Nevertheless, it is also known that the outcome of a collision is influenced by the initial internal structure of the parent body and that, depending on the initial structure, the fragment size distribution may be more or less continuous. In order to check this, Michel et al. (2003, 2004) modeled parent bodies with an internal structure composed of different zones of voids and fractures, as if they had first been shattered during their collisional history before undergoing a major event leading to their disruption, as explained in section 3. The simulations of the Eunomia and Koronis family formations were redone using pre-shattered parent bodies (Michel et al., 2004), and the results were compared with those obtained using monolithic parent bodies. The best agreement was actually found with pre-shattered parent bodies. In particular, in the case of the Koronis family, an interesting result was obtained from these simulations, which may have important implications concerning the real family history. The size distribution obtained from the disruption of a pre-shattered parent body contains four largest fragments of approximately the same size, as can be seen in Fig. 1. This peculiar characteristic is shared by the real family, and has been a source of debate as it was assumed that a single collisional event cannot produce such a property (see Michel et al., 2004, for a discussion). Moreover, the simulation using a monolithic parent body did not result in such a distribution. It was then demonstrated numerically for the first time, by using a pre-shattered parent body, that these fragments can actually be produced by the original event, and therefore no subsequent mechanism needs to be invoked to form them, which would otherwise require a revision of the entire family history (Marzari et al., 1995). According to these results, which show that even old families

**Fig. 1.** Cumulative diameter distributions in log-log plots for the fragments of the simulated Koronis families. The plot on the left was obtained with a projectile colliding head-on, whereas an impact with an angle of incidence  $\theta$  equal to  $45^\circ$  gave rise to that on the right. Different symbols are used to distinguish between parent-body models. The plots also show the estimated sizes of the actual members down to the completeness limit (Tanga et al., 1999). Note that the simulations using a pre-shattered target reproduce the four nearly identical largest members.

may well have originated from pre-shattered parent bodies, it was concluded that most large objects in the present-day asteroid belt may well be pre-shattered or self-gravitating aggregates/rubble piles.

Constraints provided by the measured size distribution of family members can eliminate formation scenarios in numerical simulations. An interesting example is the Karin cluster, a small asteroid family identified by Nesvorný et al. (2002) that formed  $\sim 5.8$  m.y. ago in the outer main belt. The estimated size distribution for this family, when first identified, was fairly smooth and continuous over all sizes. In particular, there was no big gap between the size of the largest member of the family, (832) Karin, and that of the second-largest member, (4507) 1990 FV. Numerical simulations by Michel et al. (2003) indicated that the best match to the continuous size distribution was provided by the breakup of a pre-shattered or rubble-pile parent body. Simulations starting from a monolithic parent body, on the other hand, produced size distributions showing a large gap between the sizes of the largest and next-largest fragments. The finding that the parent body of the Karin cluster needed to be a rubble pile was actually consistent with its history. Specifically, the parent asteroid of the Karin cluster is thought to have been produced by an early disruptive collision that created the much larger Koronis family some 2–3 G.y. ago. According

to the results of Koronis family-formation simulations, the parent asteroid of the Karin cluster should have been formed as a rubble pile from Koronis family debris.

However, Nesvorný et al. (2006) later revised the definition of the Karin cluster. In particular, they found that the original second-largest identified member of the family, (4507) 1990 FV, is in fact a background asteroid with no relation whatsoever to the recent breakup at the origin of the Karin cluster. Once this body is removed from the cluster membership, a large gap opens between the size of the largest family member and smaller members, a distribution that is now best reproduced in simulation by starting with a monolithic parent body. This change in implication for the internal structure of the parent body shows the importance of having a reliable estimate of the actual size distribution of family members. However, in the case of the Karin cluster, this change is problematic because the parent body of the Karin cluster is expected to be a rubble pile, if it is an original fragment of the Koronis-forming event. A solution proposed by Nesvorný et al. (2006) is that the Karin cluster parent body was really formed by reaccumulation of smaller fragments during the Koronis family formation, as found in numerical simulations, but then was somehow consolidated into a more coherent body by various possible processes (lithification of regolith filling the interior, etc.). Another pos-

sibility is that in simulations, we are missing cases in which large intact fragments are created, so that the Karin cluster parent body could really have been a monolithic body. In fact, this systematic absence of large intact fragments in asteroid disruption simulations is often mentioned as a potential issue when discussing, for example, the internal structure of Eros, imaged by the Near Earth Asteroid Rendezvous (NEAR) Shoemaker spacecraft (see section 5.1).

A model of fragmentation adapted for microporous bodies (for a definition of microporosity, see the chapter by Jutzi et al. in this volume) has recently been implemented into an SPH hydrocode and tested against experiments on pumice targets (Jutzi et al., 2008, 2009). It then became possible to simulate the formation of asteroid families from a microporous parent body. A microporous structure is assumed to be appropriate for parent bodies of dark taxonomic type or primitive asteroid families. In effect, several pieces of evidence point to the presence of a high degree of porosity in asteroids belonging to the C-complex, such as the low bulk density ( $\approx 1.3 \text{ g cm}^{-3}$ ) estimated for some of them, for instance, the asteroid (253) Mathilde encountered by the NEAR Shoemaker spacecraft (Yeomans et al., 1997), and as inferred from meteorite analysis (Britt et al., 2006). This model adapted for microporous bodies was used to reproduce the formation of the Veritas family, which is classified as a dark-type family whose members have spectral characteristics of low-albedo, primitive bodies, from C to D taxonomic types (Di Martino et al., 1997). This family is located in the outer main belt and is named after its apparent largest constituent, the asteroid (490) Veritas. The family age was estimated by two independent studies to be quite young, around 8 m.y. (Nesvorný et al., 2003; Tsiganis et al., 2007). Therefore, current properties of the family may retain signatures of the catastrophic disruption event that formed it. Michel et al. (2011) investigated the formation of the Veritas family by numerical simulations of catastrophic disruption of a 140-km-diameter parent body, which was considered to be the size of the original family parent body, made of either porous or nonporous material. Pumice material properties were used for the porous body, while basalt material properties were used for the nonporous body. Not one of these simulations was able to produce satisfactorily the estimated size distribution of real family members. Previous studies devoted to either the dynamics or the spectral properties of the Veritas family treated (490) Veritas as a special object that may be disconnected from the family. Simulations of the Veritas family formation were then performed representing the family with all members except Veritas itself. For that case, the parent body was smaller (112 km in diameter), and a remarkable match was found between the simulation outcome, using a porous parent body, and the real family. Both the size distribution and the velocity dispersion of the real reduced family were reproduced, while the disruption of a nonporous parent body did not reproduce the observed properties very well (see Fig. 2). This finding was consistent with the C spectral type of family members, which suggests that the parent body was porous and showed the importance

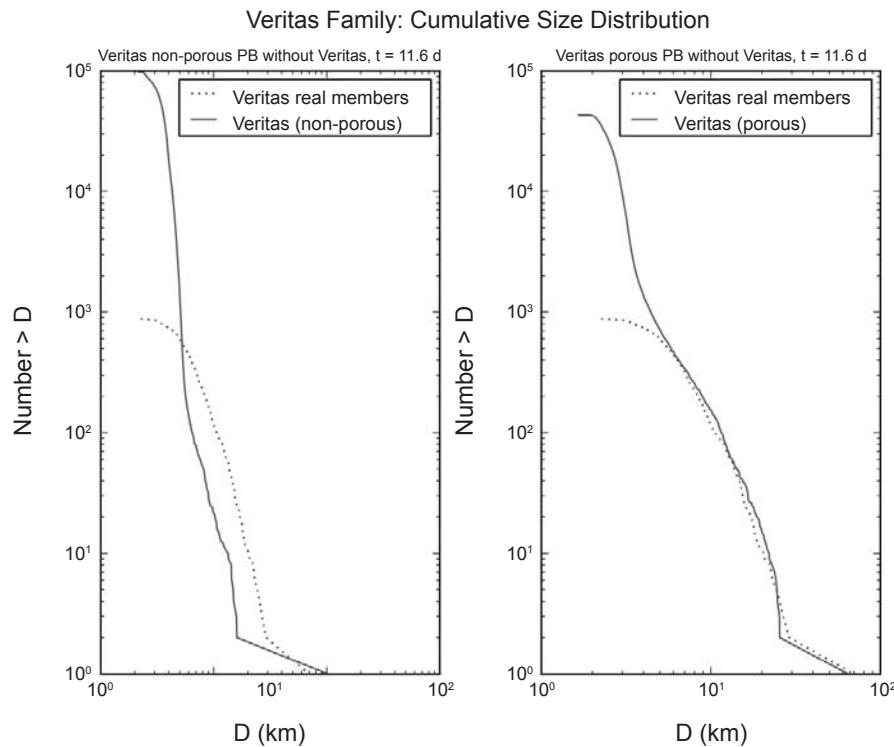

of modeling the effect of porosity in the fragmentation process. It was then concluded that it is very likely that the asteroid (490) Veritas and probably several other small members do not belong to the family as originally defined, and that the definition of this family should be revised. This example shows how numerical modeling can better constrain the definition of (or the belonging to) an asteroid family, provided that (1) the fragmentation model used to simulate its formation is consistent with the possible material properties of the parent body, and (2) the family is young enough that a direct comparison with the modeling is possible.

#### 4.2. The Ejection Velocity Distribution of Family Members

In addition to fragment sizes, numerical simulations also provide the ejection velocities. In general, impact simulations find that smaller fragments tend to have greater ejection speeds than larger ones. However, there is still a wide spread of values for fragments of a given mass, which makes it difficult to define a power-law relationship between fragment masses and speeds, such as the ones often used in collisional evolution models (see, e.g., Davis et al., 2002). Figure 3 shows an example of this relation for a simulation reproducing the Eunomia family as a result of the disruption of a monolithic (basalt-like) parent body impacted at an impact angle of 45°.

In the case of real asteroid families, however, the dispersion of their members is characterized through their orbital proper elements, in particular their proper semimajor axis, eccentricity, and inclination. These elements have long been assumed to be essentially constants of motion that remain practically unchanged over astronomically long timescales (e.g., Milani and Knezević, 1994), although some perturbations have been found to be capable of modifying them, as we will explain below. Thus, we do not have direct access to the ejection velocities of family members. Fortunately, ejection velocities can be converted into a dispersion in orbital elements through Gauss' equations (Zappalà et al., 1996), provided that both the true anomaly and the argument of perihelion of the family parent body at the impact instant are known or assumed. For a given family, the estimated values of the barycenter semimajor axis, eccentricity, and inclination can be used with the Gauss formulae up to first order in eccentricity to compute for each member the distance of its orbital elements  $\delta a$ ,  $\delta e$ , and  $\delta I$  from the barycenter of the family

$$\left\{ \begin{array}{l} \frac{\delta a}{a_b} = \frac{2}{na_b\sqrt{1-e_b^2}} [(1+e_b \cos f_0)V_T + e_b \sin f_0 V_R] \\ \delta e = \frac{\sqrt{1-e_b^2}}{na_b} \left[ \frac{e_b + 2 \cos f_0 + e_b \cos^2 f_0}{1+e_b \cos f_0} V_T + \sin f_0 V_R \right] \\ \delta I = \frac{\sqrt{1-e_b^2}}{na_b} \frac{\cos(\omega + f_0)}{1+e_b \cos f_0} V_W \end{array} \right. \quad (1)$$

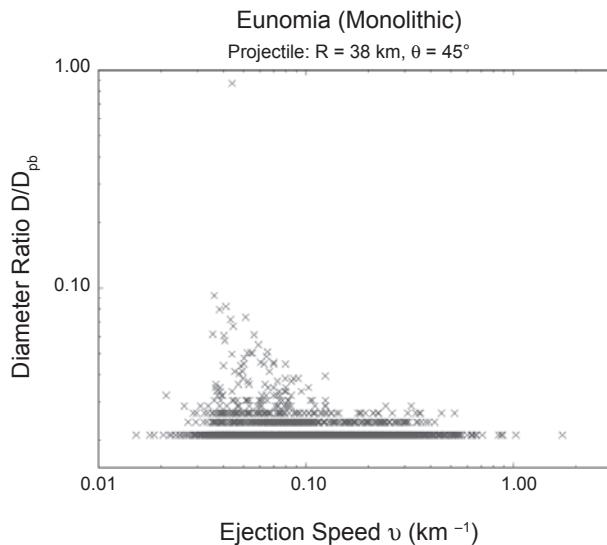

**Fig. 2.** Cumulative size distributions of fragments from the simulations of the disruption of a Veritas monolithic parent body, either nonporous (left) or porous (right). The impact angle is  $0^\circ$  (head-on) and the impact speed is  $5 \text{ km s}^{-1}$ . The distribution of the real family is also shown for comparison. In this case, the family consists of all members except Veritas itself, which reduces the size of the parent body to 112 km. The simulated time is about 11.6 d after the impact.

where  $V_T$ ,  $V_R$ , and  $V_W$  are the components of the ejection velocity in the along-track, radial, and out-of-plane directions, respectively,  $n$  is the mean motion,  $f_0$  is the true anomaly of the parent body at the instant of the breakup, and  $\omega$  is its argument of perihelion. Since these last two angles are not known, their values must be assumed. Zappalà *et al.* (1996) showed that the most sensitive angle is  $f_0$ . Assuming different values of this angle changes the shape of the cluster containing the family members in orbital element space. In other words, it defines whether the breakup generates a family that is spread in semimajor axis, in eccentricity, or in inclination.

