However, the ability to draw conclusions about the physical characteristics

of the *total* NHATS-compliant NEA population (including objects not yet discovered) from the currently available data is limited because the data are likely influenced by observational bias; accessible NEAs will tend to closely approach Earth, and smaller (less bright) NEAs are often only detectable when near Earth.

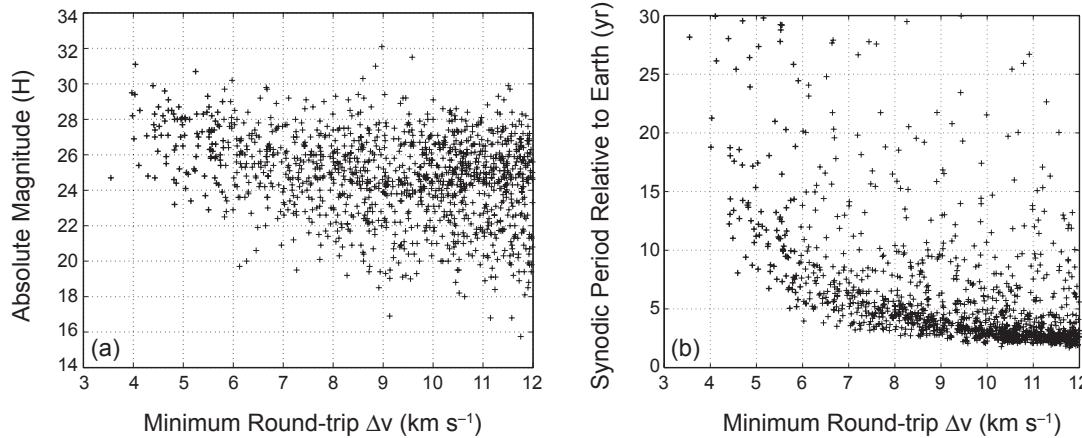

### 3.3. Dynamical Considerations for the Entire Near-Earth Asteroid Population

The aforementioned role of observational bias may also be evident in the relationship between minimum round-trip  $\Delta v$  for the NHATS-compliant NEAs and their absolute magnitudes, shown in Fig. 6a, which indicates that the more accessible (lower  $\Delta v$ ) NEAs also tend to be smaller (i.e., have larger absolute magnitudes). Nevertheless, Fig. 6a also shows that there are some rather bright ( $\sim 100$ -m-class) NEAs for which the round-trip  $\Delta v$  requirements are modest.

A consequence of accessible NEAs occupying Earth-like orbits is that the synodic period between such NEAs and Earth can be large. This is shown in Fig. 6b, which presents the minimum round-trip  $\Delta v$  for the NHATS-compliant NEAs vs. their synodic periods relative to Earth. Figure 6b shows only synodic periods  $< 30$  years so that the plot scale allows the fine structure of interest to be visible. Not included in Fig. 6b are the several dozen NHATS-compliant NEAs with

**Fig. 5.** Distributions of orbit semimajor axis, orbit eccentricity, orbit inclination, and absolute magnitude for the known NHATS-compliant NEAs and all known NEAs.

**Fig. 6.** NHATS-compliant NEA minimum round-trip  $\Delta v$  vs. (a) absolute magnitude and (b) synodic period relative to Earth.

synodic periods  $>30$  years; approximately one-third of those have a synodic period between one and several centuries, although the synodic period calculation can be misleading for such cases (Adamou, 2013). Care must be exercised when computing the synodic period relative to Earth for NEAs with very Earth-like orbits. For example, NEAs on “horseshoe” orbits, which are oscillating orbits as seen from Earth, will tend to have effective synodic periods (i.e., the elapsed time between close encounters with Earth) that are much smaller than what the typical synodic period calculation reports using the standard equation based on Keplerian orbit dynamics. Figure 6b shows that the most accessible NEAs have relatively large synodic periods, on the order of one to several decades.

However, Fig. 6b also shows that there are a number of NEAs with low to modest round-trip  $\Delta v$  requirements and relatively small synodic periods approaching five years or less. Note that the NEAs with large synodic periods *and* large  $\Delta v$  requirements are NEAs with very Earth-like semimajor axes (near 1 AU), but high orbit inclinations and/or orbit eccentricities. Large synodic periods mean that accessible NEAs discovered when they are near Earth will not return to Earth’s vicinity for a considerable amount of time after departing; this clearly complicates efforts to deploy missions to such NEAs. A spacebased survey telescope stationed far from Earth would be capable of discovering accessible NEAs before they closely approach Earth, potentially affording enough advance notice to plan and execute human and/or robotic missions to those NEAs.

The tendency of known NHATS-compliant NEAs to closely approach Earth is further illustrated by comparing them to known PHAs. An NEA is classified as a PHA if its MOID with Earth’s orbit is  $\leq 0.05$  AU and its absolute magnitude H is  $\leq 22$ . Currently, 1034 of the known NHATS-compliant NEAs (83%) have Earth MOID  $\leq 0.05$  AU and compose 21% of all known NEAs with Earth MOID  $\leq 0.05$  AU. However, only 178 known NHATS-compliant NEAs (14%) have H  $\leq 22$ . The number of known NHATS-compliant NEAs that are classified as PHAs (both Earth MOID  $\leq 0.05$  AU and H  $\leq 22$ ) is 115.

Thus, only 9% of the currently known NHATS-compliant NEAs are also classified as PHAs, but this is largely based on their H values rather than their Earth MOID values, meaning these asteroids are too small to be formally classified as PHAs.

Additionally, although the NHATS analysis is specifically designed to identify NEAs that are particularly accessible for round-trip human space flight missions, it also has a more general use. NHATS-compliant NEAs will tend to be generally accessible for other types of missions, including one-way or round-trip robotic missions involving longer mission durations and more complicated flight plans (e.g., incorporating additional deep-space maneuvers, gravity assist planetary flybys, etc.). For example, almost every NEA that has been visited, is currently scheduled to be visited, or has been seriously considered as a potential target for funded robotic science missions has turned out to be NHATS-compliant. Examples include (25143) Itokawa (1998 SF<sub>36</sub>), (101955) Bennu (1999 RQ<sub>36</sub>), (162173) Ryugu (1999 JU<sub>3</sub>), and (341843) 2008 EV<sub>5</sub>, all of which are also classified as PHAs. Itokawa was visited by JAXA’s Hayabusa (samples returned in 2010), Bennu will be visited by NASA’s OSIRIS-REx (launch in 2016 with samples to be returned in 2023), and Ryugu will be visited by the Japan Aerospace Exploration Agency’s (JAXA) Hayabusa2 (launched on December 3, 2014, with samples to be returned in 2020). In addition, 2008 EV<sub>5</sub> was the target of the European Space Agency’s (ESA) proposed MarcoPolo-R sample return mission, but the mission was not selected for funding. In summary, the subpopulation of NHATS-compliant NEAs provides an excellent starting point for identifying low- $\Delta v$  candidate targets for a wide variety of possible mission types.

Table 3 summarizes the properties of selected accessible NEAs. These NEAs were selected by querying NASA’s NHATS website for NEAs offering mission opportunities that meet the following criteria:  $\Delta v \leq 6 \text{ km s}^{-1}$ , total mission duration  $\leq 360$  days, stay time at NEA  $\geq 8$  days, and Earth departure dates between the years 2020 and 2030. These criteria are considered notionally representative of an accessible NEA. As expected, these NEAs all occupy relatively Earth-like orbits

TABLE 3. Selected accessible NEAs and their physical, orbital, and accessibility properties.

and their optimal mission opportunities tend to involve flight times of approximately six months to one year. Note that only two of these NEAs have been observed by radar, and none of them have a known spectral type or rotation period; additional characterization of these and other accessible NEAs is greatly needed, though challenging to accomplish using only groundbased observing assets. That said, the diligence of the current groundbased surveys is evidenced by the fact that most of these accessible NEAs have an orbit condition code (OCC)  $\leq 5$ . The OCC is a 0 to 9 integer scale measuring how well an NEA's orbit is known, and numerous high-quality observations are needed to provide good knowledge of an NEA's orbit. An OCC  $\leq 5$  is accepted as a notional threshold for an NEA not being "lost" (not locatable in the sky at what should be its next apparition). Note that it is generally required that OCC = 0 before launching a spacecraft to an NEA. Finally, not shown in Table 3 are the departure declinations associated with the mission trajectory solutions. For the trajectories given in Table 3, the associated Earth departure declinations vary between 8° and 62°, with an average of approximately 33°. The departure declination is a significant mission parameter because if the absolute value of the declination is larger than the launch site latitude, then additional out-of-plane  $\Delta v$  will be required to reach the Earth departure hyperbola, thus reducing the mass performance of the launch vehicle. For reference, the latitude of NASA's Kennedy Space Center (KSC) is 28.5°.

Even though the NHATS analysis system was designed and implemented prior to the conception of NASA's proposed Asteroid Redirect Mission (ARM), which seeks to capture and return a multi-ton boulder from a large NEA and place it in a lunar distant retrograde orbit (LDRO) for human visitation, the mission accessibility of NEAs classified as NHATS-compliant is sufficiently general that candidate ARM targets also tend to be NHATS-compliant.

Figure 7 illustrates the concepts described above by comparing the round-trip mission accessibility of selected NHATS-compliant NEAs to the accessibility of an object in LDRO (see section 5 for a discussion of ARM robotic mission options). For reference, the  $\Delta v$  and round-trip duration requirements for visiting the LDRO are approximately 4.5 km s<sup>-1</sup> and 25 days, respectively, where 5 of the 25 days are spent at the NEA. The data in Fig. 7 demonstrate that the most accessible of the NHATS-compliant NEAs have mission accessibility approaching that of an NEA in LDRO. However, this comparison can be extended and tied to the discussion of NEA accessibility during discovery epochs by applying the NHATS algorithm to selected NHATS-compliant NEAs during the timeframe surrounding their discovery epochs. That analysis was performed for 2006 RH<sub>120</sub> and 2009 BD, the former of which was discovered when it was temporarily captured by Earth from approximately September 2006 through June 2007.