Thanks to this conversion, it is thus possible to assess the realism of a numerical simulation of a family formation by comparing the dispersion of family members and simulated fragments in the same space. Unfortunately, other mechanisms exist that, depending on the age of the considered family, can obscure the original dispersion of family members. In fact, once a family is created, its members are subjected to various perturbations. In particular, high-order secular resonances, mean-motion resonances even involving multiple planets (Morbidelli and Nesvorný, 1999), and the Yarkovsky thermal effect (Farinella and Vokrouhlický, 1999) have been shown to be capable of altering the proper elements. Therefore, while proper elements have been assumed conventionally to retain the memory of the disruption

outcome conditions, these later studies demonstrated that this is not necessarily true, even for the proper semimajor axis in the case when the asteroid is small enough that Yarkovsky drift is effective (see Bottke *et al.*, 2002; chapter by Vokrouhlický *et al.* in this volume). Depending on how old the family is, the current proper elements of family members cannot be interpreted as reflecting their starting conditions; rather, they must be seen as a result of such secular processes acting over time, whose effects are to cause a slow diffusion of family members in orbital-element space, starting from a smaller dispersion. The Koronis family is a good example showing these effects. The current distribution of Koronis family members in proper-element space is quite spread and its shape suggests that it has been subjected to the Yarkovsky effect as well as to the effects of nearby secular resonances and mean-motion resonances. Bottke *et al.* (2001) computed the dynamical evolutions of 210 simulated Koronis family members under the influence of the Yarkovsky effect and dynamical diffusion due to several resonances (namely, the 5:2 and 7:3 mean-motion resonances with Jupiter, a secular resonance that involves the precession rate of the small body's longitude of perihelion  $g$  and the fundamental frequencies of Jupiter  $g_5$  and Saturn  $g_6$ ). The test family members were started with a dispersion that is consistent with the ones obtained from impact simulations of Koronis

**Fig. 3.** Fragment diameter  $D$  (normalized to that of the parent body  $D_{pb}$ ) vs. ejection speed in a log-log plot obtained from a monolithic Eunomia parent body simulation using a projectile impacting at an angle of incidence  $\theta = 45^\circ$ . Only fragments with size above the resolution limit (i.e., those that underwent at least one reaccumulation event) are shown here. From Michel et al. (2004).

family formation. They were integrated over 700 m.y., which is still shorter than the estimated age of the family ( $>1$  G.y.). However, this evolution showed that the current shape of the family cluster in proper-element space does not represent the original shape from the collisional event but is well explained by its subsequent evolution.

Fortunately, if a family is young enough, its dispersion can still be close to the original one resulting from the parent body breakup, and in that case, the comparison between numerical simulations of family formation and actual family dispersion is straightforward. On the other hand, the degree of spreading observed now, together with the knowledge of the degree of dispersion resulting directly from the breakup by numerical simulations, can better constrain the age of the family, once the efficiency of the diffusion processes is well assessed. Nesvorný et al. (2002, 2003) identified several asteroid families with formation ages smaller than 10 m.y. These families represent nearly the direct outcome of disruptive asteroid collisions, because the observed remnants of such recent breakups have apparently suffered limited dynamical and collisional erosion (Bottke et al., 2005). As already described in the previous section, the Karin cluster and the Veritas family belong to this group of young families.

Figure 4 shows an example in which the dispersion of the actual Veritas family is compared with that of fragments from an impact simulation of Veritas family formation. The simulated dispersion matches the shape of the ellipses representing the real dispersion. This result is consistent with the expectation that the orbital extent of the family is not produced by post-diffusion processes, which gives some cred-

ability to family-formation simulations that reproduce both the size distribution and velocity dispersion of actual members.

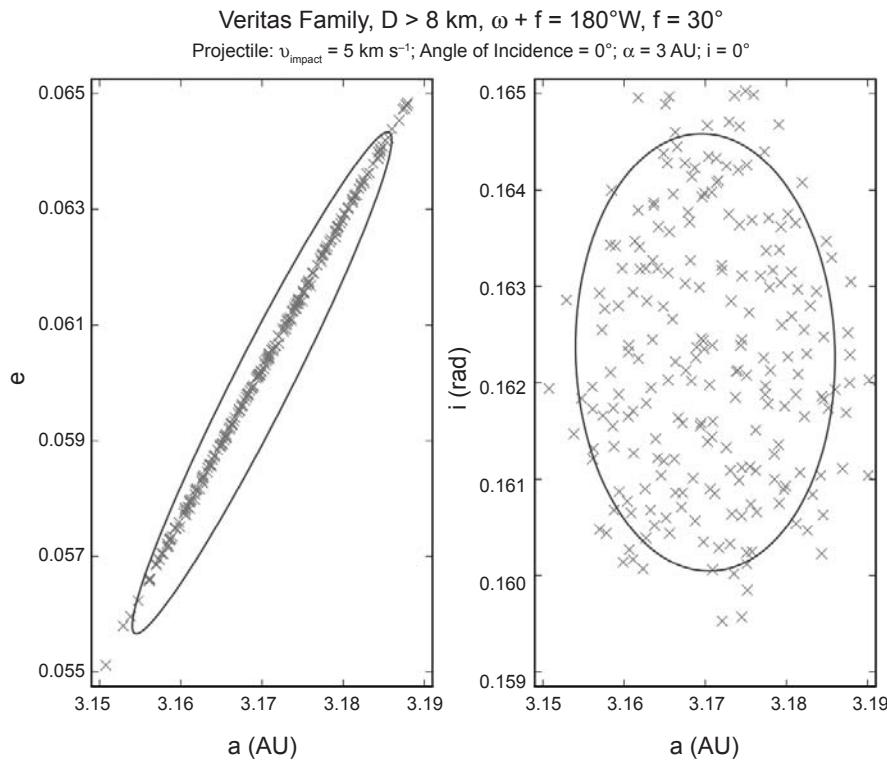

## 5. IMPLICATIONS

### 5.1. Internal Structure of Asteroids

According to numerical simulations of family formation, all fragments produced by the catastrophic disruption of a large asteroid (typically larger than 1 km in diameter, e.g., in the gravity regime) consist of self-gravitating aggregates, except the smallest ones. If this is correct, then most asteroids that are at least second generation should be rubble piles. We note that Campo Bagatin et al. (2001) ran a number of simulations of main-belt collisional evolution to assess the size range where reaccumulated bodies should be expected to be abundant in the main asteroid belt. They found that this diameter range goes from about 10 to 100 km, but may extend to smaller or larger bodies, depending on the prevailing collisional response parameters, such as the strength of the material, the strength scaling law, the fraction of kinetic energy of the impact transferred to the fragments, and the reaccumulation model.

The collisional lifetime of bodies larger than a few tens to hundreds of kilometers in diameter is longer than the age of the solar system, suggesting that most bodies in that size range are likely to be primordial, while smaller bodies are probably collisional fragments (see, e.g., Bottke et al., 2005, and the chapter by Bottke et al. in this volume). The exact size above which a body is more likely to be primordial is somewhat model-dependent. Binzel et al. (1989), from a study of light curves, suggested that this transition occurs at a diameter of  $\approx 125$  km. However, as this is a statistical measure, some smaller asteroids may still be primordial and some larger ones may have broken up in the past. In fact, due to the variability in possible interior starting compositions, and variations in the chaotic dynamics of accumulation, the size above which a body is more likely to be primordial is dependent on the specific formation scenario, as well as the compositions, masses, and velocities involved. Thus, some asteroids smaller than 100 km may still be primordial, and some larger ones may have broken up catastrophically in the past. This is especially true if one goes back to the very earliest formation, in the first few million years, when considering hit-and-run collisions (see the chapter by Asphaug et al. in this volume). These may have completely disrupted some of the largest asteroids, as projectiles, when they experienced grazing collisions into larger target embryos. This makes the internal structure of middle-sized asteroids one of the most important aspects of these bodies that can be determined by future space missions and observations, allowing us to test our interpretations based on theoretical collisional studies (see also the chapter by Scheeres et al. in this volume).

During the past 4 b.y., catastrophic disruption has been the result of hypervelocity collisions. Bottke et al. (2005) estimate that about 20 asteroid families have formed from the breakup of parent bodies larger than 100 km diameter over

**Fig. 4.** Distribution of fragments larger than 8 km from a simulation of disruption of a porous monolithic Veritas family parent body excluding Veritas itself as a result of a head-on impact of a projectile at  $5 \text{ km s}^{-1}$  with orbital semimajor axis  $a$  of 3 AU and inclination  $i$  of  $0^\circ$ . The outcome is represented in the  $a-e$  plane (left) and  $a-i$  plane (right). The superimposed ellipse is an equipartition curve for speed cutoff of  $40 \text{ m s}^{-1}$ , parent body true anomaly  $f = 30^\circ$  and argument of perihelion  $\omega = 150^\circ$ . This curve was defined by Tsiganis *et al.* (2007) as that closest to representing the dispersion of the real Veritas family in orbital element space. From Michel *et al.* (2011).

the last 4 b.y. But several hundred asteroids currently exist in the 100-km size range, making it likely that most of these are original bodies. In this regard, asteroid (21) Lutetia, approximately 90 km in diameter, is a scientifically important object of which we have obtained a quick glimpse during Rosetta's 2010 flyby (see the chapter by Barucci *et al.* in this volume). The relatively high measured mass (bulk density  $3.1 \text{ g cm}^{-3}$ ) led Weiss *et al.* (2012) to interpret Lutetia as being a partly differentiated, impact-shattered, but largely intact parent body, covered in a predominately chondritic outer component. Other interpretations are of course possible.

Assuming that the transition between primordial and second-generation bodies occurs at diameters  $\sim 100$  km, what about (433) Eros, whose diameter is much below this threshold and therefore should be a fragment of a larger body? There is still a debate about the internal structure of this asteroid, as the images of its surface can be explained by either a fractured (but solid/strength-dominated) structure or a rubble pile (Asphaug, 2009; chapter by Marchi *et al.* in this volume). However, if Eros is not a rubble pile, its formation as a fragment of a large asteroid would need a solution that is not yet found in numerical simulations of catastrophic disruptions.

Another point of view could thus be that it is a monolithic body that has been shattered in place (e.g., Housen, 2009; Buczkowski *et al.*, 2008). In this case, major impacts fracture it in place, introducing only modest increases to its porosity. This requires a very low strain rate of expansion, e.g., a small elastic strain at fracture, which may be consistent with size-dependent relationships for brittle failure. So this is probably feasible to form a shattered monolith when a single monolithic body is impacted, but with relatively low energy compared to disruption. But then one must ask, where did the single monolithic body come from to begin with, and why has it not been subsequently fragmented and jumbled by slightly more energetic collisions? The alternative is that the grooves have nothing to do with brittle failure, but are instead planes of granular failure.

Thus, so far, the formation of a dispersed cloud of sizable fragments (larger than a few hundreds of meters) systematically requires that the parent body is first fragmented into small pieces, down to the resolution limit of simulations (a few hundreds of meters), and then that gravitational reaccumulation takes place to form larger final remnants. This is probably what happened for (25143) Itokawa, which appears

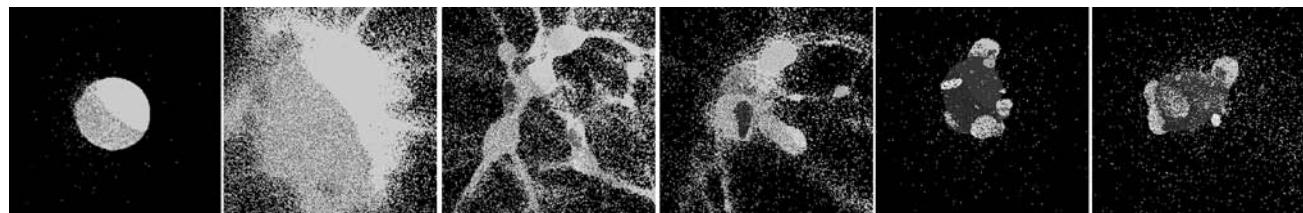

to be a rubble pile (*Fujiwara et al.*, 2006). In fact, if the major blocks on Itokawa were intact monolithic, then they would give us a kind of lower size range of intact fragments produced from large impacts. Using the version of *pckgrav* with enhanced collision handling to preserve shape and spin information of reaccumulated bodies (*Richardson et al.*, 2009), *Michel and Richardson* (2013) showed that the process of catastrophic disruption and gravitational reaccumulation can form fragments with shapes similar to that of Itokawa, and can explain the presence of a large amount of boulders on the surface, as observed. Figure 5 shows the outcome of such a simulation. We note that in this kind of modeling, the shapes of the aggregates formed by the reaccumulation process are parameter dependent. In particular, if we change the assumed strength of the aggregates or the bouncing coefficients (see *Michel and Richardson*, 2013, for a definition of these parameters), the final shape may be different. For instance, a preliminary simulation using a lower strength leads to a final largest aggregate that is more spherical. Because of the lower assumed strength, reaccumulating aggregates break more easily as a result of tidal and rotational forces, and therefore the object produced by this reaccumulation has difficulty keeping its irregular shape and instead becomes more and more rounded. Further studies are required to determine whether this type of outcome has some interesting implications, and to assess the actual sensitivity of the final shapes of reaccumulated objects to the parameters. It may be that we can provide some rough constraints on some of the mechanical properties of asteroids whose shapes are known, based on the parameters required to form them using this model. An extensive set of simulations that will require long runs with current computer power is planned for this purpose.