The results show that 2006 RH<sub>120</sub> could have been visited using a total  $\Delta v$  of only 4.451 km s<sup>-1</sup> and a round-trip mission duration of only 58 days in mid-January 2007, while 2009 BD could have been visited for a total  $\Delta v$  of 5.998 km s<sup>-1</sup> and a round-trip mission duration of 50 days in mid-April 2011.

Thus, both 2006 RH<sub>120</sub> and 2009 BD were at their most accessible locations near the times when they were discovered, and their accessibilities during those times, especially that of 2006 RH<sub>120</sub>, rival that of an NEA in LDRO. Note that the mid-April 2011 launch for 2009 BD would have come about two years after its discovery and so a sufficiently long observation arc could have been obtained to characterize its orbit and ascertain that it was not an artificial object. However, 2006 RH<sub>120</sub> did not even receive its minor planet designation until February 2008, so January 2007 would have been much too early to launch a mission to the NEA.

**Fig. 7.** Comparison of round-trip mission accessibility for selected NHATS-compliant NEAs and an entire small NEA or captured boulder in LDRO.

These results serve to emphasize (1) how accessible NEAs can be in their natural orbits, and (2) that a spacebased telescope stationed far from Earth would be needed to discover and characterize NEAs sufficiently far in advance of their peak mission accessibility seasons to enable missions for which we would otherwise not have enough advance notice.

### 3.4. Near-Earth Object Human Spaceflight Accessible Targets Study Algorithm

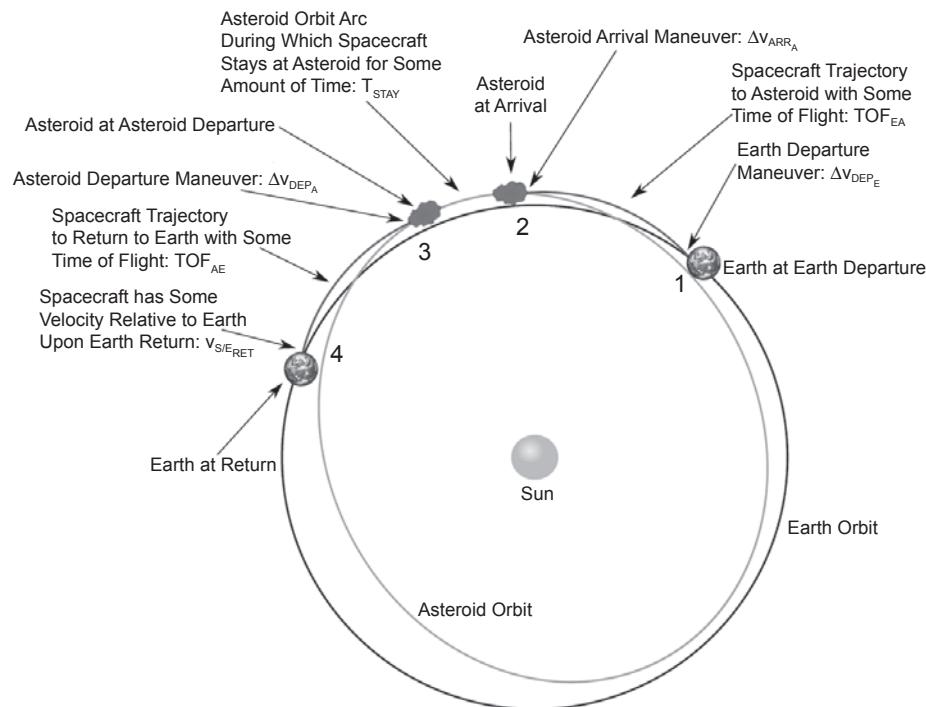

The NHATS algorithm uses the method of embedded trajectory grids (Barbee et al., 2010, 2011, 2013) to perform a comprehensive analysis of available round-trip trajectories to a particular NEA. The notional mission sequence is depicted in Fig. 8, which illustrates the four key parameters that must be varied in order to identify optimal round-trip trajectories to an NEA: (1) Earth departure epoch, (2) time of flight to reach the NEA, (3) stay time at the NEA, and (4) duration of return flight to Earth. The method of embedded trajectory grids is utilized to efficiently compute solutions for all combinations of those parameters within a four-dimensional parameter space and locate optimal solutions (e.g., minimum total mission  $\Delta v$  or minimum total mission duration). Each of the four key parameters are stepped through at eight-day intervals.

The NHATS trajectory constraints are shown in Table 4. These constraints were developed in 2010 by a human exploration committee, and the constraint values were selected

such that any mission meeting the constraints would be less demanding (e.g., in terms of  $\Delta v$  and/or duration) than any round-trip mission to Mars (e.g., conjunction class, opposition class, short stay, long stay, or Mars free-return flyby; all with or without Venus gravity assist).

The Earth departure  $C_3$  is twice the specific (per unit mass) energy of the spacecraft with respect to Earth. The total mission  $\Delta v$  is the sum of the following  $\Delta v$  maneuvers: (1) departure from a circular 400-km-altitude LEO; (2) NEA arrival (matching NEA's heliocentric velocity at the time of arrival); (3) NEA departure; and (4) reduction of Earth atmospheric entry speed if necessary (the atmospheric entry speed reduction  $\Delta v$  is modeled as being performed at Earth's gravitational sphere of influence for conservatism; some trajectories will naturally have Earth atmospheric entry speed  $\leq 12 \text{ km s}^{-1}$ ). These calculations use a value of  $3.986004415 \times 10^5 \text{ km}^3 \text{ s}^{-2}$  for Earth's gravitational parameter and a value of  $6378.136 \text{ km}$  for Earth's radius. The total round-trip mission duration is the sum of (1) the time of flight required to reach the NEA from Earth, (2) the stay time at the NEA, and (3) the time of flight required to return to Earth from the NEA.

The trajectories to/from the NEAs are computed by solving Lambert's problem with precise ephemeris files for Earth and NEAs obtained from the JPL Horizons system (<http://ssd.jpl.nasa.gov/?horizons>, accessed June 9, 2015), and using a value of  $1.32712440018 \times 10^{11} \text{ km}^3 \text{ s}^{-2}$  for the Sun's gravitational parameter. The Lambert trajectory solutions

**Fig. 8.** Round-trip mission profile assumed in NHATS.

TABLE 4. NHATS trajectory analysis parameter constraints.

Parameter	Constraint
Earth departure date	2015-01-01 to 2040-12-31
Earth departure $C_3$ ( $\text{km}^2 \text{ s}^{-2}$ )	$\leq 60$
Total mission $\Delta v$ ( $\text{km s}^{-1}$ )	$\leq 12$
Total round-trip mission duration (d)	$\leq 450$
Stay time at NEA (d)	$\geq 8$
Earth atmospheric entry speed ( $\text{km s}^{-1}$ )	$\leq 12$

omit mid-course maneuvers and gravity assists, but those trajectory design techniques are unlikely to be useful when total round-trip mission duration is limited to no more than 450 days. Additionally, the Lambert solutions have been found to be quite accurate when compared to precision trajectory solutions obtained via differential corrections and high-fidelity force models for the spacecraft (Barbee *et al.*, 2011).

The NHATS criteria are defined such that any NHATS-compliant NEA is more dynamically accessible than Mars (and, therefore, the martian moons Phobos and Deimos). Table 5 illustrates this by providing a summary comparison of mission parameters for NHATS NEAs and Mars in various modalities: round-trip visits to the surface of Mars, round-trip visits to a highly elliptical orbit around Mars (no landing) with and without a Venus flyby, and free-return round-trip missions to Mars that neither enter orbit around Mars nor land on the surface of Mars (with and without a Venus flyby). Table 5 shows that no possible Mars mission opportunity of any kind requires both round-trip  $\Delta v \leq$

$12 \text{ km s}^{-1}$  and round-trip duration  $\leq 450$  days. Furthermore, the most aggressive Mars mission options are only sparsely available during particular Earth departure years and entail close approaches to the Sun (Venus orbit distance or less).

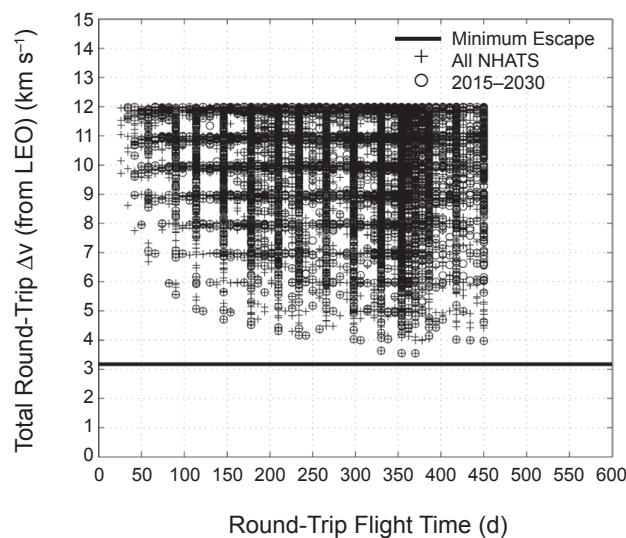

It is important to recognize that while the NHATS criterion for  $\Delta v$  extends up to  $12 \text{ km s}^{-1}$ , the most desirable NEA mission opportunities involve total mission  $\Delta v$  of only  $6\text{--}7 \text{ km s}^{-1}$ . Thus, the fact that >1000 NHATS-compliant NEAs are currently known should not be misconstrued to imply that an enhanced survey for additional target NEAs is unnecessary. On the contrary, additional enhanced NEA survey efforts are very much needed.

Thus far a number of NEAs have been discovered that offer very low- $\Delta v$  and short-duration mission opportunities. This point must be kept in mind when considering the NHATS analysis criteria in the context of Table 5. Although these criteria extend up to  $\Delta v$  of  $12 \text{ km s}^{-1}$  and mission duration of 450 days, some NEAs offer mission opportunities requiring much less  $\Delta v$  and shorter mission duration. This is seen in Fig. 9, which depicts the 62,138 round-trip trajectory solutions available in the NHATS website database for the 1245 known NHATS-compliant NEAs. The grid-like nature of the data points is simply an artifact of the binning scheme used within the NHATS website database to keep the data volume manageable (many millions of trajectory solutions are in fact computed and stored outside of the website database). The data points in Fig. 9 represent optimal (minimum  $\Delta v$  and minimum mission duration) round-trip solutions that satisfy NHATS analysis constraints. The solid line in Fig. 9 indicates the minimum  $\Delta v$  from LEO to barely reach Earth escape conditions; the  $\Delta v$  requirement for any viable NEA mission

TABLE 5. Comparison of mission parameters for NHATS NEAs and Mars.