The production of rubble goes up with size, because it gets harder and harder (with increasing gravity) to liberate mass to escape speed than to beat it into small fragments that eventually can reaccumulate. The implication is that if Itokawa is a rubble pile, then Eros should be even more so. Whether this is in fact reality awaits direct seismic or internal-structure exploration (e.g., by radar tomography)

of objects Eros-sized and larger (see also the chapter by Scheeres et al. in this volume).

## 5.2. Compositions

Originally families were only identified on the basis of dynamical considerations. Then, once spectral observations became available, it was found that the vast majority of those families identified by dynamics showed remarkable homogeneous spectral properties (see the chapter by Masiero et al. in this volume). So, homogeneity in terms of spectral properties seems to be the norm. However, when an object satisfies the distance criterion to be associated with a family, it is often considered as an interloper when its spectral properties do not match. Therefore, the identification of family membership also relies on homogeneous spectral properties and whether the homogeneity in spectral properties is a reality, or an assumption is not yet clear. Such homogeneity can only be explained if the family parent body was homogenous itself, so that when fragments reaccumulate during the reaccumulation phase, there's no mixture of different materials taking place. Alternatively, it may also be that the reaccumulation process does not mix different materials that could be initially present in the parent body or mixes it so well that the outcome still looks homogeneous. Otherwise, if the parent body was heterogeneous in composition and if some mixtures happened, then the resulting family would show a variety of spectral properties within its members. In fact, if reaccumulation is a random process, we expect the particles of a given large fragment to originate from uncorrelated regions within the parent body. In that case, if the parent body was heterogeneous in composition, then the composition of reaccumulated fragments could be a mixture of various material. Conversely, if the initial velocity field imposed by the fragmentation process determines the reaccumulation phase, the particles belonging to the same fragment should originate from well-defined areas inside the parent body. In addition, the position and extent of these regions would provide indications about the mixing occurring as a result of the reaccumulation process.

**Fig. 5.** Snapshots of the reaccumulation process following the disruption of a 25-km-diameter asteroid. From left to right: first instant at the end of the fragmentation phase when all fragments (white dots) are about 200 m in diameter; the ejection of those fragments a few seconds later; the first reaccumulations that occur because of the slow relative speed between some fragments, showing the formation of a few aggregates represented by different gray levels; the formation of the largest fragment of this disruption by reaccumulation of several aggregates into a single body; and the final largest fragment shown at two different instants: The boulders on its surface and its overall shape are reminiscent of Itokawa. Credit: Michel and Richardson, A&A, 554, L1, 2013, reproduced with permission ©ESO.

*Michel et al.* (2004) traced back, at least for some of the largest fragments, the original positions within the parent body of the particles that end up forming the aggregates during some family formations. As an example, they traced the particles belonging to the three largest fragments of their simulation of the Koronis family formation back to their original positions inside the parent body. Recall that the Koronis family was formed in a highly catastrophic event, as its largest member is estimated to contain only 4% of the parent body's mass. In such an event, the reaccumulation process lasts up to several days, much longer than for a barely disruptive event, and gives rise to many gravitational encounters. Therefore, this kind of event may well lose the memory of the initial velocity field. Nevertheless, it was found that particles forming a large reaccumulated fragment originate from well-clustered regions within the parent body. This indicates that reaccumulation is definitely not a random process. Interestingly, the position of the original region depends greatly on the internal properties of the parent body. The largest remnant of the pre-shattered model of the Koronis parent body involves particles that were initially located between the core and the region antipodal to the impact point. Conversely, in the monolithic parent body, those particles were initially much more clustered in the core region, with no particles originating from the antipode. This difference also holds true for the next-largest fragments. Nevertheless, these results indicate that the velocity field arising from the fragmentation phase has a major influence on the reaccumulation process. Particles that eventually belong to a given fragment originate from the same region inside the parent body. However, this location (as well as its extent, which determines the degree of mixing of the fragments) depends also on the parent body's internal properties in a complex way. Recently *Michel et al.* (2015) looked at the cases of parent bodies with internal structures that could represent large asteroids formed early in solar system history. Some results are shown in the chapter by Jutzi et al. in this volume. They confirm that most particles in each reaccumulated fragment are sampled from the same original region within the parent body. However, they also found that the extent of the original region varies considerably depending on the internal structure of the parent body and seems to shrink with its solidity.

As a conclusion, the spectral homogeneity within a family may represent the material homogeneity of the initial parent body. It may also be due to the way reaccumulation takes place. But in that case, and if the parent body was heterogeneous, although each family member would still be homogeneous, we may expect different spectral properties from one member to another, depending on which original region of the parent body it samples. The fact that most families do not show strong spectral variations between family members, at least in the data from groundbased observations — except if this is imposed by the membership criterion — is consistent with the theory of homogeneity of the family parent body.

## 6. CONCLUSIONS

Our understanding of the collisional physics and our account for gravity in large asteroid disruptions have allowed numerical simulations to successfully reproduce the formation of asteroid families, in agreement with the idea that these families originate from the disruption of a large parent body. Simulation results indicate that asteroid family members are not just the product of the fragmentation of the parent body, leading to intact fragments, but rather the outcome of the subsequent gravitational phase of the event, which allows some of the intact fragments to reaccumulate and form gravitational aggregates, or rubble piles. For all considered cases so far (family parent bodies of diameter typically larger than tens of kilometers), this outcome is systematic for fragments larger than a few hundred meters. Thus, according to simulations, since it is believed that most bodies smaller than 100 km in diameter originate from the disruption of a larger body, then they should be rubble piles or heavily shattered bodies, which is consistent with the low measured bulk densities for some of them and the finding by *Campo Bagatin et al.* (2001) based on main-belt collisional evolution modeling. Therefore, exploring the origin of asteroid families unexpectedly led to a result that has great implications for the entire asteroid population and its history.

Moreover, it was also found that the outcome of a disruption is very sensitive to the original internal structure of the parent body, in particular the kind and amount of internal porosity. Thus, the comparison between simulation outcomes for various kinds of parent-body structures (monolithic, pre-shattered, microporous, rubble pile) and real family properties can help to constrain the internal properties of the parent body of the considered families and in the family identification itself. For instance, it was found that the Veritas family is very well reproduced if the asteroid Veritas itself is excluded from its family, which was already recognized as a possibility before disruption simulations were performed to model the formation of this family.

Thanks to the improved sensitivity of observations, allowing us to reach smaller asteroid sizes, and to the tools developed to better define asteroid families, new asteroid families keep being identified, especially small and young ones. The latter, which have not yet been affected by dynamical diffusion or post-collisional processes, are a good test for numerical simulations, which must be able to reproduce them as they are. Such an exercise, which has already been done successfully for some young families (e.g., Veritas, Karin), must keep being performed as a check for our numerical models. In particular, new fragmentation models are continuously being developed, accounting for various possible strength models and fragmentation modes. Once they are validated at small laboratory scales by comparison with impact experiments, they can be used at large scale (with an associated N-body code) to reproduce young family properties, allowing us to increase the range of internal

structures and fragmentation modes that can be considered for the parent body. This modeling work, calling for different models, is crucial to better constrain the possible internal structure of family parent bodies, to refine the definition of a family, and to understand whether some families are formed from differentiated/heterogeneous parent bodies, despite their apparent (or assumed) homogeneities. Asteroid families are very important tracers of the entire asteroid belt history and as we have already seen, our understanding of them can have profound implications on determination of the physical properties of asteroids in general.

More work is also required to check in which context large intact fragments can be produced in numerical simulations of large asteroid disruptions. Although there is no firm conclusion about Eros' internal structure, the fact that it may be a shattered object only and not a rubble pile raises the issue of the formation of such large fragments in a collision. It may also be that the reaccumulation process is followed by internal processes that may consolidate boulders. Such processes would eventually transform reaccumulated fragments into a coherent body. If this were the case, then reaccumulation would not necessarily imply a rubble-pile structure. Simulations of the reaccumulation phase now include the possibility of accounting for the final possible shapes of reaccumulated fragments. This modeling needs further improvement to increase its realism, but it will be very difficult, if even possible, to achieve the level of complexity needed to model the internal processes that may consolidate boulders. Asteroid internal processes are poorly understood and depend on too many parameters and unknowns.

Space missions dedicated to direct measurement of internal structures, and possibly to their response to an impact (e.g., by using a kinetic impactor), are thus crucial to improve our understanding of these important internal properties of asteroids and to check our modeling of the collisional and internal processes. Moreover, sample return missions as well as visits/flybys of members of asteroid families would also provide detailed information on their physical properties and would allow us to check whether groundbased measurements wash out some important data regarding their composition and possible variations among members. Asteroid families and the collisional process, which is at the heart of family formation and evolutionary main-belt history, rely on our efforts to combine complex models and space-/groundbased measurements.

---

In the past decade, the number of known binary near-Earth asteroids has more than quadrupled and the number of known large main-belt asteroids with satellites has doubled. Half a dozen triple asteroids have been discovered, and the previously unrecognized populations of asteroid pairs and small main-belt binaries have been identified. The current observational evidence confirms that small ( $\leq 20$  km) binaries form by rotational fission and establishes that the Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) effect powers the spin-up process. A unifying paradigm based on rotational fission and post-fission dynamics can explain the formation of small binaries, triples, and pairs. Large ( $\geq 20$  km) binaries with small satellites are most likely created during large collisions.

## 1. INTRODUCTION

### 1.1. Motivation

Multiple-asteroid systems are important because they represent a sizable fraction of the asteroid population and because they enable investigations of a number of properties and processes that are often difficult to probe by other means. The binaries, triples, and pairs inform us about a great variety of asteroid attributes, including physical, mechanical, and thermal properties, composition, interior structure, formation processes, and evolutionary processes.

Observations of binaries and triples provide the most powerful way of deriving reliable masses and densities for a large number of objects. The density measurements help us understand the composition and internal structure of minor planets. Binary systems offer opportunities to measure thermal and mechanical properties, which are generally poorly known.

The binary and triple systems within near-Earth asteroids (NEAs), main-belt asteroids (MBAs), and transneptunian objects (TNOs) exhibit a variety of formation mechanisms

(Merline et al., 2002c; Noll et al., 2008). As such, they provide an invaluable window on accretional, collisional, tidal, and radiative processes that are critical in planet formation. The distribution and configurations of the multiple-asteroid systems also provide a rich array of constraints on their environment, their formation, and their evolutionary pathways.

Observations rely primarily on groundbased telescopes and the Hubble Space Telescope (HST). For an up-to-date list of binaries and triples in the solar system, see Johnston (2014). We describe observational techniques only briefly because this material is available elsewhere (e.g., Merline et al., 2002c). A few emerging techniques will be described in more detail. Likewise, we refer the reader to other texts for an extensive history of the field (e.g., Merline et al., 2002c) and highlight only a few of the developments here.

### 1.2. History

Early search programs for asteroid satellites were unsuccessful, returning negative or dubious results, such that the authors of the *Asteroids II* review chapter chose the prudent title “Do asteroids have satellites?” (Weidenschilling et al.,

1989). The chapter provides an excellent discussion of the physics of several formation mechanisms that were postulated at the time. The perspective changed with the flyby of (243) Ida by the Galileo spacecraft in 1993 and the discovery of its small satellite Dactyl (Chapman *et al.*, 1995; Belton *et al.*, 1995). Groundbased efforts intensified and resulted in the discovery of a satellite around (45) Eugenia by Merline *et al.* (1999). Several other discoveries followed in rapid succession. The relatively small sizes of the MBA satellites suggested formation in subcatastrophic or catastrophic collisions (Durda, 1996; Doressoundiram *et al.*, 1997).

The discovery of MBA satellites, coupled with analysis of terrestrial doublet craters (Bottke and Melosh, 1996a,b) and anomalous lightcurve observations (Pravec and Hahn, 1997), suggested the existence of binary asteroids in the near-Earth population as well. The unambiguous detection of five NEA binaries by radar cemented this finding and indicated that NEA satellites form by a spin-up and rotational fission process (Margot *et al.*, 2002). Lightcurve observers reached the same conclusion independently (Pravec and Harris, 2007). Both radar and lightcurve observations revealed that, far from being rare, binary asteroids are relatively common (Pravec *et al.*, 1999, 2006; Margot *et al.*, 2002). By the time the *Asteroids III* review chapter was written, a more decisive title (“Asteroids do have satellites”) had become appropriate (Merline *et al.*, 2002c). This review focuses on the developments that followed the publication of *Asteroids III*.

### 1.3. Terminology

Two- and three-component asteroids that are gravitationally bound will be referred to as binary asteroids (or binaries) and triple asteroids (or triples), respectively. (Triple is favored over the more directly analogous terms trinary and ternary because of long-established usage in astronomy.) Asteroid pairs denote asteroid components that are genetically related but not gravitationally bound. Paired binaries or paired triples are asteroid pairs where the larger asteroid is itself a binary or triple asteroid. The larger component in binaries, triples, and pairs is referred to as the primary component or primary. The smaller component in binaries is referred to as the secondary component or secondary.

There has been some confusion in the literature about the meaning of the word “asynchronous.” Here, we adopt the terminology proposed by Margot (2010) and later implemented by Jacobson and Scheeres (2011b) and Fang and Margot (2012c). Binaries with an absence of spin-orbit synchronism are called asynchronous binaries. Binaries with a secondary spin period synchronized to the mutual orbit period are called synchronous binaries. Binaries with both primary and secondary spin periods synchronized to the mutual orbit period are called doubly synchronous binaries. If generalization to systems with more than one satellite is needed, we affix the terms synchronous and asynchronous to the satellites being considered.