Destination	Round-Trip $\Delta v$ (km s <sup>-1</sup> )	Round-Trip Duration (d)	Stay Time at Destination (d)	Closest Approach to Sun	Earth Departure Year(s)	Notes
NHATS NEAs	$\leq 12$	$\leq 450$	$\geq 8$	Usually near 1 AU	2015–2040	
Lowest $\Delta v$ Mars surface visit	12.530	923	500	Usually near 1 AU	2035	Round-trip to Mars surface
Lowest $\Delta v$ visit to Mars orbit	6.290	923	500	Usually near 1 AU	2035	No landing; stay in elliptical Mars orbit
Very short visit to Mars orbit	12.136	422	7	~0.72	2034	No landing; stay in elliptical Mars orbit
Short visit to Mars orbit (with Venus flyby)	12.813	485	45	0.70	2035	No landing; stay in elliptical Mars orbit
Short visit to Mars orbit (with Venus flyby)	8.120	588	45	0.62	2033	No landing; stay in elliptical Mars orbit
Mars free-return flyby	9.010	501	0	0.73	2018	No landing; no stay in Mars orbit
Mars free-return (with Venus flyby)	6.065	582	0	0.70	2021	No landing; no stay in Mars orbit

Mars mission data taken from NHATS summary chart available at [http://www.lpi.usra.edu/sbag/science/NHATS\\_Accessible\\_NEAs\\_Summary.png](http://www.lpi.usra.edu/sbag/science/NHATS_Accessible_NEAs_Summary.png) (accessed September 12, 2014).

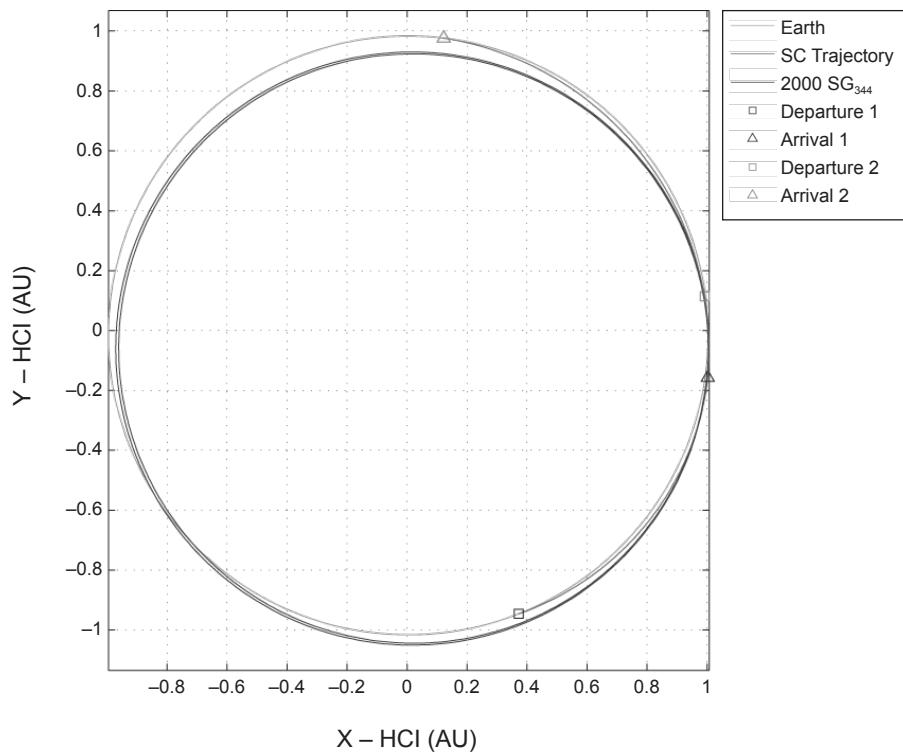

**Fig. 9.** Round-trip  $\Delta v$  and mission duration for selected mission opportunities to the NHATS-compliant NEAs.

trajectory will always be at least slightly higher. Note that several mission opportunities identified by NHATS closely approach this threshold. Also, the data markers in Fig. 9 indicate when particular mission opportunities are available with Earth departure dates between 2025 and 2030; that particular range of years may be programmatically desirable, and marking the data in that way illustrates the concept that NEA missions must launch during certain Earth departure seasons.

For added context, when examining Fig. 9, consider that round-trip missions to a low-altitude circular lunar orbit or the lunar surface require a total mission  $\Delta v$  of 5 or 9 km s<sup>-1</sup>, respectively, and one to several weeks of mission duration. Some of the NHATS mission solutions have durations that begin to approach lunar mission duration, but a substantial number of NHATS mission solutions require less  $\Delta v$  than a lunar mission. Specifically, as of September 12, 2014, there are 522 NHATS-compliant NEAs that can be visited round-trip for less total  $\Delta v$  than a round-trip mission to the lunar surface ( $\Delta v \leq 9$  km s<sup>-1</sup>), and 44 NHATS-compliant NEAs that can be visited round-trip for less total  $\Delta v$  than a round-trip mission to a low-altitude circular lunar orbit ( $\Delta v \leq 5$  km s<sup>-1</sup>). Finally, it is also useful to compare the data points shown in Fig. 9 to the Mars mission data contained in Table 5.

It is illustrative to further examine a particular mission opportunity to an exemplar NEA. Consider NEA 2000 SG<sub>344</sub>, which is currently regarded as the most accessible of the NHATS-compliant NEAs because it offers the overall lowest mission  $\Delta v$  and the largest number of mission trajectory solutions within the NHATS analysis interval. A round-trip mission opportunity to spend 16 days at 2000 SG<sub>344</sub> is available with an Earth departure date of July 14, 2029, a total mission  $\Delta v$  of 4.989 km s<sup>-1</sup>, and a total mission duration of 154 days. The Earth atmospheric entry speed upon return would be 11.157 km s<sup>-1</sup> (nearly as low as the fastest atmospheric entry ever logged by humans: 11.069 km s<sup>-1</sup> during Apollo 10), the minimum distance to the Sun would be 0.976 AU, the maximum distance from the Sun would be 1.027 AU, and the maximum distance from Earth would be only 0.055 AU.

**Fig. 10.** Heliocentric inertial view of a 154-day round-trip mission to NEA 2000 SG<sub>344</sub>.

(21.226 lunar distances). Figure 10 depicts a heliocentric inertial view of the mission trajectory.

#### 4. INTERNATIONAL EFFORTS AND CONTRIBUTIONS

##### 4.1. Japanese Perspective

**4.1.1. Hayabusa and Hayabusa2 missions.** Asteroid sample return missions are regarded as one of the most important space goals for space-related science and engineering in Japan. The successful Hayabusa mission (see the chapter by Yoshikawa et al. in this volume), conducted by JAXA, was the world's first attempted asteroid sample return mission. The second such mission, Hayabusa2, is currently underway (Yoshikawa et al., 2014).

Hayabusa was launched in May 2003, arrived at its target asteroid (25143) Itokawa in September 2005, and returned to Earth in June 2010. After its seven-year voyage, the Hayabusa spacecraft successfully returned asteroidal surface material from Itokawa, although much less than was originally hoped for. The curation facility, located at JAXA's Sagamihara Campus, has retrieved approximately 400 particles from the spacecraft's sample catcher to date. In 2012 and 2013, two international Announcements of Opportunity (AOs) related to Itokawa particles were issued, and the samples were distributed to approximately 30 research groups all over the world. Many sample analysis results have already been reported and the analyses are still ongoing (e.g., Yurimoto et al., 2011).

A few years before the return of the Hayabusa spacecraft, JAXA began planning its next asteroid sample return mission, Hayabusa2. Hayabusa was considered an engineering demonstration mission, but Hayabusa2 will primarily focus on science, with a goal of furthering understanding of the origin and evolution of the solar system, particularly as relates to water and organic matter. It is generally understood that C-type asteroids contain more organic matter and hydrated minerals than S-type asteroids such as Itokawa. Therefore, C-type asteroid (162173) Ryugu (1999 JU<sub>3</sub>) was selected as Hayabusa2's target. From a technological point of view, the purpose of Hayabusa2 is to develop more reliable and robust systems for sample return exploration. The scale of the spacecraft is similar to Hayabusa, but many parts have been modified or redesigned to prevent most of the difficulties experienced by the Hayabusa spacecraft. The Hayabusa2 spacecraft will carry new instrumentation as well, such as an impactor that will create a small crater on the surface of the asteroid. The spacecraft launched in December 2014 and is scheduled to arrive at Ryugu in June 2018. It will remain at the asteroid for approximately 18 months, departing in December 2019 and arriving at Earth in December 2020.

**4.1.2. Solar sail missions.** Hayabusa and Hayabusa2 are both considered challenging missions, but JAXA is currently considering an even more challenging mission in which a spacecraft powered by a solar power sail will return a sample from a Jupiter Trojan asteroid (e.g., an asteroid located in the L<sub>4</sub> or L<sub>5</sub> Lagrange points that precede or follow Jupiter in its orbit) (Kawaguchi, 2004). A solar sail is a large mem-

brane that uses the pressure of sunlight to propel a spacecraft; it therefore has no need to consume any propellant as long as it can obtain enough energy from sunlight. A solar power sail is an original Japanese concept in which electrical power is additionally generated by thin-film solar cells on the sail membrane. This power can be used for electrical propulsion to supplement the thrust from photon pressure, thus turning the spacecraft into a hybrid propulsion vehicle. JAXA completed the world's first demonstration of a solar power sail by the Interplanetary Kite-craft Accelerated by Radiation of the Sun (IKAROS), which was launched on an interplanetary voyage in May 2010. IKAROS achieved its primary mission goals during its first seven months, and then entered an extended operation phase at the beginning of 2011 (*Mori et al.*, 2010).