It is useful to present results for small and large asteroids. We place an approximate dividing line at the size at which

objects are substantially affected by the Yarkovsky-O’Keefe-Radzievskii-Paddack (YORP) effect during their lifetime. For typical NEAs and MBAs, this dividing line corresponds to a diameter of about 20 km (Jacobson *et al.*, 2014a). We define very small asteroids as those with diameters of <200 m. This is the approximate size below which many asteroids are observed to spin faster than the disruption rate of a body with no shear or tensile strength  $\omega_d = \sqrt{4\pi\rho G/3}$ , where  $\rho$  is the density and  $G$  is the gravitational constant.

We use two additional acronyms. The YORP effect is a radiation-powered rotational acceleration mechanism for small asteroids (Rubincam, 2000). The binary YORP (BYORP) effect is a radiation-powered acceleration mechanism that may expand or contract the orbits of some synchronous asteroids (Čuk and Burns, 2005).

## 2. OBSERVATIONS

Several observational techniques are available for discovering, detecting, and studying binaries, triples, and pairs, each with its strengths and weaknesses. This section describes recent results and illustrates the complementarity of the observational techniques that characterize individual asteroid systems and entire populations.

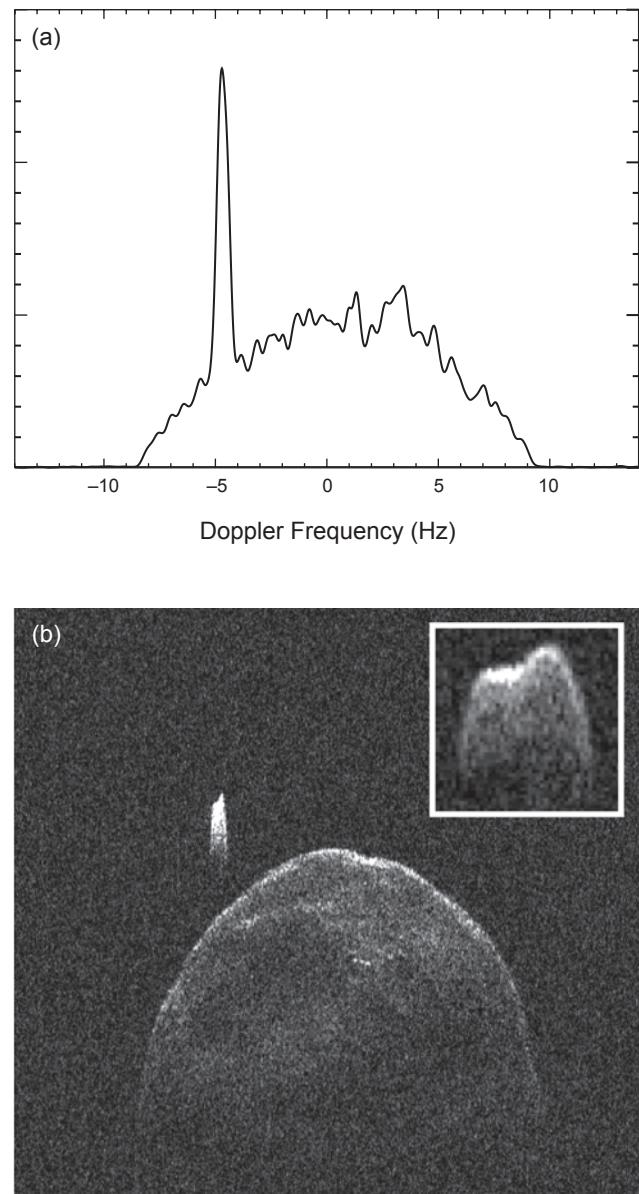

### 2.1. Radar Observations of Near-Earth Asteroid Systems

Radar has proven to be a powerful method of detecting secondaries to NEAs, enabling the discovery (as of September 2014) of the satellites in 71% of the 49 known multiple-component NEA systems, including 33 of 47 binaries and both undisputed triple systems. Of the 14 binary NEAs discovered via optical lightcurve techniques, 6 have been confirmed with follow-up radar observations during later apparitions. Overall, radar detections suggest that about one in six NEAs larger than 200 m in diameter are multiple-asteroid systems (Margot *et al.*, 2002; Taylor *et al.*, 2012a), although 200 m is not a sharp cutoff. Three binary NEA systems identified by radar have primary components with suggested diameters of 120 m to 180 m: 2003 SS<sub>84</sub> (Nolan *et al.*, 2003), (363599) 2004 FG<sub>11</sub> (Taylor *et al.*, 2012c), and 1994 CJ<sub>1</sub> (Taylor *et al.*, 2014). For comparison, the largest primaries of binary NEAs imaged with radar — (5143) Heracles (Taylor *et al.*, 2012b), the possible triple (276049) 2002 CE<sub>26</sub> (Shepard *et al.*, 2006), and (285263) 1998 QE<sub>2</sub> (Springmann *et al.*, 2014) — are more than an order of magnitude larger at >3 km in diameter. It is likely that ~8-km-diameter (1866) Sisyphus has a secondary based on analysis of frequency-only observations obtained on four separate dates in 1985 (S. Ostro, personal communication, 2001).

Radar observations can be used to detect asteroid satellites because of the ability to resolve the components of the system both spatially (along the observer’s line of sight) and in terms of frequency (due to Doppler shifts from the rotational and orbital line-of-sight velocities), resulting in

a measurable separation between the components in two dimensions. Direct detection of a satellite in frequency-only spectra or radar images typically occurs within one observing session and often within minutes of observation. The bandwidth of the echo of a component scales directly with the diameter and rotation rate. Thus, in a frequency-only experiment, the signal of the smaller, relatively slowly rotating satellite is condensed to a smaller bandwidth that is superimposed upon the broadband signal of the larger, often rapidly rotating, primary (Fig. 1a). Not all radar-observed binaries present this characteristic spectrum (e.g., where the secondary spins faster than the synchronous rate), but all are readily detected in radar images when the components are also resolved spatially (Fig. 1b). Because the spatial resolution achieved with radar instruments corresponds to an effective angular resolution of better than  $\sim 1$  milliarcsecond (mas), there is no bias against the detection of satellites orbiting very close to the primary component. Multiple measurements of the range and frequency separations of the components over days of sky motion provide the geometric leverage required to determine the orbit of the secondary around the primary. This can be done for any orbital orientation and yields the total system mass, a property that is difficult to estimate otherwise. Other techniques involve analyzing spacecraft flyby and orbit trajectories (e.g., Yeomans *et al.*, 1999), measuring the Yarkovsky orbital drift in conjunction with thermal properties (e.g., Chesley *et al.*, 2014), or observing the gravitational perturbations resulting from asteroid encounters (e.g., Hilton, 2002).

Most binary NEA systems observed to date have a rapidly rotating primary and a smaller secondary on the order of a few tenths the size of the primary (a secondary-to-primary mass ratio of roughly 0.001 to 0.1), whose rotation is synchronized to the mutual orbit period. The majority of primaries rotate in less than 2.8 h, although they range from 2.2593 h for (65803) Didymos (Pravec *et al.*, 2006) to 4.749 h for 1998 QE<sub>2</sub> (P. Pravec, personal communication, 2013). The known outlier is the nearly equal-mass binary (69230) Hermes, whose components both appear to have 13.894-h periods synchronized to their mutual orbit period (Margot *et al.*, 2006). This doubly synchronous configuration is most likely due to rapid tidal evolution (Taylor and Margot, 2011). While the rotations of satellites in NEA binaries tend to be tidally locked to their orbital mean motions with periods typically within a factor of 2 of 24 h (often resulting in the characteristic appearance shown in Fig. 1), about one in four radar-observed multiple-asteroid systems have an asynchronous satellite (Brozović *et al.*, 2011), all of which rotate faster than their orbital rate. Well-studied examples include (35107) 1991 VH (Naidu *et al.*, 2012), (153958) 2002 AM<sub>31</sub> (Taylor *et al.*, 2013), (311066) 2004 DC (Taylor *et al.*, 2008), and the outer satellites of both undisputed triple systems (153591) 2001 SN<sub>263</sub> (Nolan *et al.*, 2008; Fang *et al.*, 2011; Becker *et al.*, 2015) and (136617) 1994 CC (Brozović *et al.*, 2011; Fang *et al.*, 2011). Of the known asynchronous satellites, all have wide component separations ( $>7$  primary radii), translating to

**Fig. 1.** Binary near-Earth asteroid (285263) 1998 QE<sub>2</sub> as detected using the Arecibo planetary radar system. **(a)** In this frequency-only spectrum showing echo power as a function of Doppler frequency, the narrowband echo of the tidally locked secondary stands out against the broadband echo of the larger, faster-rotating primary. **(b)** In this radar image, the components are spatially resolved (7.5 m/pixel). The vertical axis represents distance from the observer increasing downward. The horizontal axis is Doppler frequency due to the orbital and rotational motion of the components. Note that if one summed the pixel values in each column of the image, the intensity as a function of Doppler frequency would approximate the spectrum above. The secondary is roughly one-fourth the size of the primary (measured in the vertical dimension), although the Doppler breadth of the primary gives the illusion of a greater size disparity. The shape of the secondary (inset on **(b)**) is distinctly nonspherical when viewed with finer frequency resolution.

longer-than-typical orbital periods, and/or eccentric orbits ( $>0.05$ ) that are either remnants of their formation mechanism or products of subsequent dynamical evolution (Fang and Margot, 2012c).

The shortest orbital periods detected with radar so far are those of Didymos and 2006 GY<sub>2</sub> with  $P_{\text{orb}} = 11.90^{+0.03}_{-0.02}$  h and  $11.7 \pm 0.2$  h, respectively (Benner et al., 2010; Brooks, 2006). For Didymos, the semimajor axis is  $a = 1.18^{+0.04}_{-0.02}$  km, just outside the classical fluid Roche limit of  $\sim 1$  km for equal-density components. Other systems with satellites orbiting near the Roche limit include 2002 CE<sub>26</sub> and 2001 SN<sub>263</sub>. The significance of this is unclear, as  $\sim 100$ -m secondaries with a cohesion comparable to comet regolith or sand can likely survive on orbits interior to the Roche limit (Taylor and Margot, 2010, and references therein).

Inversion of a series of radar images can provide a three-dimensional shape model and complete spin-state description given sufficient signal, resolution, and orientational coverage (Hudson, 1993; Magri et al., 2007). Shape reconstruction of the larger component of (66391) 1999 KW<sub>4</sub> (Ostro et al., 2006) demonstrated that the canonical shape of an NEA primary has a characteristic circular equatorial bulge, uniformly sloped sides, and polar flattening akin to a spinning top. Such a shape is shared by the primaries of 2004 DC, 1994 CC, 2001 SN<sub>263</sub>, and (185851) 2000 DP<sub>107</sub> (Naidu et al., 2015), although some primaries have less pronounced equatorial belts, e.g., 2002 CE<sub>26</sub> and 1998 QE<sub>2</sub>. Some single asteroids have a similar shape, e.g., (101955) Bennu (Nolan et al., 2013) and (341843) 2008 EV<sub>5</sub> (Busch et al., 2011), but do not have satellites, possibly because one has not yet formed or has been lost in the past. Shape model renditions are shown in the chapter by Benner et al. in this volume. Often the resolution of radar images of the smaller satellites is insufficient for shape inversion, but radar images suggest that the satellites are typically elongated, e.g., 2000 DP<sub>107</sub>, 1999 KW<sub>4</sub>, 2001 SN<sub>263</sub>, 1991 VH, and 1998 QE<sub>2</sub>.

Shapes and volumes obtained from inversion of radar images, combined with the system mass derived from the orbital motion observed in radar images, provide the density of the system (or of the individual components if the mass ratio is measurable from reflex motion). Low densities on the order of  $1 \text{ g cm}^{-3}$  (Shepard et al., 2006; Becker et al., 2015) to  $2 \text{ g cm}^{-3}$  (Ostro et al., 2006; Brozović et al., 2011) suggest significant internal macroporosity on the order of 50%, implying a rubble-pile internal structure for the components. At such low densities, the rapid rotation of the primary places particles along the equatorial belt in a near-weightless environment. The combination of rapid rotation, shape, and implied porosity and rubble-pile structure has implications for the formation mechanism of small multiple-asteroid systems (section 4).

While radar allows for direct, unambiguous detection of asteroid satellites, its range is limited. Because radar requires the transmission and reception of a signal, the strength of the received signal falls as the fourth power of the distance to the target and, thus, is best suited for detecting multiple-component systems passing within  $\sim 0.2$  astronomical units

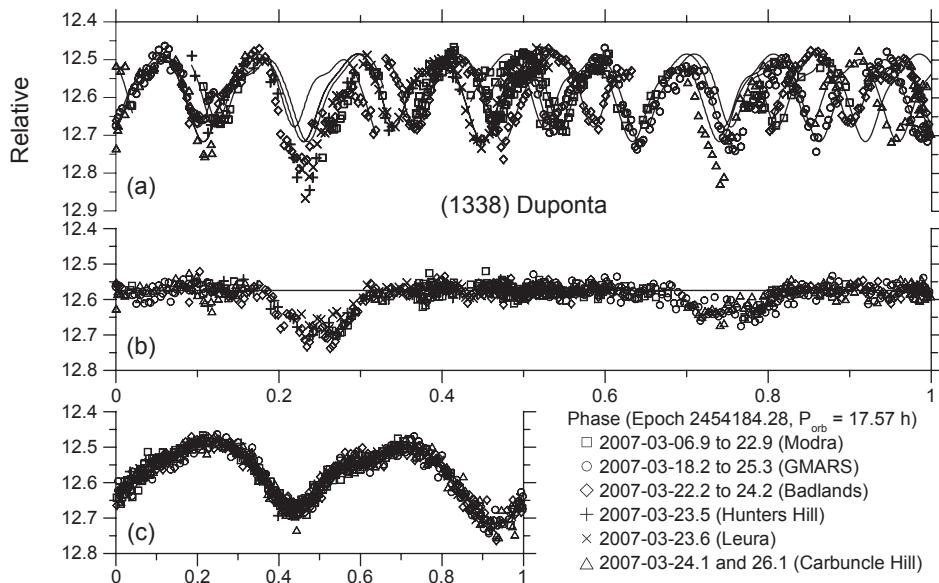

(AU) of Earth. Satellites in the main asteroid belt simply tend to be too small and too far away to detect with present radar capabilities and require application of different observational techniques.