For JAXA's proposed asteroid sample return mission using a solar power sail, the target asteroid will be much further away than either Itokawa or Ryugu. The science purpose of this mission will be to study a D-type asteroid, which is a more primitive asteroid type than Itokawa (S-type) and Ryugu (C-type). JAXA believes that sample return missions from primitive bodies are very important for both the science of the solar system and space mission engineering in general.

Another advantage of the solar power sail concept is that it will allow a deep-space probe powered by the hybrid propulsion of solar photon acceleration and ion engines to explore the outer planetary regions of the solar system without relying on nuclear technology. JAXA is currently planning an outer solar system exploration mission using the demonstrated solar power sail technology. The spacecraft will travel first to Jupiter, where it will perform a flyby of a Trojan asteroid. According to a preliminary mission analysis, a sail ~50 m wide should be deployed for this mission. JAXA plans to initiate the project within the next few years, with the launch occurring in or around 2020. In order to extend the mission's output, the feasibility of an optional sample return mission by a small probe is being studied. That part of the mission would be considered in the extra success category; it is defined as an engineering mission and could take almost 30 years to complete its round trip back to Earth.

**4.1.3. Future activities.** A number of countries, including Japan, have participated in the International Space Exploration Coordination Group (ISECG), which studies human exploration missions from a global perspective. The group released the Global Exploration Roadmap, which identified two representative types of missions to the Moon and the NEAs. The discussion that follows is the preliminary study of JAXA's proposed human missions to the NEAs (JAXA, 2010). This study of human exploration of NEAs looks at the currently known NEO population as accessible targets in the 2015 to 2035 timeframe. All known NEAs are initially considered as potential targets, to keep the initial population as large as possible. The target size is restricted to absolute magnitudes  $H \leq 21.5$ , which corresponds to a diameter range of 130–300 m, thereby minimizing the probability that the target is a superfast rotator (*Pravec et al.*, 2002; Pravec, personal communication, 2015). A restriction of the departure

orbits to free-return trajectories is also considered to provide some amount of safety for the spacecraft crew. The results are evaluated by on-orbit mass requirement, mission duration, target properties, and the overall accessibility of the target. Within these constraints, only a fraction of the 8049 known NEAs (as of May 2011) fulfill the mission requirements imposed by safety considerations and scientific value without exceeding the already high on-orbit mass limit of 500 metric tons. The number of accessible target asteroids in the next 20 years is thereby limited to a total of three, with the asteroid (99942) Apophis being the most likely candidate.

Removing the restriction to free-return trajectories can be another option to reduce mass and increase the number of available targets, although the increased risk must be taken into account and possibly mitigated by additional safety features. Other mission scenarios, going beyond the scope of the presented baseline mission, have yet to be investigated in detail. These scenarios include the launch of supplies and payloads to the asteroid ahead of the crewed spacecraft, as well as the use of a Deep-Space Port (DSP) at the Sun-Earth or Earth-Moon Lagrange points.

Japan and JAXA intend to take part in NASA's proposed ARM (see section 5) by making robotic and/or human architecture contributions to the mission. In addition, JAXA intends to collaborate with international partners to contribute to the planetary defense activity represented by either NASA's Grand Challenge initiative or the activities proposed by the Technical Subcommittee of the United Nations Committee on the Peaceful Uses of Outer Space (COPUOS). For this purpose, JAXA will continue its efforts to discover new NEAs. In turn, the increasing discovery rates of NEAs in recent years will increase the chances of finding better targets than those that are currently available, in addition to improving the identification of possibly hazardous objects.

## 4.2. European Perspective

ESA has performed several studies of space missions to asteroids in the last decade and has successfully conducted two asteroid flybys (one in 2008, the other in 2010) with its probe Rosetta. Rosetta reached its final target, Comet 67P/Churyumov-Gerasimenko, in August 2014, and for the first time performed the successful deployment of a lander, called Philae, on a comet's surface in November 2014.

**4.2.1. Mitigation missions to near-Earth asteroids.** In July 2002, the general studies program of ESA funded preliminary studies of six space missions, three observational and three rendezvous and/or deflection missions, that could make significant contributions to our knowledge of NEAs. Following the presentation of the study results, ESA's Near-Earth Object Mission Advisory Panel (NEOMAP) was established in January 2004. NEOMAP, which consists of six European scientists active in studies of NEAs, was charged with the task of advising ESA on cost-effective options for ESA participation in an asteroid space mission to contribute to the understanding of the terrestrial impact hazard and the physical nature of NEAs. In particular, NEOMAP was charged with:

- identifying the advantages of, and defining a solid rationale for, the utilization of space missions for the assessment of the impact hazard;
- identifying which of those advantages would best complement groundbased observations and data;
- revising the scientific rationale for the six missions studied in the light of current knowledge and international initiatives; and
- producing a set of prioritized recommendations for observatory and rendezvous missions in an international context.

Taking all factors into account, NEOMAP unanimously agreed that the proposed rendezvous mission concepts were of significantly higher priority in terms of risk assessment and mitigation than the observatory mission concepts. At the time of the NEOMAP work, it was expected that ground-based facilities, such as Pan-STARRS, would be operational before any of the considered space observatory missions were launched. Therefore, it was expected that an 80–90% discovery rate for  $H < 20.5$  bodies would have been achieved within the next decade even without space observatory missions. For that reason, NEOMAP decided to reconsider a spacebased NEO observatory mission in 10–15 years once the residual hazard of NEOs that are unobservable from groundbased surveys has become better defined. In particular, NEOMAP noted that the ability to change the orbit of an NEO has not yet been demonstrated, so a vital link in the chain from threat identification to threat mitigation is missing.

Of the three rendezvous missions reviewed, NEOMAP considered the Don Quijote mission concept to be most compatible with the criteria and priorities established in their report. This concept involves an orbiter that would characterize the asteroid target, followed six months later by a hypervelocity vehicle that would impact the target. The orbiter would then observe the event and measure the deflection resulting from the impact. Don Quijote was considered to have the potential to discover a great deal, not only about the internal structure of an NEO, but also how to mechanically interact with it; it was also judged capable of providing the vital missing link between threat identification and mitigation. NEOMAP also felt that the Don Quijote concept could readily attract the attention of potential partners outside of ESA. A Phase A study was performed in 2007 but no actual plan was made to study the concept further, despite the recommendation from the international community to perform such a test (*National Research Council of the National Academies*, 2010; *International Academy of Astronautics*, 2013).

In 2011, ESA, NASA, the Applied Physics Laboratory (APL) of The Johns Hopkins University (JHU), the Côte d'Azur Observatory, and the German Space Agency (DLR) began a study of a mission similar to the Don Quijote concept called the Asteroid Impact and Deflection Assessment (AIDA) mission. This mission would be the first to actually demonstrate asteroid impact hazard mitigation by using a kinetic impactor to deflect an asteroid.

At the time of this writing, AIDA is a joint ESA-NASA cooperative project, which includes the ESA Asteroid Impact Mission (AIM) rendezvous spacecraft and the NASA Double Asteroid Redirection Test (DART) mission. AIM is equipped with a visual imaging system, a small lander, a thermal infrared imager, a high-frequency (decimeter-wave) radar, and a low-frequency (60-MHz) radar, to measure surface and subsurface physical properties and to study internal structures. AIM also includes an interplanetary optical communication demonstration that can be used as a laser altimeter and an intersatellite link with its deployed CubeSat payloads. The DART payload consists of a high-resolution visible imager to support the primary mission objective of impacting the target body through its center. The DART imager is required to support optical navigation on approach and autonomous navigation in the terminal phase.

The AIM study entered Phase A/B1 at ESA in early 2015 and will proceed through summer 2016. The DART study should enter NASA Phase A in early fall 2015 and will also proceed through summer 2016. ESA and NASA will decide whether to proceed to the next phases of AIM and DART, respectively, in early 2017.

The primary goals of AIDA are to (1) investigate the binary NEA (65803) Didymos, (2) test our ability to impact its moon with a hypervelocity projectile in 2022, and (3) measure and characterize the impact deflection both from space with AIM and from groundbased observatories. AIM is not meant to be a purely scientific mission but rather a demonstration of several technologies that can then be applied to future missions. However, AIM will drastically improve our scientific knowledge of small asteroids in terms of asteroid geophysics, granular mechanics, impact processes, and thermal effects/properties. It is worth noting that because none of the medium- or large-class missions identified by ESA's Cosmic Vision Program are devoted to asteroids, AIM provides the only opportunity for ESA to conduct an asteroid mission for the next 20 years.

If selected for launch in 2020, AIDA will return fundamental new information on a binary asteroid system; on its mechanical response; on the impact cratering process; and consequently on the collisional evolution of asteroids with implications for planetary defense, human spaceflight, and solar system science. AIDA will be the first fully documented impact experiment at real asteroid scale, allowing numerical codes and modeling to be tested and used for similar and other scientific applications at those scales (see the chapters by Jutzi et al. and Harris et al. in this volume).

**4.2.2. Science missions to asteroids.** In 2004, ESA launched the space mission Rosetta. The primary goal of this mission was to land on Comet 67P/Churyumov-Gerasimenko and obtain data on its physical and compositional properties by performing *in situ* measurements. The spacecraft reached its target in August 2014, and the resultant images quickly showed that the comet's shape and morphology were completely different than anything previously observed. The deployment of the lander Philae was successfully accomplished, although it bounced off the surface and then landed

in a different zone on the comet's surface; its precise location has not been determined at the time of this writing.

In addition, given the current high interest in small bodies, ESA chose a trajectory that allowed multiple asteroid flybys before reaching the final destination. In October 2008, Rosetta encountered the asteroid (2867) Šteins, and in July 2010 it encountered the asteroid (21) Lutetia (see the chapter by Barucci et al. in this volume). With a diameter of approximately 100 km, (21) Lutetia was the largest visited asteroid at that time, before Dawn visited one year later the second largest asteroid in the main belt, (4) Vesta, which is approximately 540 km in diameter (see the chapter by Russell et al. in this volume).

In 2007, the Marco Polo mission was selected by ESA, along with a few other mission concepts, for the assessment study phase of the first medium-class missions of its program Cosmic Vision 2015–2025. Marco Polo's goal was to return a sample from a primitive asteroid in partnership with JAXA. The scientific rationale was highly ranked by ESA committees but the mission was not selected for the next phase because the estimated cost was higher than the allotted amount for a medium-class mission. In 2011, ESA selected a second proposal, called MarcoPolo-R, for the assessment study phase of the third medium-class competition. Thanks to collaboration with APL/JHU and JPL, the new concept, with a lower budget, was proposed for coordination with ESA's Cosmic Vision Call for Proposal. The original target was the primitive binary asteroid 1996 FG<sub>3</sub> (Barucci et al., 2011; Michel et al., 2014). The scientific objectives were similar to those of two other sample return missions in development, namely OSIRIS-REx (NASA) and Hayabusa2 (JAXA), but the selection of a binary target would allow the mission to acquire additional information on the geophysics of such systems, which represent 15% of the NEO population. The target was later changed to asteroid 2008 EV<sub>5</sub>, which is not a binary system. Contrary to the OSIRIS-REx and Hayabusa2 targets, which have albedos below 0.05, 2008 EV<sub>5</sub>'s albedo is moderate for a primitive asteroid, with a value about 0.12, while its spectrum is characteristic of a primitive body (Reddy et al., 2012). In effect, spectroscopic observations strongly suggest that 2008 EV<sub>5</sub> is a particularly primitive object that may have accreted in a volatile-rich region. Its spectrum shares similarities with CI carbonaceous chondrite meteorites, such as Orgueil, believed to represent the most primitive material available on Earth (Reddy et al., 2012). 2008 EV<sub>5</sub> is expected to contain water in the form of hydrated minerals, as well as organics such as amino acids, and may correspond to a transitional object between asteroids and comets. With this target, MarcoPolo-R could therefore make a unique contribution to our better understanding of the origin and evolution of the solar system, Earth, and life itself. Unfortunately, although MarcoPolo-R was ranked first by the ESA Solar System and Exploration Working Group, the ESA Space Science Advisory Committee instead elected to move forward with the PLAnetary Transits and Oscillations of stars (PLATO) mission, which is devoted to the discovery of extrasolar planets. Nevertheless,

both the ESA internal studies as well as industrial studies related to MarcoPolo-R that have been conducted since 2007 have generated valuable information about and experience on small-body sample return missions that will prove useful in the future. In fact, part of the knowledge gained regarding various payloads and operations, particularly as related to guidance, navigation, and technology, is being used in the study of the AIM spacecraft (see section 4.2.1.).

**4.2.3. Human exploration.** Asteroids are not considered a priority destination in ESA's human spaceflight program; the program is primarily focused on the ISS, where significant technological and research achievements have already been realized. Human-tended operations in LEO have enabled Europe to develop critical capabilities in human spaceflight, first with Spacelab in the early 1980s and then through its participation in the ISS program. Major technological achievements include the development and operations of the Columbus laboratory, as well as the development and implementation of the Automated Transfer Vehicle (ATV) cargo supply vehicle. Exploitation of the ISS is foreseen by the ISS partners until at least 2020 and possibly until 2028. The decision of the ESA Council in March 2011 paved the way for European participation in ISS exploitation up to 2020. Moreover, the approval of the development of the European Service Module (ESM) for the NASA Multi-Purpose Crew Vehicle (MPCV), within the framework of an ISS barter agreement, created for the first time a role on the critical path for Europe in human space transportation. This decision not only helps stabilize ESA activities on the ISS up to 2020 but also opens up new perspectives for Europe's role in human missions targeting destinations beyond LEO.

Whereas international space agencies agree that the ultimate goal in this century is to land humans on Mars, the route to achieving this goal is under discussion and a clear international political commitment is still lacking. Current ESA programs aim to advance European exploration goals and developing perspectives for strong European participation in international exploration scenarios beyond 2020.

ESA's strategic interests are realized through cooperation with international partners, in particular NASA and Roscosmos, and in the future possibly also the Chinese Manned Space Agency (CMSA). Considering their already proven or quickly developing capabilities in human space transportation, these partners are in a position to take initiatives in the field of space exploration. Regarding ESA's cooperation with NASA, based on the development of the ESM of the MPCV, a continued production of the ESM for future crew missions could be envisioned. In parallel, ESA could start the development of complementary transportation and technology elements, leveraging its lunar robotic exploration activities, technology demonstrators, and all of the European ISS program elements with the post-2020 LEO exploitation scenario. The ultimate goal is to generate a role for Europe in human missions to the Moon and eventually to Mars. ESA's cooperation with Roscosmos has been formalized in relation to ESA's current contribution to Mars exploration with the ExoMars program. The success of the two ExoMars

missions to be launched in 2016 and 2018 will enable ESA and Europe to fully engage in future robotic exploration missions with their Russian partners. Through the Mars Robotic Exploration Program, ESA is studying post-ExoMars candidate missions designed as technology precursors for Mars sample return missions. ESA is also currently defining and developing, using a step-wise approach, a European contribution to the Russian-led Luna-Resurs (2019) and Lunar Polar Sample Return (2021+) missions, enabling participation in a potential future international lunar human exploration program. Regarding cooperation with China, in recent months ESA and CMSA have been attempting to identify opportunities for collaboration, particularly in the areas of astronaut training and crewed missions.

In conclusion, ESA's Agenda 2015 defines LEO, the Moon, and Mars as its three strategic destinations. On this basis, integrated planning for human spaceflight activities post-2020 is under review, addressing both future engagement in LEO exploitation and participation in human missions beyond LEO. Near-term preparatory activities are currently focused on engaging with international partners in determining future mission scenarios, identifying and defining potential future roles for ESA, and advancing and demonstrating technologies for securing such roles. In particular, the development of the service module for the NASA Orion crew vehicle, implemented in the context of the ISS program, opens further perspectives for European roles in human transportation. Asteroids are viewed with great interest by ESA's science program but are not a priority or even an explicit goal in the exploration program. However, participation in an asteroid mission is not explicitly excluded, due to the collaboration with NASA concerning the development of the ESM for NASA's MPCV. In this context, technologies developed by ESA may be used in NASA human missions to asteroids, which would open the possibility for additional European participation.

## 5. ASTEROID REDIRECT MISSION

A major element of NASA's Asteroid Initiative is ARM, which is a capability demonstration mission that combines robotic and crewed segments to develop, test, and utilize a number of key capabilities that will be needed for future exploration of Mars and other solar system destinations, as well as providing other broader benefits. ARM will develop a high-power solar electric propulsion (SEP) spacecraft and capture a multi-ton boulder (minimum-maximum extent of 1–6 m) from a large NEA 100–1000 m in size (*Mazanek et al.*, 2014), and move the boulder into an LDRO, where it would be accessible for human exploration via flights of the Orion crew vehicle. *Brophy et al.* (2012) originally proposed a robotic mission concept to capture an entire small asteroid (4–10 m in size) to leverage several of NASA's key ongoing activities in human exploration, space technology, and planetary defense, with the collection of a boulder from a large asteroid as an alternate approach. NASA evaluated both mission approaches, designated the Small Asteroid

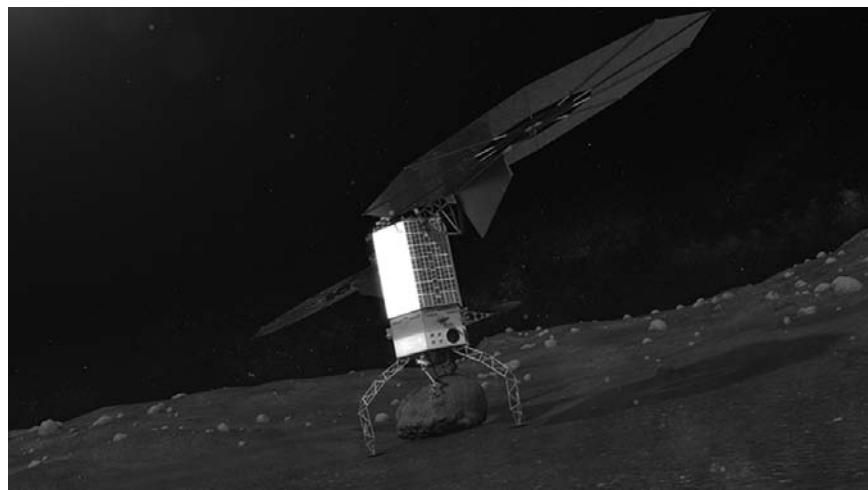

Capture Option (Option A) and the Robotic Boulder Capture Option (Option B), to determine their feasibility, identify the important differences between them, and evaluate the key risks and figures of merit (FOMs) for each concept. On March 25, 2015, NASA announced the selection of Option B for the robotic segment of ARM.

A major focus of ARM is the development and flight demonstration of a multi-purpose, next generation SEP vehicle. This propulsive element, known as the Asteroid Redirect Vehicle (ARV), will feature higher power levels than ever used before (~40 kW available to the electric propulsion system), test new high-efficiency magnetically shielded electric propulsion Hall thrusters, and provide an essential capability for moving large payloads around the solar system. For the robotic segment, the ARV will be outfitted to enable boulder capture for this first demonstration mission (Fig. 11), but could also become, with minor modifications, a general-purpose tug for deploying cargo modules in support of future human missions to deep-space destinations, such as NEAs and Mars. The ARV is currently planned to launch at the end of 2020 and the duration will be approximately five years between departure and return to the Earth-Moon system. After the boulder has been collected from the parent asteroid and secured, the ARV will demonstrate a planetary defense technique known as an Enhanced Gravity Tractor (EGT). During the EGT phase, the ARV will operate in a halo orbit around the parent asteroid, using the mass of the vehicle and captured boulder to slowly alter the asteroid's orbit (*Mazanek et al.*, 2013, 2015).