## 2.2. Lightcurve Observations of Near-Earth-Asteroid and Small-Main-Belt-Asteroid Systems

A photometric lightcurve is a time series of measurements of the total brightness of an asteroid. Detections of binary asteroids by photometric lightcurve observations utilize the fact that the components can obscure or cast a shadow on one another, producing occultations or eclipses, respectively. The attenuations can be used to both reveal and characterize binaries (Fig. 2). The observational, analysis, and modeling techniques were described in Pravec et al. (2006), Scheirich and Pravec (2009), and Scheirich et al. (2015).

Early reports (Tedesco, 1979; Cellino et al., 1985) of asteroids suspected to be binaries on the basis of anomalous lightcurves [including (15) Eunomia, (39) Laetitia, (43) Ariadne, (44) Nysa, (49) Pales, (61) Danae, (63) Ausonia, (82) Alkmene, (171) Ophelia, and (192) Nausikaa] have remained largely unconfirmed despite extensive follow-up searches. The first serious candidate for detection with this technique was NEA (385186) 1994 AW<sub>1</sub> (Pravec and Hahn, 1997), whose binary nature was confirmed by photometric observations in 2008 (Birlan et al., 2010). Since 1997, nearly 100 binaries among NEAs and small MBAs have been detected with the photometric method. The binary asteroid database constructed by Pravec and Harris (2007) (<http://www.asu.cas.cz/~asteroid/binastdata.htm>) includes data for 86 MBA and NEA binaries that were securely detected by photometry and for which basic parameters have been derived, such as the primary spin period, the orbital period, and the primary-to-secondary mean diameter ratio. A few tens of additional MBAs and NEAs are suspected to be binaries and await confirmation with more detailed observations in the future.

Among the main findings obtained from photometric observations is that binary asteroids are ubiquitous. They have been found among NEAs and Mars-crossers (MCs), as well as throughout the main belt, both among asteroids that have been identified as family members and among asteroids that have not. Pravec et al. (2006) derived the fraction of binaries among NEAs larger than 300 m to be  $15 \pm 4\%$ . A binary fraction among MBAs has not been derived precisely due to less-well-characterized observational selection effects, but their photometric discovery rate is similar to the discovery rate of binaries among NEAs. Thus, binaries are suspected to be as frequent among MBAs as they are among NEAs. There appears to be an upper limit on the primary diameter for photometrically detected binaries of about 13 km; the largest detected binary is (939) Isberga with  $D_p = 13.4 \pm 1.3$  km (Carry et al., 2015). A lower size limit on the primary diameter  $D_p$  is less clear. The smallest detected binary is 2000 UG<sub>11</sub> with  $D_p = 0.26 \pm 0.03$  km (Pravec et al., 2006), but smaller binaries are known to exist (section 2.1). Their

**Fig. 2.** Lightcurve data of (1338) Duponta, which has a secondary-to-primary diameter ratio of about 0.24. (a) The original data showing both lightcurve components, folded with the orbit period. (b) The orbital lightcurve component, derived after subtraction of the primary lightcurve component, showing the mutual events between components of the binary system. (c) The primary lightcurve component. Figure from Pravec et al. (2012).

absence in lightcurve datasets may be due in part to a bias against detecting small binaries in the initial surveys.

Another key finding is that small binary asteroids have, with only two or three exceptions, a near-critical angular momentum content (Fig. 3). As shown by Pravec and Harris (2007), their angular momentum is consistent with formation by fission of critically spinning parent bodies of a cohesionless, rubble pile structure. The exceptions are the semi-wide systems (32039) 2000 JO<sub>23</sub> and (4951) Iwamoto, and possibly also (1717) Arlon, with orbital periods of 117 h to 360 h and supercritical total angular momentum content.

The orbital poles of main-belt binaries were found to have a highly anisotropic distribution, concentrating within 30° of the poles of the ecliptic (Pravec et al., 2012). The preferential orientations of the orbital poles suggest that their parent bodies or the primaries were tilted by the YORP effect toward the asymptotic spin states near obliquities 0° and 180°, consistent with observations of single asteroids (Hanuš et al., 2011).

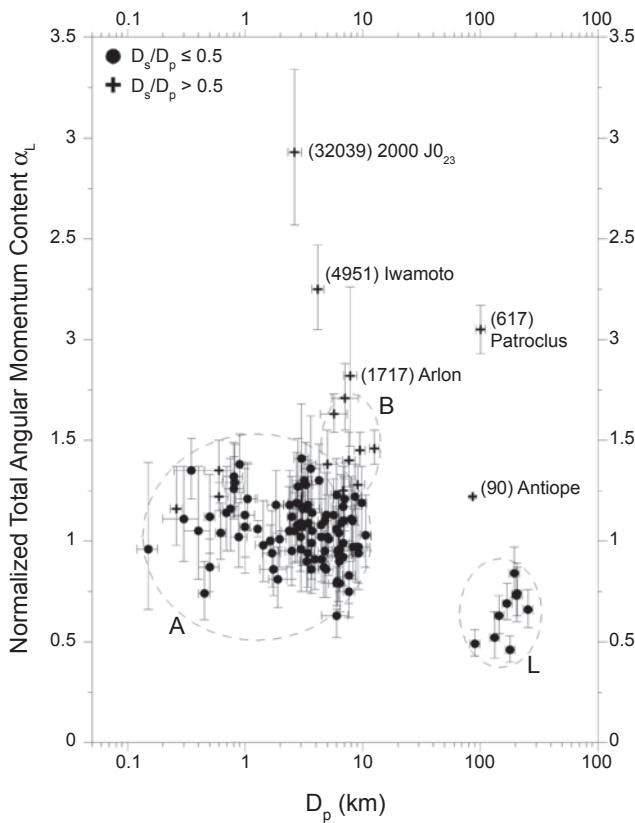

Another significant finding is that there appears to be a lower limit on the separation between components of binary systems of about  $a/D_p = 1.5$ , corresponding to an orbital period of 11–12 h for typical densities. Lightcurve observations indicate that the orbital period of Didymos is  $P_{\text{orb}} = 11.91 \pm 0.02$  h (Pravec et al., 2006), consistent with the radar estimate. This suggests an orbit close to the Roche limit for strengthless satellites (but see prior remark about orbits interior to the Roche limit).

Photometric observations of a binary system over multiple apparitions can be used to detect a change in the separation

of the components due to the effect on mutual event timing. An extensive set of photometric observations of the synchronous binary (175706) 1996 FG<sub>3</sub> obtained during 1996–2013 places an upper limit on the drift of its semimajor axis that is 1 order of magnitude less than estimated on the basis of the BYORP theory (Scheirich et al., 2015). This system may be in an equilibrium between BYORP and tidal torques, as proposed for synchronous binary asteroids by Jacobson and Scheeres (2011a).

Some datasets strongly suggest the presence of triple asteroids. In these cases, an additional rotational component that does not belong to the primary or the close eclipsing secondary is present in the lightcurve. This additional rotational component does not disappear during mutual events where the eclipsing close secondary is obscured by or in the shadow of the primary. Pravec et al. (2012) identified three such cases: (1830) Pogson, (2006) Polonskaya, and (2577) Litva. The latter has been confirmed by direct imaging observations of the third body (second satellite) on a wide orbit (Merline et al., 2013).

Other datasets reveal the existence of paired binaries/triples. Two such cases have been published: the pair composed of (3749) Balam and 2009 BR<sub>60</sub> (Vokrouhlický, 2009, and references therein) and the pair composed of (8306) Shoko and 2011 SR<sub>158</sub> (Pravec et al., 2013). Balam is a confirmed triple, with a distant satellite detected by direct imaging (Merline et al., 2002a) and a close satellite detected by lightcurve observations (Marchis et al., 2008d). Shoko is a suspected triple as well: Using lightcurve observations, Pravec et al. (2013) detected an eclipsing, synchronous close

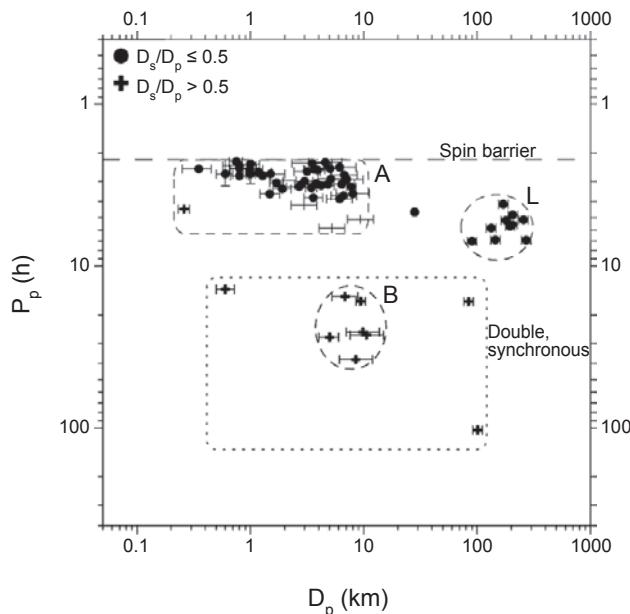

**Fig. 3.** Estimated values of the normalized total angular momentum content of binaries vs. primary diameter. The quantity  $\alpha_L$  is the sum of orbital and spin angular momenta normalized by the angular momentum of an equivalent sphere spinning at the critical disruption spin rate  $\omega_d = \sqrt{4\pi\rho G/3}$  where  $\rho$  is the density and  $G$  is the gravitational constant. In the Darwin notation,  $\alpha_L = 1$  corresponds to  $J/J' = 0.4$ . Group A contains small NEAs, MC, and MBA binaries. Group B consists of doubly synchronous small MBAs with nearly equal-sized components. Group L represents large MBAs with small satellites (section 2.5). Two exceptional cases are the doubly synchronous asteroids (90) Antiope and (617) Patroclus (section 2.5). Figure updated from Pravec and Harris (2007).

satellite with  $P_{\text{orb}} = 36.2$  h and a third rotational component attributed to an outer satellite.

While the population of binary NEAs and small MBAs is composed primarily of synchronous systems, and secondarily of asynchronous systems with low secondary-to-primary size ratios ( $D_s/D_p < 0.5$ ), doubly synchronous binaries with nearly equal-sized components also exist (Fig. 4). Nine such systems with  $D_s/D_p > 0.7$  and orbital periods between 15 h and 118 h have been reliably identified in the main belt (e.g., Behrend *et al.*, 2006; Kryszczyńska *et al.*, 2009) (see also the Pravec and Harris binary database described above).

Another important observation is that, with the exception of doubly synchronous systems, all binaries have unelongated, near-spheroidal primary shapes, as evidenced by their low primary amplitudes not exceeding 0.3 mag (when

**Fig. 4.** Primary rotation period vs. primary diameter. Groups A, B, and L are defined in the caption of Fig. 3. Three doubly synchronous asteroids with nearly equal-sized components lie isolated in the plot: (69230) Hermes on the left, and (90) Antiope and (617) Patroclus on the right of group B. Note that members of group A cluster near the disruption spin limit for strengthless bodies. Figure from Pravec and Harris (2007).

corrected to zero phase angle). This suggests that their primaries may have shapes similar to the top-like shapes that have been observed for 1999 KW<sub>4</sub> (Ostro *et al.*, 2006) and several other binaries by radar.

All the properties revealed by photometric observations indicate that binary systems among NEAs and small MBAs were formed from critically spinning cohesionless parent bodies, with YORP as the predominant spin-up mechanism. This finding is consistent with the fact that the observed 0.2–13-km size range of binaries corresponds to the size range where the spin barrier against asteroid rotations faster than about 2.2 h has been observed (e.g., Pravec *et al.*, 2007).