Once the ARV, along with its asteroidal payload, has been successfully returned to the Earth-Moon system and maneuvered into the LDRO, the crewed segment of the mission will be conducted. This will consist of an Orion capsule with a two-person crew launched in late 2025 using NASA's Space Launch System (SLS). Orion will first fly by the Moon and then maneuver into the LDRO, where it will rendezvous and dock with the ARV and the captured boulder. The crew will then perform two EVAs to collect asteroid samples and deploy instruments before returning to Earth (Fig. 12). The crewed portion of the mission will last approximately 25 days, and will represent the longest-duration human mission beyond LEO since the Apollo program. Subsequent human and robotic missions to the asteroidal material will also be facilitated by its presence in cislunar space and will benefit scientific and partnership interests, expanding our knowledge of small celestial bodies and enabling the demonstration of mining asteroid resources for commercial and exploration needs.

### 5.1. Rationale and Objectives

To achieve its long-term goal of sending humans to Mars, NASA plans to proceed in a series of incrementally more complex human spaceflight missions. Sending humans on shorter deep-space missions to explore accessible asteroids is a compelling intermediate step toward Mars, but even those missions are a significant leap beyond current capabilities.

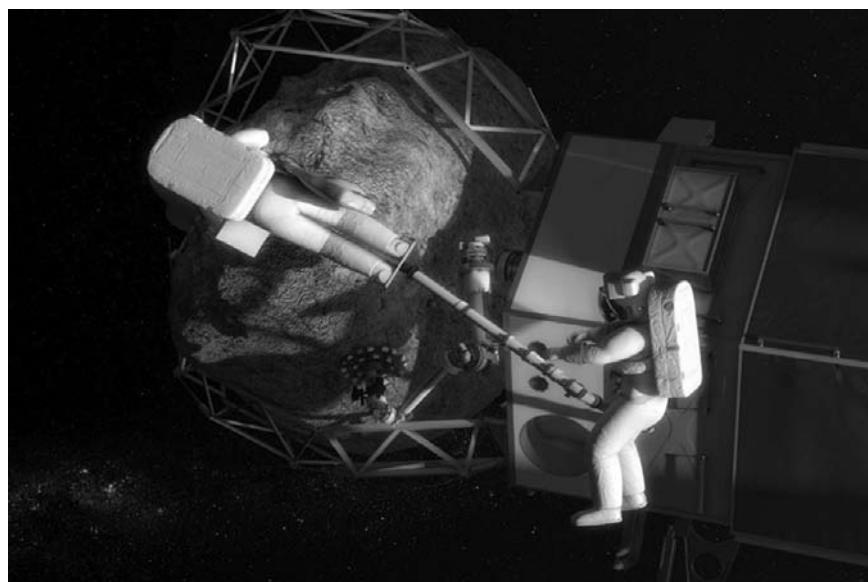

**Fig. 11.** Illustration of ARM robotic segment with ARV on the surface of the parent asteroid.

Today, human flight experience extends only to LEO, from which a crew can return to Earth in a matter of minutes to hours should problems arise during a mission. The next logical step for human spaceflight is to gain flight experience in the vicinity of the Moon. These cislunar missions provide a “proving ground” for the testing of systems and operations while still accommodating an emergency return path to Earth that would last only several days. Cislunar mission experience will be essential for more ambitious human missions to NEAs and eventually Mars, which will require weeks, months, or even years of transit time. Flight hardware to support cislunar Orion missions is already under development, and those missions are scheduled to be launched as early as 2021. The additional habitation modules and crew

propulsive stages needed to support multi-month human missions into deep space are only in the proposal stage, and those flights are clearly many years farther down the road than the proving-ground cislunar flights.

A principle objective of ARM is the development of a high-power SEP vehicle, and the demonstration that it can operate for many years in interplanetary space. NASA has long had plans for developing and demonstrating a next generation “SEP tug” vehicle that would offer a more efficient cargo transportation capability and would be critical for affordable deep-space exploration missions. In particular, current NASA architectures for human missions to Mars or its moons will require large SEP tugs to predeploy support modules, habitation modules, and propulsive stages not

**Fig. 12.** Illustration of ARM crewed segment with astronauts performing an EVA to collect samples from the returned asteroid boulder.

only into cislunar space, but also into Mars orbit (*Price et al.*, 2014).

The ARV developed for ARM will include a general-purpose SEP Module (SEPM) and Mission Module (MM). The majority of ARM's development cost is for the SEPM and MM rather than the asteroid Capture Module (CM), which current estimates predict would only be a minor part of ARM's total cost, and significantly less than the cost of a typical NASA Discovery-class mission. The SEP demonstration could be performed with only cargo modules or ballast, but ARM will allow collection of many tons of asteroidal material and the demonstration of planetary defense techniques at comparatively little additional cost.

A second prime objective of ARM is to conduct a human spaceflight mission involving in-space interaction with a natural object, in order to provide the systems and operational experience that will be required for eventual human exploration of Mars, including the martian moons Phobos and Deimos. ARM provides a compelling science focus for the early flights of the Orion program, which will take place before the infrastructure for more ambitious flights will be available. Astronauts will participate in the scientific in-space investigation of nearly pristine asteroid material, at most only minimally altered by the capture process. ARM will provide the opportunity for human explorers to work in space with unaltered asteroid material, testing the activities that would be performed and tools that would be needed for later exploration of primitive body surfaces in deep space. The operational experience would be gained close to our home planet, with a relatively quick return to Earth if problems should arise. There will also be opportunities to revisit the returned boulder, to further refine asteroid exploration techniques.

Another important objective for ARM is the demonstration of some basic planetary defense techniques that would inform future strategies for impact hazard mitigation. The EGT will use the mass of the spacecraft enhanced by that of the boulder to move the asteroid through mutual gravitational attraction. The acceleration imparted on the parent asteroid will be very small, and the spacecraft will be able to approach the center of mass of the asteroid to within a few hundred meters. Approximately two months of ARV operation will be required to impart a measurable velocity change on the parent asteroid. The tracting duration would likely be much longer if this technique were required for an actual deflection mission, but this amount of time would depend on the size of the impactor and the mass that can be collected. Since the material would not need to be returned to cislunar space for a deflection mission, the collected mass could be much greater, which would significantly enhance the gravitational acceleration. The operational experience gained from performing the EGT technique would be the main benefit of the demonstration.

A final objective for ARM is to pursue a target of opportunity to examine the possible uses of small celestial bodies for *in situ* resource extraction and utilization. The possibility of extracting water and/or oxygen from asteroids has been proposed as the key that might enable affordable expansion of humankind throughout the solar system. Hydrated miner-

als are likely abundant in certain types of carbonaceous (C-type) asteroids, and it is therefore highly desirable to target an asteroid of this class. Because it is easier to obtain high signal-to-noise spectra for large as opposed to small NEAs, it is therefore easier to confirm the presence of volatiles. This definitive spectral information is critical for achieving ARM's resource utilization objectives.

## 5.2. Mission Benefits

ARM provides the ability for the science community to select a well-characterized multi-ton boulder with geological context that astronauts can explore and from which they can return samples. The robotic segment enables centimeter-level characterization over an entire large NEA and the ability to identify the NEA's compositional type (e.g., a water/volatile-rich carbonaceous target), while also being robust to programmatic uncertainties by allowing the return mass to be varied. The robotic segment also provides additional experience operating at a low-gravity planetary body, including extended surface contact critical to future human and robotic missions and the ability to demonstrate one or more planetary defense deflection techniques on an NEA of hazardous size, which will inform planetary defense strategies. The ARV capture module comprises multiple, complementary robotic systems. The Contact and Restraint Subsystem (CRS) consists of three "legs" that facilitate the low-gravity landing (LGL) of the ARV on the asteroid surface, and can be directly extended to enable missions to a wide range of low-gravity, airless bodies. After the LGL is completed, two seven-degree-of-freedom robotic arms will capture the boulder using an innovative microspine gripper and anchoring mechanism. After boulder capture, the CRS will perform the ascent maneuver by mechanically pushing off the asteroid, and later will provide the restraint of the boulder during the ARV's return to cislunar space. The CM robotic elements will demonstrate key capabilities that can be used on many future missions, including delivery of surface assets to NEAs or the martian moons, robotic servicing of spacecraft, and mobility options for exploring other destinations. For example, the robotic arms will include a tool change-out mechanism that allows both for mission-specific tools to be mated to the multi-mission arms, and for tools to be changed during the mission. The microspine gripper could also demonstrate a novel approach for collecting samples on a variety of future human and robotic missions (e.g., anchoring with low-gravity drilling, climbing lava tubes or canyon walls, etc.).

In addition, ARM can change the paradigm of ISRU by delivering many tons of water/volatile-rich carbonaceous asteroidal material to cislunar space where ISRU techniques and equipment can be tested and refined on an industrial scale. These demonstrations can be performed teleoperatedly in this region, with very little latency, from Earth or a crewed spacecraft in cislunar space, and the associated equipment could be serviced by astronauts when needed.

Much of the planetary science community's interest in asteroids is focused on primitive, water/volatile-rich car-

bonaceous targets that could provide valuable information on the formation of our solar system and the origins of life on Earth. ARM allows the return of a well-characterized sample with geological context from an NEA of a known compositional type (e.g., a large carbonaceous boulder and one or more parent-body surface samples). The mission also provides numerous opportunities for mission enhancements to support science objectives, including robotic arm sample collection (e.g., drilling, coring, surface sample collection, and caching), the ability to host and deploy free-flyers or surface rovers/hoppers, and additional scientific instrumentation for *in situ* or remote observation of a large NEA. Additionally, the advanced SEP technologies, instrumentation, and low-gravity-body autonomous operations required for the robotic segment will help enable more capable future robotic missions.

### 5.3. Candidate Near-Earth Asteroid Targets

Four NEAs are currently being considered as selectable targets for ARM: (341843) 2008 EV<sub>5</sub>, (101955) Bennu (1999 RQ<sub>36</sub>), (162173) Ryugu (1999 JU<sub>3</sub>), and (25143) Itokawa (1998 SF<sub>36</sub>). Precursor reconnaissance is planned for two candidate carbonaceous asteroids, Bennu and Ryugu, while one stony asteroid, Itokawa, was visited by JAXA's Hayabusa spacecraft in 2005 (see section 4.1.1 and the chapter by Yoshikawa et al. in this volume). Bennu will be visited by NASA's OSIRIS-REx spacecraft and Ryugu will be visited by JAXA's Hayabusa2 spacecraft; both will

rendezvous with their respective targets in 2018 and provide detailed mapping and characterization of their targets' physical properties. 2008 EV<sub>5</sub> has been well characterized by groundbased radar (signal-to-noise ratio >5000) (Busch et al., 2011) and in the infrared wavelengths with the Wide-field Infrared Survey Explorer (WISE) spacecraft. Groundbased measurements of 2008 EV<sub>5</sub>, Bennu, and Ryugu show that these NEAs are carbonaceous chondrite targets (C-types) that are believed to be water/volatile-rich, possibly containing significant amounts of organic materials (Clark et al., 2011; Reddy et al., 2012; Moskovitz et al., 2013). The physical and orbital properties of the current ARM candidate targets are summarized in Table 6.

It is possible that additional candidate targets for ARM could be identified and sufficiently characterized using radar observations prior to launch of the ARV. A preliminary scan using a ranking parameter and a thrust-limited, multi-revolution Lambert's solver identified numerous asteroids that could be reached with ballistic trajectories and a low enough velocity change ( $\Delta v$ ) needed for significant mass return. Trajectories to over 60 target NEAs with upcoming radar observations were identified, but opportunities for observations with high signal-to-noise ratios to confirm or infer the existence of boulders are limited. But even without additional targets, the existence of three high-value carbonaceous targets (two with planned precursor missions) and the knowledge of a well-characterized target (Itokawa) provide a robust set of candidate NEAs for ARM.

TABLE 6. Physical and orbital characteristics of ARM target NEAs.

Parameter	2008 EV <sub>5</sub>	(101955) Bennu	(162173) Ryugu	(25143) Itokawa
<i>Physical properties</i>				
Dimensions	420 × 410 × 390 m	492 × 508 × 546 m	870 m diameter	535 × 294 × 209 m

Orbital condition code (OCC)	0	0	0	0

## 6. HUMAN MISSIONS TO NEAR-EARTH ASTEROIDS

### 6.1. Target Identification and Characterization

**6.1.1. Near-Earth object (NEO) survey telescope.** The most suitable targets for human missions are NEAs in Earth-like orbits with long synodic periods. This makes these objects difficult to detect from groundbased telescopes because their orbits place them in viewing geometries that are close to the Sun as viewed from Earth. Hence these objects often spend much of their time in daytime skies, and are only observable during their close approaches to Earth. However, these NEAs are often not observable from Earth until the timeframe of their most favorable human mission opportunities, which does not provide enough time for target characterization and future mission development.

A spacebased infrared survey telescope could find these targets in a more efficient, timely, and affordable manner. Such a system will not only be able to discover new objects, but will also be able to track and characterize objects of interest for human space flight consideration. Those objects with characteristic signatures representative of volatile-rich or metallic materials will be considered as top candidates for further investigation due to their potential for resource utilization and scientific interest.

The best targets for the initial piloted missions would be those NEAs that:

- have Earth-like orbits (low eccentricity and low inclination);
- make very close Earth approaches (i.e., within ~0.05 AU of Earth);
- are principal-axis “slow” rotators (i.e., not tumbling with a rotation period of several hours);
- are single, solitary objects (~one-sixth of all NEAs are binary or ternary bodies; see the chapter by Margot et al. in this volume); and
- are asteroidal in nature (i.e., not an extinct or dormant comet)

Based on these high-level parameters, in order to find potential targets for human exploration, a preliminary filter began to emerge, based on semimajor axis ( $a$ ), eccentricity ( $e$ ), and inclination ( $i$ ) (with respect to the ecliptic):  $0.5 \text{ AU} < a < 1.5 \text{ AU}$ ,  $e < 0.5$ , and  $i < 4^\circ$ . Only a very small fraction of the current NEA catalog in the NHATS subset deemed “human-accessible” have inclinations  $<2^\circ$ . Nearly every degree of orbital inclination requires  $\sim 0.5 \text{ km s}^{-1}$  of post-Earth escape  $\Delta v$ ; therefore, for the first piloted missions to these bodies, potential asteroid targets must truly have Earth-like orbits about the Sun. As a result, the NHATS effort continues to identify potential targets that fit within the accessibility filter constraints. The first tier characteristics for accessibility include short round-trip mission length (ideally  $\sim 30\text{--}180$  days), slower rotation rate (i.e.,  $>2$  h), and

larger size ( $>30$  m in diameter). Second-tier characteristics preclude binary systems or potential volatiles and surface activity, and perhaps indicate a preference for certain mineralogical compositions and internal structures. To date, the various sets of studies have identified only a few potential NEA targets for human missions, all of which are small (i.e.,  $<30$  m across).

Hence the most pertinent knowledge needed to prepare for any human exploration missions to NEAs is to discover a sufficient number of suitable candidate targets. Such detailed knowledge of the NEA population would also have the ancillary benefit of informing planetary defense initiatives, since those targets that are the most accessible also present the greatest impact threat to Earth. Identification of human-accessible NEAs will not be met in a timely manner by existing or planned groundbased surveys (Abell et al., 2009; Adamo et al., 2010; Cheng et al., 2011). This point has also been the recent focus of the small-bodies scientific community, which has repeatedly called for the rapid development and operation of a spacebased infrared survey telescope as a foundational asset for future space exploration initiatives.

**6.1.2. Strategic knowledge gaps (SKGs).** For the past several years NASA has been interested in identifying the key SKGs related to future human destinations. These SKGs highlight the various unknowns and/or data gaps of targets that the science and engineering communities would like to have filled in prior to committing crews to explore the solar system. An action team from the NASA-chartered Small Bodies Assessment Group (SBAG) was formed specifically to identify the small body SKGs under the direction of the Human Exploration and Operations Missions Directorate (HEOMD), given NASA’s recent interest in NEAs and the martian moons as potential human destinations (Rivkin and Sykes, 2013). The action team organized the SKGs into four broad themes: (1) identify human mission targets; (2) understand how to work on and interact with the small-body surface; (3) understand the small-body environment and its potential risks/benefits to crew, systems, and operational assets; and (4) understand the small-body resource potential.

Each of these themes was further subdivided into categories to address specific SKG issues. Robotic reconnaissance missions should be able to address specific aspects related to SKG themes 1 through 4. Theme 1 deals with the identification of human mission targets within the NEA population. The current guideline indicates that human missions to fast-spinning, tumbling, or binary asteroids may be too risky to conduct successfully from an operational perspective. However, no spacecraft mission has been to any of these types of NEAs before, so further knowledge of objects with these attributes would be desired in order to fully understand the suite of potentially available targets for human exploration.

Theme 2 addresses the concerns about interacting on the small-body surface under microgravity conditions, and how the surface and/or subsurface properties affect or restrict the interaction for human exploration. A robotic precursor with remote sensing instruments combined with *in situ* payloads (e.g., rovers, landers, penetrators, impactors, etc.) will pro-

vide key insights into the asteroid's surface and near-surface physical properties. Knowledge of these physical properties is necessary in order to inform and develop the correct tools, instruments, and operational procedures required to fully investigate and explore the NEA safely and efficiently.

SKG theme 3 deals with the environment in and around the small body that may present a nuisance or hazard to any assets operating in close proximity or on the surface of the NEA. Impact and surface experiments will help address issues related to particle size, particle longevity, internal structure, and the near-surface mechanical stability of the asteroid. Understanding or constraining these physical characteristics is important for mission planning given that multiple assets may be operating in the vicinity of the NEA. It would be useful to identify those characteristics that could result in nonbenign failure modes that would jeopardize the mission and/or crew.

Theme 4 addresses the resource potential of small bodies. This is a particularly important aspect of human exploration since the identification and utilization of resources is a key aspect for deep-space mission architectures to the martian system and other destinations. There is good evidence from the analysis of meteorite samples and remote sensing data that a significant number of NEAs may contain useful resources (e.g., water and volatile materials). Identification of such resources, their locations, and their relative accessibility with respect to NEAs is something that could be readily achieved through precursor spacecraft.

**6.1.3. Robotic precursors.** Robotic precursor reconnaissance of small bodies can provide a wealth of information relevant to the science of NEAs as well as planetary defense. However, such missions can also provide key insights into small-body SKGs and contribute to the overall success for human exploration missions to asteroids. Ideally, robotic precursor missions to potential NEA targets would be implemented since this would significantly reduce operational risk to the crewed mission. NEAs may have small satellite(s) or complex surface morphologies that may not be detectable from prior groundbased observations. These prior missions would be useful in identifying any potential hazards to the astronauts, their spacecraft, and any deployable assets/instruments. Such in-depth examinations by small robotic spacecraft would help identify the surface and interior physical characteristics of a potential NEA selected for study. A robotic precursor mission to an NEA would be akin to the Ranger and Surveyor probes that preceded the crewed Apollo missions. Knowledge of the NEA's gravitational field, shape, surface topography, and general composition would aid in planning for later proximity operations. Additionally, the information obtained about the NEA's basic physical characteristics would be crucial for planning operational activities, designing in-depth scientific/engineering investigations carried by the spacecraft and its astronauts, and identifying sites on the NEA for sample collection.

One of the more interesting aspects of employing a robotic precursor is its usefulness during crew activities at the NEA, and also after the crew departs the asteroid for the return to

Earth. During crew activities it can provide enhanced situational awareness and act as a communication relay for the crew and assets performing operations out of the line of sight. Once the crew departs the NEA, the robotic precursor could remain behind to observe a high kinetic energy experiment at the NEA to investigate cratering excavation and formation, ejecta processes, seismic propagation, interior composition, and momentum transfer [similar to the activities planned in 2022 by the NASA/ESA joint AIDA mission (see section 4.2.1)]. Such information would not only be extremely valuable in terms of science, but would also provide crucial data relevant for hazard mitigation and planetary defense. The precursor spacecraft could also continue to relay data from any science or engineering packages left on the surface of the NEA, while at the same time monitoring the asteroid and refining the orbital motion (e.g., Yarkovsky effect) and rotation rate changes [e.g., Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) effects] over time.