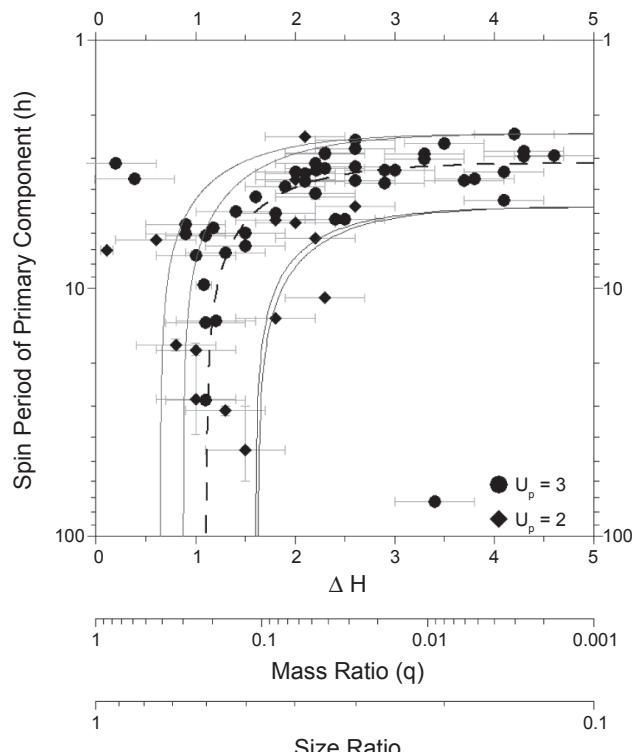

Although lightcurve observations provide powerful constraints on binaries, there are limitations. Detection of mutual events requires an edge-on geometry and observations at the time of the events, such that some binaries remain undetected [e.g., (69230) Hermes during its 2003 apparition]. Small satellites also escape detection because their effect on the lightcurve is not measurable (e.g., satellites with  $D_s/D_p \leq 0.17$  remain undetected if the minimum detectable relative brightness attenuation is  $\sim 0.03$  mag). The probability of mutual event detection is larger at smaller semimajor axes (expressed in units of primary radius) and at larger size ratios, resulting in observational biases (e.g., Pravec *et al.*, 2012). Finally, lightcurve observations yield relative, not absolute, measurements of orbital separations. Detection of small or distant secondaries and direct measurement of orbital separation must instead rely on other observational techniques.

### 2.3. Lightcurve Observations of Asteroid Pairs

*Vokrouhlický and Nesvorný* (2008) reported evidence for pairs of MBAs with bodies in each pair having nearly identical heliocentric orbits. Because chance associations can be ruled out, the asteroids in each pair must be genetically related. Quantifying the difference in orbital parameters is accomplished with a metric  $d$  that corresponds roughly to the relative velocity between the bodies at close encounter. *Vokrouhlický and Nesvorný* identified 44 asteroid pairs (excluding family members) with a distance between the orbits of their components amounting to  $d < 10 \text{ m s}^{-1}$ . They showed that, when integrated backward in time, the orbits converge at a certain moment in the past with a physical distance much less than the radius of the Hill sphere and with a low relative velocity on the order of  $1 \text{ m s}^{-1}$ .

*Pravec and Vokrouhlický* (2009) developed a method to identify probable asteroid pairs by selecting candidate pairs with a similar distance criterion, then computing the probability that each candidate pair emerged as a result of a coincidence between two unrelated asteroids. They identified 72 probable asteroid pairs, reproducing most of the 44 previously known pairs. Most of the new candidates were later confirmed to be real pairs using backward integrations of their heliocentric orbits.

*Vokrouhlický and Nesvorný* (2008) proposed a few possible formation mechanisms for the asteroid pairs: collisional disruption, rotational fission, and splitting of unstable asteroid binaries. *Pravec et al.* (2010) conducted a survey of the rotational properties of asteroid pairs, and they found a strong correlation between the primary rotational periods and the secondary-to-primary mass ratio (Fig. 5). They showed that this correlation fits precisely with the predictions of a model by *Scheeres* (2007) in which a parent body with zero tensile strength undergoes rotational fission. The model predicts that primaries of low-mass-ratio pairs ( $q \leq 0.05$ ) have not had their spin substantially slowed down in the separation process and should rotate rapidly with frequencies close to the fission spin rate. The observed periods are between 2.4 and 5 h. Primaries of medium mass ratio pairs ( $q = 0.05$  to  $\sim 0.2$ ) have had their spin slowed down according to the model because a substantial amount of angular momentum was taken away by the escaped secondary. This trend is observed in the data (Fig. 5). Finally, high-mass-ratio pairs with  $q > 0.2$  should not exist, as the free energy in the protobinary system formed by rotational fission would be negative and the components would be unable to separate. Observations mostly corroborate this prediction: All 32 pairs in the sample of *Pravec et al.* (2010) were found to have a mass ratio  $\leq 0.2$ . However, an expanded photometric survey with 64 asteroid pairs observed between 2012 and the date of this writing reveals 3 pairs with high mass ratio ( $q > 0.5$ ). Their formation requires an additional supply of angular momentum. Another important finding by *Pravec et al.* (2010) is that the primaries of asteroid pairs have lightcurve amplitudes that imply shapes with a broad range of elongations; i.e., unlike the primaries of binaries (sec-

**Fig. 5.** Primary rotation periods vs. mass ratios of asteroid pairs. The mass ratio values were estimated from the differences between the absolute magnitudes of the pair components,  $\Delta H$ . Circles are data points with quality code rating  $U_p = 3$ , meaning a precise period determination. Diamonds are data points with  $U_p = 2$ , which are somewhat less certain estimates. Error bars are one standard deviation. The data match the predictions (curves) of a model of rotational fission with a few adjustable parameters. In the model,  $A_{\text{ini}}$  is the binary system's initial orbit semimajor axis,  $\alpha_L$  is the normalized total angular momentum of the system (Fig. 3), and  $a_p, b_p, c_p$  are the long, intermediate, and short axis of the dynamically equivalent equal mass ellipsoid of the primary. All models shown assume  $b_p/c_p = 1.2$ . The dashed curve shows the best-fit model with  $\alpha_L = 1.0$ ,  $a_p/b_p = 1.4$  and  $A_{\text{ini}}/b_p = 3$ . Solid curves represent upper and lower limiting cases with  $\alpha_L = 0.7$ – $1.2$ . Figure updated from *Pravec et al.* (2010).

tions 2.1 and 2.2), the primaries of asteroid pairs do not tend to be nearly spheroidal.

### 2.4. Spectral Observations of Asteroid Pairs

Colorimetric and spectral observations of about 20 asteroid pairs indicate that members of an asteroid pair generally have similar spectra (*Duddy et al.*, 2012, 2013; *Moskovitz*, 2012; *Polishook et al.*, 2014a; *Wolters et al.*, 2014). In some pairs, the authors observed subtle spectral differences between the components and attributed them to a larger amount of weathered material on the surface of the primary. In two pairs, they observed somewhat more significant spectral differences. For the pair (17198)–(229056), both *Duddy et al.* (2013) and

*Wolters et al.* (2014) found that the primary is redder, i.e., it has a somewhat higher spectral slope than the secondary in the observed spectral range 0.5–0.9  $\mu\text{m}$ . It is unclear why their spectra differ despite a strong dynamical link between the two asteroids. For the pair (19289)–(278067), *Wolters et al.* (2014) observed a spectral difference similar to that seen in (17198)–(229056), but *Duddy et al.* (2013) observed very similar spectra. Cross-validation of the methods or additional observations, perhaps rotationally resolved, are needed to resolve the discrepancy.

## 2.5. Direct Imaging of Main-Belt-Asteroid and Trojan Systems

Direct imaging of asteroids can reveal the presence of satellites and, following the long tradition of orbit determination of binary stars and planetary satellites, lead to estimates of orbital parameters (Fig. 6). This observing mode remains challenging because the satellites are generally much smaller and fainter than their respective primaries and because most satellites known to date orbit at angular separations below 1 arcsec. Satellite discoveries have therefore followed the development of adaptive optics (AO), and recent advances have enabled the detection of asteroid satellites that had remained undetected in prior searches.

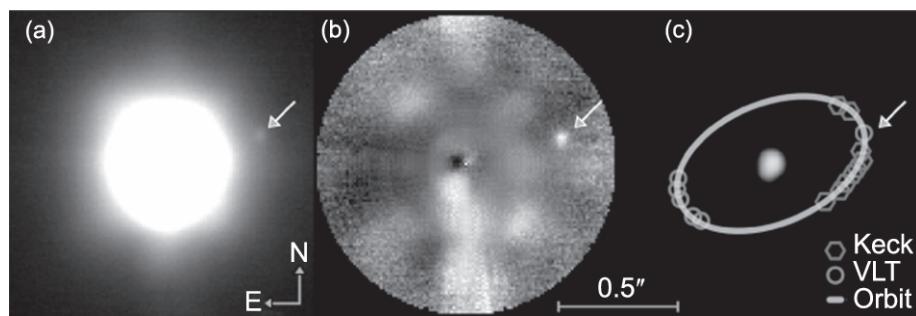

Instruments must have sufficient contrast and resolving power to detect asteroid satellites with direct imaging. For a 50–100-km-diameter asteroid in the main belt orbited by a satellite a few kilometers across, the typical angular separation is generally less than an arcsecond with a contrast of 5–10 mag [computed as  $2.5 \log(F_p/F_s)$ , where  $F$  is the flux and  $p$  and  $s$  indicate primary and secondary, respectively].

In some situations, direct images can actually resolve the primary. A 50–100-km-diameter asteroid at 2 AU subtends 34–68 mas while the diffraction limit of a 10-m telescope at a typical imaging wavelength of 1.2  $\mu\text{m}$  is about 30 mas. Although the diffraction limit is not reached, it can be approached with high-performance AO instruments in excellent

conditions. With a sequence of disk-resolved images that provide sufficient orientational coverage, it is possible to estimate the three-dimensional shape of the primary. This enables volume and density determinations.

Instruments capable of meeting the contrast and resolution requirements include HST and large (10-m-class) ground-based telescopes equipped with AO. Spacecraft encounters provide an opportunity to detect small satellites at small separations because of proximity to the target and the absence of the point-spread-function halo that affects groundbased AO instruments.

At the time *Asteroids III* was published, MBA satellite discoveries included one by spacecraft [(243) Ida], one by HST [(107) Camilla], and six by groundbased AO instruments. Since then, groundbased AO instruments have been responsible for almost all large MBA satellite discoveries: (121) Hermione (*Merline et al.*, 2002b), (379) Huenna (*Margot*, 2003), (130) Elektra (*Merline et al.*, 2003c), a second satellite to (87) Sylvia (*Marchis et al.*, 2005b) and to (45) Eugenia (*Marchis et al.*, 2007), (702) Alauda (*Rojo and Margot*, 2007), (41) Daphne (*Conrad et al.*, 2008), two satellites to (216) Kleopatra (*Marchis et al.*, 2008b) and (93) Minerva (*Marchis et al.*, 2009), and (317) Roxane (*Merline et al.*, 2009). The wide binaries (1509) Esclangona (*Merline et al.*, 2003a) and (4674) Pauling (*Merline et al.*, 2004), which are small asteroids in our classification, have also been identified using AO-fed cameras. HST enabled detections of two additional wide binaries: (22899) 1999 TO<sub>14</sub> (*Merline et al.*, 2003b) and (17246) 2000 GL<sub>74</sub> (*Tamblyn et al.*, 2004), both of which are small MBAs. No satellites have been discovered around any of the seven asteroids recently visited by spacecraft: (4) Vesta, (21) Lutetia, (2867) Šteins, (4179) Toutatis, (5535) Annefrank, (25143) Itokawa, and (132524) APL. The number of known large MBAs with satellites is now 16, which includes the only known large doubly synchronous system, (90) Antiope (*Merline et al.*, 2000; *Michałowski et al.*, 2004; *Descamps et al.*, 2007, 2009). The fraction of large MBAs with satellites is difficult

**Fig. 6.** Satellite detection by direct imaging with adaptive optics (AO). **(a)** Image of asteroid (41) Daphne ( $V_{\text{mag}} = 10$ ) obtained with a groundbased AO-fed camera (NACO at ESO VLT, 5 s exposure). **(b)** Same image after subtraction of the flux from the primary, enabling more accurate measurements of the flux and position of the secondary. **(c)** Orbit determination. The relative positions of the satellite from VLT/NACO and Keck/NIRC2 images are indicated. Figure adapted from *Carry* (2009).

to estimate because of a complex dependence of satellite detectability on primary-to-secondary angular separation and primary-to-secondary flux ratio. However, because several independent programs have surveyed more than 300 large MBAs, it is likely that the abundance of binaries in large MBAs is substantially smaller than the ~16% abundance in NEAs and small MBAs.

Properties of large MBA binaries and triples are summarized in Figs. 7 and 8. With the exception of the nearly equal-mass binary (90) Antiope, the known satellites have secondary-to-primary mass ratios between  $10^{-6}$  and  $10^{-2}$ . All have orbital periods between 1 and 5.5 d, except (379) Huen-na, whose orbit has a period of ~88 d and an eccentricity of ~0.2 (Marchis et al., 2008c). Many orbits have near-zero eccentricity (e.g., Marchis et al., 2008a), likely the result of tidal damping, but the inner satellites of triples generally have nonzero eccentricities. These eccentricities may have originated when orbits crossed mean-motion resonances while tidally expanding (e.g., Fang et al., 2012).

At first glance, large MBA densities appear to cluster in two groups, between 1 and 2 g cm<sup>-3</sup> and above 3 g cm<sup>-3</sup>. However, interpretations are limited by the possibility of systematic errors, including overestimates of volumes and underestimates of densities (Pravec and Harris, 2007). Because volume uncertainties almost always dominate the error budget for binary asteroid densities (e.g., Merline et al., 2002c; Carry, 2012), it is important to assess the realism of uncertainties associated with volume determinations. Some published density values should be regarded with caution because overconfidence in the fractional uncertainty of volume estimates has led to underestimates of bulk density uncertainties. The platinum standard of an orbiting spacecraft yields densities with ~1% accuracy. The gold standard of radar observations where tens of images with hundreds or thousands of pixels per image are used to reconstruct a detailed three-dimensional shape model yields volumes (and densities) with ~10% accuracy. In contrast, AO images contain at most a few independent resolution cells of the target asteroid. Shape reconstructions based on AO images and/or lightcurve data may not routinely yield volume accuracies at the 10% level, although one analysis reached that level (Carry et al., 2012). In the absence of precise volume information, one might be tempted to infer bulk densities from the theory of fluid equilibrium shapes, but this approach is problematic (Holsapple, 2007; Harris et al., 2009).