## 6.2. Human Near-Earth Asteroid Missions Beyond the Earth-Moon System

Human missions to NEAs would be the first human expeditions to interplanetary bodies beyond the Earth-Moon system and would prove useful for testing technologies required for human missions to Mars, Phobos and Deimos, and other solar system destinations. Current analyses of operational concepts suggest that stay times of 15 to 30 days may be possible at an NEA with total mission duration limits of 180 days or less. Hence these missions would undoubtedly provide a great deal of technical and engineering data on spacecraft operations for future human space exploration while simultaneously conducting detailed investigations of these primitive objects with instruments and equipment that exceed the mass and power capabilities delivered by robotic spacecraft. All these activities will be vital for refinement of resource characterization and identification as well as development of extraction and utilization technologies to be used on airless bodies under low- or microgravity conditions. In addition, gaining enhanced understanding of an NEA's geotechnical properties and its gross internal structure will assist in the development of hazard mitigation techniques for planetary defense.

The spacecraft would require several basic capabilities in order to complete the scientific and technical objectives of the mission. These would involve equipment and techniques supporting remote sensing, telerobotic operations, multiple crewmember EVAs, deployment/redeployment of surface experiment packages, and surface/subsurface sampling. Previous groundbased observations and precursor mission data of the target should have adequately characterized the surface and local space environment to reduce the risk to the crew, spacecraft, and other mission assets (e.g., EVA tools and equipment, science and engineering packages, etc.). Hence the majority of the operations should be able to take place in close proximity (approximately a few to several hundred meters) from the NEA. Such operations have been found

to be challenging for remotely controlled spacecraft due to round-trip light delay times of several tens of seconds or minutes, but should be much more tractable for the crew. Based on previous Apollo and space shuttle experience, the crew should be able to match the rotation of the NEA, or hover over its surface, while maintaining a stable attitude from which to conduct detailed investigations of the target.

One of the more attractive aspects of human missions to NEAs is having the ability to adapt to specific situations in real time, and adjust operations with much more flexibility than possible when operating a robotic spacecraft. Furthermore, a crewed mission would have the capability via EVA to precisely place, adjust, redeploy, and retrieve relatively small scientific or engineering packages on the surface. Packages such as remotely operated or autonomous rovers/hoppers could greatly increase the amount of data obtained, helping to refine site selection for subsequent sample collection and enhancing the diversity of samples to be collected from the surface. *In situ* experiments designed to test such technologies as surface anchors/tethers, drills/excavation equipment, or resource extraction equipment could also be deployed and recovered.

Arguably, the main scientific goal of such a mission would be to collect macroscopic samples from various terrains on the NEA's surface. The crew's ability to land, traverse the NEA, and collect the samples [e.g., the Muses Sea region or the Little Woomera terrain on asteroid Itokawa (*Fujiwara et al.*, 2006)] would bring a wealth of information on physical characteristics and geotechnical properties of the asteroid such as particle size, space weathering, composition, regolith depth, cohesion, compaction, density, and porosity. The flexibility of the crew's mobility during NEA proximity operations would enable sample collection in geological context to ensure that profiles (i.e., top, middle, and bottom) could be maintained. Intact samples of the optical surface would also be used to evaluate space weathering/surface alteration effects in a deep-space environment. In addition, supplemental telerobotic collection of samples from different or difficult to reach sites on the NEA could expand the sample suite. It would also be useful to identify and collect materials that may not be indigenous to the NEA, or that may have undergone alteration processes [i.e., black boulders on the surface of Itokawa (*Fujiwara et al.*, 2006)].

Another primary goal of this mission would be to investigate and determine the interior characteristics of the target NEA. This would place some constraints on the macroporosities that may be found among this population of objects and help scientists understand the impact history of the early solar system. Such investigations could be combined with a detailed examination of any features/structures associated with crater formation in microgravity environments (crater morphology, crater internal structures, fractures, ejecta movement/secondary impacts, effects of surface topography/curvature on crater morphology, etc.) to further refine impact physics models appropriate for these primitive objects and understand NEA internal structures. Active detonation of a kinetic energy experiment after deployment of a seismic

network would also serve to characterize the interior of the NEA while gaining insights into the effects of crater excavation. Such information also has important benefits for future hazard mitigation scenarios.

### 6.3. Recent and Current Analog Activities

Since the earliest days of the Apollo program, NASA has used analog activities to test operations and procedures at various levels of fidelity in order to gain understanding, under controlled and safe conditions, of operational requirements for future space operations. In more recent years, NASA has developed a variety of analog activities specific to future NEA operations.

**6.3.1. Neutral Buoyancy Lab (NBL).** NASA's Neutral Buoyancy Lab (NBL), located at the Sonny Carter Training Facility near Johnson Space Center, has been used to simulate nearly all of NASA's EVA activities since the inception of the shuttle program. Regarding potential crewed missions to NEAs, including ARM, the NBL has been used to test the speeds and accuracy with which astronauts may be able to collect samples under the microgravity conditions that will exist in the NEA environment. Astronauts conducted tests while attached to the end of a robotic arm that was translated at various rates across two simulated NEA surfaces. In the first instance astronauts had to target specific rock samples that were attached to a rock wall and place them into a sample bag either by hand or with a simulated collection tool. The second test involved a similar approach, but instead of targeting specific samples, the astronauts collected bulk regolith samples as they translated across the surface.

**6.3.2. NASA Extreme Environment Mission Operations (NEEMO).** The NASA Extreme Environment Missions Operation (NEEMO) is a program that sends astronauts, scientists, and engineers to live in Aquarius, currently the world's only permanent undersea research station, located approximately 3.5 miles off of Key Largo in Florida. To date, NEEMO has conducted operations lasting up to three weeks intended to simulate missions to the Moon, the martian system, and NEAs (*Chappell et al.*, 2013a,b). Astronaut crews have simulated three types of EVA: tethered, jetpack, and robotic arm attached to a submersible intended to represent a free-flying spacecraft. Additionally, crews have tested communication protocols that incorporate the signal delays that would occur between Mission Control and a spacecraft during missions to NEAs or the martian system.

**6.3.3. NASA Research and Technology Studies (RATS).** NASA's Research and Technology Studies (RATS) team runs simulations at both Johnson Space Center and selected remote environments, such as desert regions located in Arizona. In particular, RATS has simulated crew activity in rovers meant to represent small two-person excursion vehicles that would conduct *in situ* investigations during NEA missions (*Abercromby et al.*, 2013a,b). RATS has also employed a virtual reality wall displaying detailed images of Itokawa based on data supplied by Hayabusa; two crew members in the simulated excursion vehicle interacted with the reproduced

environment while communicating with a science officer, including the appropriate signal delay, back at Mission Control. The crew were able to “visit” various sites on Itokawa and simulate sample collection and instrument deployment.

## 7. SUMMARY

The collective human spaceflight experience of the Apollo, space shuttle, Salyut, Mir, and ISS programs underscores the world’s space agencies’ capability to meet operational challenges and solve problems in the space environment. Despite the current uncertainty surrounding the future of human exploration beyond LEO, humanity could be poised to execute historic missions of exploration and discovery by reaching for the resources and knowledge of NEAs, which are the nearest waypoints in interplanetary space. Such missions would represent humanity’s first forays beyond the Earth-Moon system and would pave the way for future missions to Mars and other solar system destinations (Fig. 13). Exploration of NEAs with robotic and human missions would also provide a wealth of information about the formation of the solar system and the Earth-Moon system, while simultaneously aiding the development of planetary defense strategies. The critical themes of exploration, science, resource utilization, and planetary defense are what make NEAs such intriguing and compelling future destinations for humanity.

Meteorites, general (*continued*)

- unequilibrated 636
- ureilites 269, 270, 584
- xenolith 749
- Meteorites, individual
- Acfer 094 24, 558
- Allan Hills (ALH) A81001 545
- Allende 29, 473, 479, 485, 545, 557
- Almahata Sitta (*see also* Asteroids, individual, 2008 TC<sub>3</sub>) 9, 28, 56, 253, 258, 265, 269, 627, 749, 763
- Angra dos Reis 545
- Benesov 270
- Bunburra Rockhole 57
- Campo del Cielo 749
- Carancas 749
- Chelyabinsk 8, 28, 57, 254, 265, 272, 275, 282, 326, 332, 747, 836, 837, 852
- parent body atmospheric fragmentation 272
- parent body mass and size 272
- Galim 270
- Grimsby 748
- Hoba 749
- Holbrook 747
- Kaidun 28, 271
- Kapoeta 741
- Maribo 271, 274, 282
- Neuschwanstein 271, 275
- Orgueil 274, 282, 501
- Park Forest 748
- Příbram 258, 271, 275
- Sainte Marguerite 475
- Semarkona 24, 558
- Sikhote-Alin 749
- Sutter's Mill 271, 274, 282, 651
- Tagish Lake 24, 54, 265, 271, 494, 640, 651, 748
- Meteoroid streams 281ff
- asteroidal, epsilon Pegasids 284
- evolution 283
- formation 283
- main belt asteroid source 284
- mass 288
- Meteoroids 9, 257ff, 281ff, 523, 719
- asteroidal 273
- atmosphere entry 258
- atmospheric flight 264, 265
- bulk density 259, 264
- dynamic data 265
- dynamic mass 262
- fragmentation 259, 262
- iron 264
- mass 262
- mass influx to Earth 281
- physical properties 272
- plasma 260
- production 719
- stony 264
- strength 259

- Meteors 257, 258, 281  
 observation 286
- Meter-sized barrier 478, 482
- Micrometeorites 9, 257  
 impact 599, 612
- Microporosity 5, 344, 347, 680, 687, 695, 706, 751
- Microporous structure 347
- Mid-infrared spectroscopy 6
- Mineralogical characterization 44
- Mineralogical modeling 248
- Minimoons 806
- Minimum orbit intersection distance (MOID) 863
- Minkowski stability 186
- Minor Planet Center (MPC) 95, 312, 801
- Missing dunite problem 28
- Missing mantle problem 28
- Mobile Asteroid Surface Scout (MASCOT) 9, 845
- Model production function (MPF) 731, 732, 740
- Modified Gaussian model (MGM) 49, 251, 627