In the Jupiter Trojan population, one satellite to (624) Hektor has been reported (Marchis et al., 2006b) since the discovery of the first Trojan satellite to (617) Patroclus (Merline et al., 2001). These are the only Trojans confirmed to have satellites in spite of several active search programs. The apparent low abundance of binary Trojans is intriguing and, if confirmed, may provide additional support for the idea that Jupiter Trojans originated in the transneptunian region (Morbidelli et al., 2005; Levison et al., 2009) where they experienced a different collisional environment than in the main belt of asteroids. (624) Hektor has a satellite in a ~3-d orbit that is eccentric (~0.3) and inclined (~50°) with respect

to Hektor's equator (Marchis et al., 2014). (617) Patroclus is unusual because it has two components of similar size in a relatively tight (~680 km) orbit, with a normalized total angular momentum exceeding that available from fission of a single parent body (Marchis et al., 2006a).

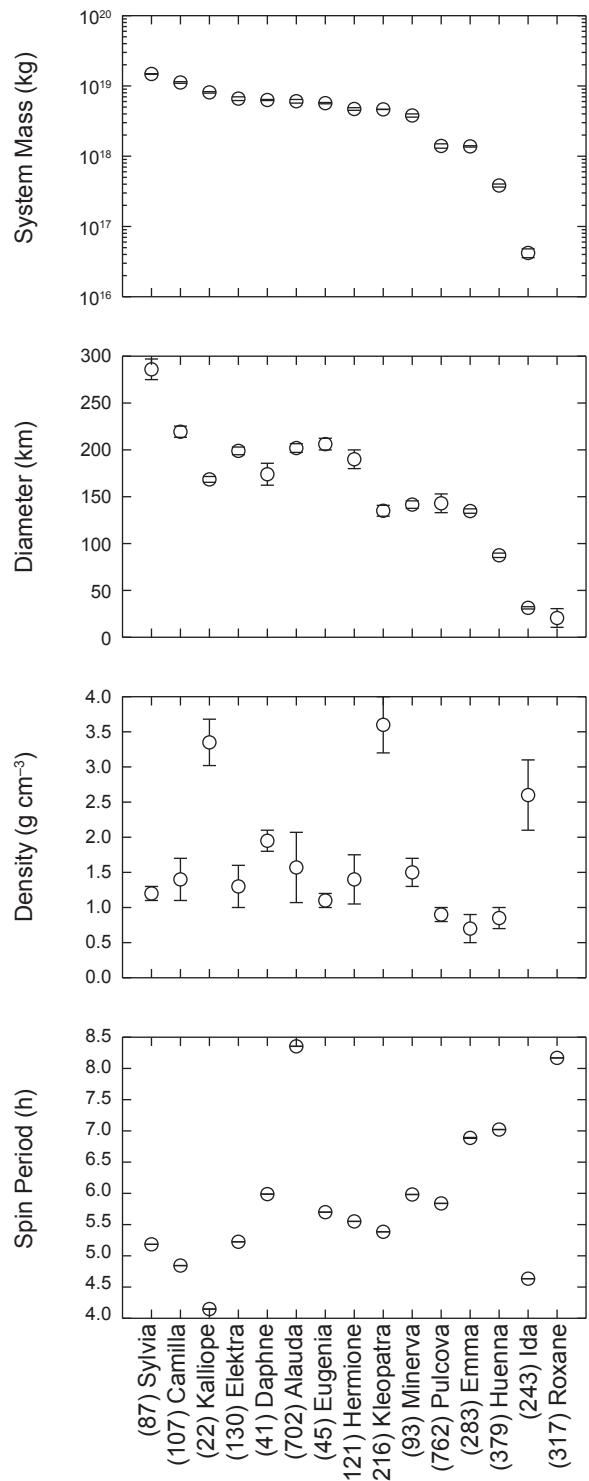

In the transneptunian region, 14 and 64 binary systems have been discovered with AO and HST, respectively (Johnston, 2014). The apparent larger abundance of binary TNOs in the cold classical belt may be due to a different dynamical environment and formation mechanism (section 5).

Objects in the Trojan and TNO populations are generally too faint for AO observations in natural guide star (NGS) mode, in which the science target is also used to measure the properties of the wavefront and command the deformable mirror. These objects can be observed in appulse when their sky position happens to be within  $\leq 1$  arcmin of a bright star. The advent of laser guide star (LGS) adaptive optics has been an important development that has freed the observer from finding such chance alignments and has opened up a larger fraction of the sky for observation of faint objects. Even with LGS, however, the availability of a tip-tilt star ( $R_{\text{mag}} \leq 18$ ) within  $\leq 1$  arcmin of the target is still required.

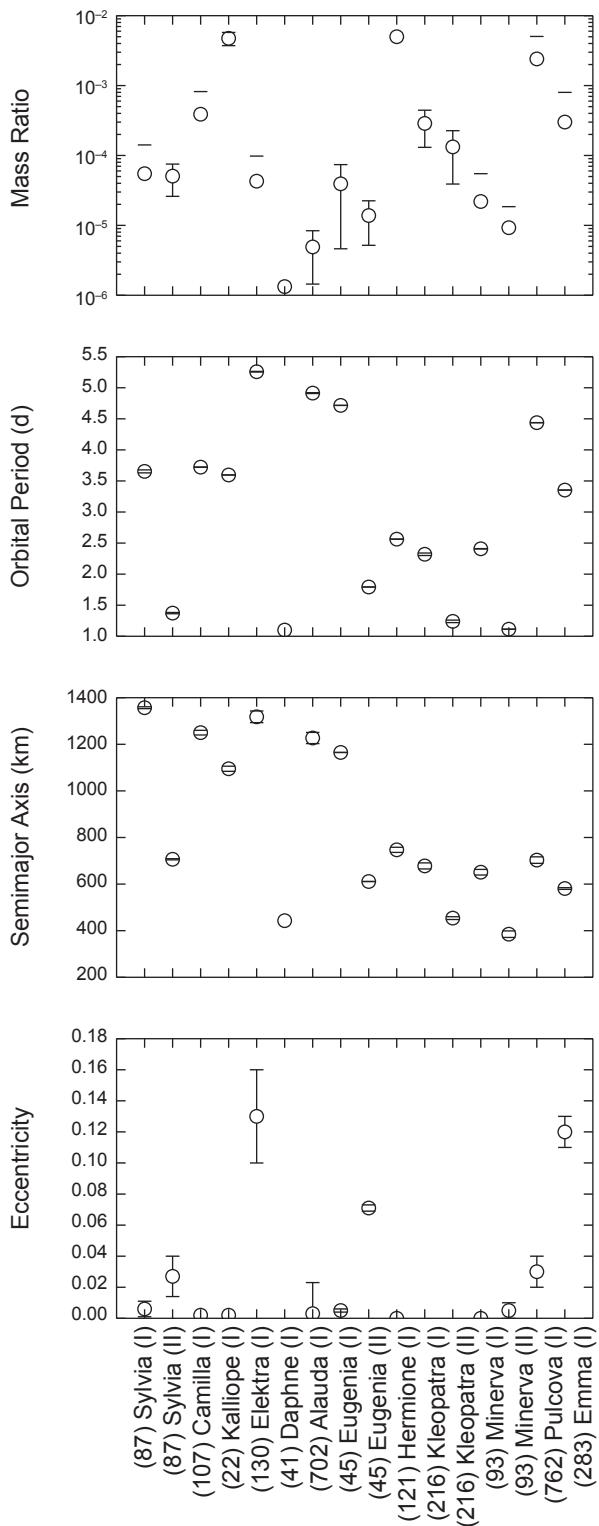

High-resolution and high-contrast imaging capabilities are aggressively sought by instrument builders, in part to enable direct imaging of exoplanets. Cameras equipped with high-performance AO are currently being installed or commissioned on large groundbased telescopes: the High-Contrast Coronographic Imager for Adaptive Optics (HiCIAO) on Subaru, Gemini Planet Imager (GPI) on Gemini, and Spectro-Polarimetric High-contrast Exoplanet REsearch (SPHERE) at the European Southern Observatory's (ESO) Very Large Telescope (VLT). These instruments will improve the ability to detect faint satellites orbiting close to their respective primaries. However, in most cases, asteroids fall in the faint-end range of these instrument capabilities. The next generation of large telescopes (~30 m diameter) such as the Thirty Meter Telescope (TMT) and European Extremely Large Telescope (E-ELT) will provide an improvement in sensitivity by a factor of ~10 and in angular resolution by a factor of ~3 compared to current 10-m telescopes. With the anticipated development of AO capabilities at shorter wavelengths, the second generation of instruments at these facilities is expected to provide improvements in angular resolution by a factor of ~5. Such instruments may allow detection of the small MBA binaries that are currently beyond the reach of direct imaging instruments. In many of these systems, the components are separated by only a few milliarcseconds and the size ratios are larger than in large MBA binaries, resulting in flux ratios closer to unity.

## 2.6. Spectral Observations of Main-Belt-Asteroid and Trojan Systems

It is generally difficult to separate the light emitted or reflected from the secondary from that of the brighter primary. Nevertheless, such observations can be attempted when the secondary happens to be at a large angular separation from

**Fig. 7.** Properties of large MBA binaries and triples, excluding the doubly synchronous (90) Antiope. Error bars or upper limits, when available, are shown. Based on data compiled by Johnston (2014) from references therein.

**Fig. 8.** Properties of satellites of large MBAs, excluding outliers (90) Antiope and (379) Huenna (see text). Satellites of (243) Ida and (317) Roxane, whose orbits are not well known, are not shown. Based on data compiled by Johnston (2014) from references therein.

the primary, when the system is undergoing mutual events, or with the help of an integral field spectrograph.

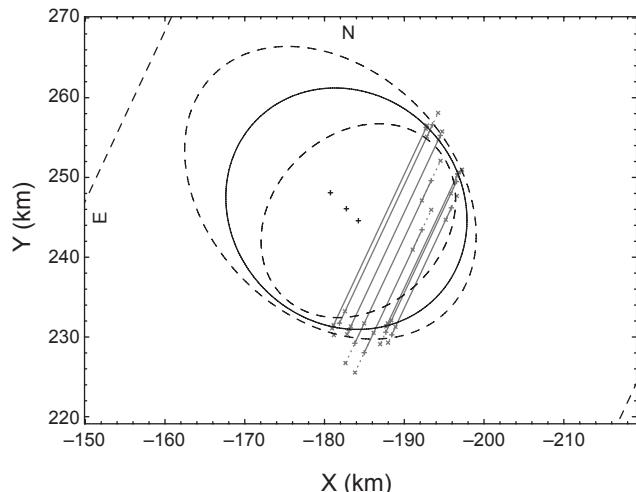

Spectra of (22) Kalliope and its satellite Linus in the 1–2.4- $\mu\text{m}$  region appear to be similar (Laver et al., 2009), which the authors attribute to satellite formation after a major impact on the precursor body. Observations of both components of (90) Antiope in the same spectral region also shows surface reflectances that are similar (Marchis et al., 2011). The spectrum of (379) Huenna is characteristic of C-type asteroids and the secondary does not exhibit a significantly different taxonomic type (DeMeo et al., 2011). Both components of (809) Lundia are consistent with a V-type classification (Birlan et al., 2014).

In the mid-infrared, Spitzer observations of the Trojan (617) Patroclus, including during mutual events, provided size estimates for its components and a thermal inertia of  $20 \pm 15 \text{ J s}^{-1/2} \text{ K}^{-1} \text{ m}^{-2}$  (Mueller et al., 2010). Spitzer observations combined with photometric results in the visible yielded size and albedo estimates for (624) Hektor (Emery et al., 2006). Spitzer observations did not resolve the binaries and results typically cannot be compared to observations that place many resolution elements on individual components. One exception is 2000 DP<sub>107</sub>, where analysis of Spitzer data yields a system density of  $0.9 \pm 0.3 \text{ g cm}^{-3}$  (Marchis et al., 2012) and the radar results indicate  $1.4 \pm 0.2 \text{ g cm}^{-3}$  (Naidu et al., 2015).

## 2.7. Stellar Occultations of Main-Belt-Asteroid and Trojan Systems

Stellar occultations provide a way of detecting components of a multiple-asteroid system, of placing bounds on component sizes, and of obtaining the relative positions of components on the plane of the sky. A recording of star light as a function of time shows a deep extinction when a target body crosses the line of sight between the observer and the star. This can be interpreted in terms of a chord on the apparent disk of the target body projected on the plane of the sky. If several observers are placed across the occultation path on the surface of Earth, multiple chords can be obtained, and the size and shape of the target projected on the sky can be reconstructed (Fig. 9). When two or more components are present, it is also possible to measure their relative position. While the reliability of this technique was disputed a decade ago due to the lack of digital recordings, the availability of low-cost cameras and global positioning systems has enabled a dramatic improvement in the precision of timing reports. Stellar occultations have become an important observational tool for the study of binary asteroids.

Early reports (e.g., Binzel and van Flandern, 1979) of asteroids suspected to be binaries on the basis of occultation data [including (3) Juno, (6) Hebe, (9) Metis, (12) Victoria, (18) Melpomene, (146) Lucina, and (532) Herculina] have remained largely unconfirmed despite extensive follow-up searches. However, it is likely that the outer satellite of (216) Kleopatra was detected during a 1980 occultation (Dunham, 1981; Descamps et al., 2011). The detection of a

**Fig. 9.** The apparent shape of Linus, a satellite of (22) Kalliope (Margot and Brown, 2003), detected by stellar occultations. In this analysis, the profile of the satellite (solid curve) fitted to the observed chords (straight lines) yields an equivalent diameter of  $30 \pm 6 \text{ km}$ . Dashed curves show the corresponding uncertainty of the fitted profile, and dashed lines show negative detections. Figure adapted from Desamps et al. (2008).

satellite around the Trojan (911) Agamemnon has been suggested (Timerson et al., 2013) but not yet confirmed. The occultation technique has also been used to detect rings around the Centaur (10199) Chariklo (Braga-Ribas et al., 2014).

One strength of the stellar occultation technique lies in the fact that the observability of the event depends mainly on the brightness of the star and not of the asteroid or satellite. Stellar occultations can thus be used to detect small (kilometer-sized) satellites, even those that are close to the primary and that would remain undetected in direct imaging.

Another strength of the technique is the potential for high-precision measurements. Stellar occultations are based on time-series photometry. Given a sufficiently high cadence (e.g., 10–30 images per second), it is possible to obtain a precision of a few milliarcseconds on the relative position of binary components, which is 5–10 times better than with direct imaging with current instrumentation.

Finally, well-sampled stellar occultations allow for recovery of the size and apparent shape of asteroids and their satellites, whereas optical lightcurves and direct imaging observations primarily provide the diameter ratio of the components and more limited shape information. So far, four successful observations of satellite size and shape have been reported: Linus, satellite of (22) Kalliope (Desamps et al., 2008); Romulus, the outer satellite of (87) Sylvia (Berthier et al., 2014); and both components of the equal-sized binaries (90) Antiope (Bartczak et al., 2014) and (617) Patroclus (Buie et al., 2014).

Despite all these strengths, there remains a relatively low number of well-covered stellar occultation events. This is due, in part, to the requirement of successful observations at

many stations. Owing to uncertainties on both the star and asteroid positions, the occultation path can shift by several tens or even hundreds of kilometers on Earth compared to the prediction. Observers must therefore spread geographically to cover an event, but the detection of a satellite by several stations requires a fine grid of observers.

The situation is, however, expected to improve dramatically with the availability of the Gaia stellar catalog and better asteroid orbits (Tanga and Delbo, 2007). Predictions of the occultation paths (for the center of mass) will be accurate to a few kilometers, and the main source of uncertainty will become the prediction of the relative position of the satellite around the primary.

## 2.8. Other Observations

There have been several attempts to use groundbased interferometers to measure the angular separation of binary systems (Delbo et al., 2009; Carry et al., 2015). However, asteroid satellites are too faint for current interferometers operating in the visible and near-infrared and at the edge of detection in the mid-infrared. Future instrumentation may allow such observations. There are also prospects for observations with the Atacama Large Millimeter Array (ALMA) submillimeter array (Busch, 2009).

## 3. DYNAMICS

In parallel with advances in instrumentation and observing capabilities, the field has seen tremendous developments in understanding the dynamical processes that affect asteroid systems. This has been enabled in large part by the availability of detailed shape models and orbital parameters, by the need to model the dynamics of newly discovered triple systems, and by the desire to understand formation and evolution processes.

A non-exhaustive list of some dynamical problems that have been explored since *Asteroids III* includes the stability of asteroid satellite orbits (Scheeres, 2002; Frouard and Compère, 2012); the dynamics around triaxial bodies (Scheeres, 2009a); the fate of asteroid ejecta (Scheeres, 2007); the formation of contact binaries via dynamical evolution (Scheeres, 2009a; Taylor and Margot, 2011, 2014); the genesis of eccentric and mutually inclined orbits (Fang et al., 2011; Fang and Margot, 2012c); the orbital determination of triple systems using point-mass approximations (Marchis et al., 2010) and full N-body calculations (Fang et al., 2012); the influence of Kozai cycles on binaries (Perets and Naoz, 2009; Fang and Margot, 2012b); the effects of close planetary encounters on mutual orbits (Fang and Margot, 2012a) and spin states (Takahashi et al., 2013); the complex spin-orbit interactions with irregular component shapes (Scheeres et al., 2006), including the libration and irregular rotation of secondaries (Naidu and Margot, 2015); the influence of internal structure (Goldreich and Sari, 2009), material properties (Taylor and Margot, 2011), and nonspherical shapes (Taylor and Margot, 2014) on tidal evolution; the possibility of tidal saltation

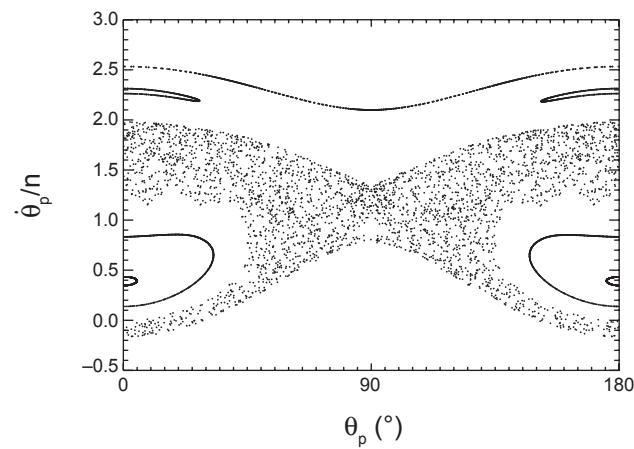

(Harris et al., 2009; Fahnestock and Scheeres, 2009); the possibility of significant radiative evolution (Ćuk and Burns, 2005; Ćuk, 2007; Ćuk and Nesvorný, 2010; McMahon and Scheeres, 2010a,b); and the possibility of a stable equilibrium between tidal and radiative evolution (Jacobson and Scheeres, 2011a).

Several radar datasets provide exquisite constraints for dynamical studies. Reflex motion has been measured for 2000 DP<sub>107</sub> (Margot et al., 2002; Naidu et al., 2015), 1999 KW<sub>4</sub> (Ostro et al., 2006), and 1991 VH (Naidu et al., 2012), allowing masses of individual components to be determined. Because detailed component shapes are also available, one can fully model the system dynamics and study spin-orbit coupling in detail (Scheeres et al., 2006; Fahnestock and Scheeres, 2008; Naidu and Margot, 2015). One finding from this work is that even moderately elongated secondaries on mildly eccentric orbits are likely to experience chaotic rotation that substantially affects binary evolution timescales (Fig. 10).

## 4. SMALL ASTEROIDS: SYNTHESIS

### 4.1. Rotational Fission Hypothesis

With the exception of the doubly synchronous binary asteroid systems, the primary asteroids of all small binary systems are rapidly rotating (within a factor of only a few of the critical disruption spin limit for bodies with no shear or tensile strength  $\omega_d = \sqrt{4\pi\rho G/3}$ ). Furthermore, almost all

**Fig. 10.** Surface of section plot showing the possible rotational regimes of the ~200 m secondary of 1991 VH (secondary elongation  $a/b = 1.5$  and mutual orbit eccentricity  $e = 0.05$ ). The plot shows the angle between the long axis and the line of apsides of the mutual orbit,  $\theta_p$ , against its time derivative,  $\dot{\theta}_p$ , normalized by the mean motion,  $n$ , at each pericenter passage. Five trajectories are illustrated (from top to bottom: nonresonant quasiperiodic, periodic, chaotic, periodic, periodic). While trapped in the sea of chaos, the secondary experiences torques on its permanent deformation that result in a highly variable spin rate, preventing BYORP-type evolution. Figure from Naidu and Margot (2015).

known small binary asteroids have high angular momentum contents (*Pravec and Harris*, 2007). These characteristics are not consistent with formation following a subcatastrophic impact, capture through a three-body interaction in the near-Earth or main belt, or capture after a catastrophic impact. Instead, they are indicative of formation from a rotational fission event (e.g., *Margot et al.*, 2002; *Pravec and Harris*, 2007). The rotational fission hypothesis posits that a parent asteroid can be torqued to a rotation rate so great that the centrifugal accelerations overpower the gravitational accelerations holding a strengthless asteroid together (*Weidenschilling*, 1980). It is possible that some small asteroids have cohesive or molecular strength in addition to self-gravity (e.g., *Rozitis et al.*, 2014). In these cases, the centrifugal accelerations must overcome these additional forces in order for the asteroid to fission (*Pravec and Harris*, 2000; *Sánchez and Scheeres*, 2014). At rapid rotation rates, loose surface material can flow from high-latitude regions to the equator along potential gradients (*Ostro et al.*, 2006). It has been shown that rotational acceleration could trigger local slope failures and landslides, which can form the canonical top shape and equatorial bulge seen on primary components in small multiple-asteroid systems (*Walsh et al.*, 2008; *Harris et al.*, 2009).

*Bottke et al.* (2002) proposed a YORP-induced rotational fission hypothesis. It has since been shown that the YORP effect controls the rotational acceleration of small asteroids (*Bottke et al.*, 2006; *Marzari et al.*, 2011) and naturally explains the period distribution among small asteroids (*Pravec et al.*, 2008; *Rossi et al.*, 2009; *Polishook and Brosch*, 2009). Furthermore, including the YORP-induced rotational fission hypothesis in size-frequency distribution models improves the agreement with observations (*Jacobson et al.*, 2014a). The observed characteristics of the systems described in sections 2.1–2.3 as well as thermal inertia observations (*Delbo et al.*, 2011) are consistent with a binary formation mechanism that involves spin-up and mass shedding. The YORP-induced rotational fission hypothesis is the leading candidate for explaining the formation of binaries, triples, and pairs among small asteroids.

#### 4.2. Asteroid Pairs

The YORP effect can increase the spin rate of asteroids beyond the critical disruption spin limit, thereby triggering rotational fission. In actuality, there is some uncertainty regarding the spin rate at which disruption occurs — there may be failure and deformation before fission (*Walsh et al.*, 2008; *Sánchez and Scheeres*, 2011; *Cotto-Figueroa et al.*, 2013). The critical disruption spin limit also depends on the detailed shapes, masses, and interlocking nature of the interior components and any cohesive forces (*Scheeres*, 2007, 2009b; *Sánchez and Scheeres*, 2014). Despite ignoring these details, simple calculations provide a rotational fission model that can be compared directly and successfully with observations.

If a spherical approximation of each component is made, then the rotational breakup spin rate  $\omega_q$  necessary for fission

as a function of the secondary-to-primary mass ratio  $q$  is (*Scheeres*, 2007)

$$\omega_q = \omega_d \sqrt{\frac{1+q}{(1+q^{1/3})^3}} \quad (1)$$

This is the exact solution for two spheres resting on each other with a mass ratio of  $q$  and rotating about the axis of maximum moment of inertia.

The spherical component model described above demonstrates the important reality that the larger the mass ratio  $q$  of the two future binary members, the slower the required rotation rate necessary to create the binary system. This slower required rotation rate translates into a small initial free energy for the ensuing binary system. The free energy  $E_f$  is the energy that is accessible to the different energy reservoirs in the system, including the rotation states of each member and the orbit. It does not include the internal binding energy of each object. The free energy is an important quantity because it determines the boundedness of the system. Bound systems have negative free energy, while unbound systems have positive free energy. An unbound binary system implies that the system is capable of disruption but does not imply that the system will disrupt. For the idealized case of two spheres, the free energy can be expressed as (*Scheeres*, 2007)

$$E_f = \frac{2\pi\rho\omega_d^2 R_p^5}{15} f(q) \quad (2)$$

where  $R_p$  is the radius of the primary and  $f(q)$  is an algebraic, monotonically decreasing function for  $0 < q \leq 1$ . For the equation above corresponding to two spheres, the function crosses zero when  $q \approx 0.204$ . Similar equations can be written for any two component shapes, but  $q \sim 0.2$  remains near the binding energy transition point, so the model uses this point as a simple approximation. This crossing point divides bound systems with negative energy and mass ratios  $q > 0.2$  and unbound systems with positive energy and mass ratios  $q < 0.2$ . Because of this fundamental difference, high-mass-ratio  $q > 0.2$  and low-mass-ratio  $q < 0.2$  binary systems evolve differently (*Scheeres*, 2009a; *Jacobson and Scheeres*, 2011b). Primarily, positive-energy low-mass-ratio systems will chaotically explore orbital phase space until the majority find a disruption trajectory creating an asteroid pair; this evolutionary route is unavailable to high-mass-ratio systems.

The asteroid pair population provides a natural laboratory to test this relationship (*Scheeres*, 2007; *Vokrouhlický and Nesvorný*, 2008). *Pravec et al.* (2010) examined many asteroid pair systems and measured the rotation rate of the primary and the absolute magnitude difference between the pair members. These two quantities should follow a simple relationship related to  $\omega_q$ , although many of the ignored details mentioned at the beginning of this section can move asteroids away from this relationship. Indeed, *Pravec et al.* (2010) discovered that asteroid pairs do follow this

relationship (Fig. 5). Furthermore, they found that the large members of asteroid pairs have a broader range of elongations than the primaries of binary systems, consistent with the findings of *Jacobson and Scheeres* (2011b) that prolate primaries are less likely to remain in a bound binary system after rotational fission. Thus, there is strong evidence to support the hypothesis that asteroid pairs are the products of rotational fission.

Asteroid pairs continue to be a fertile observational landscape. Since dynamical integrations can derive the “birthdate” of such systems, observers can test ideas regarding space-weathering timescales and YORP evolution after fission (*Polishook et al.*, 2014a; *Polishook*, 2014). Along with binary systems, the surfaces of asteroid pairs may provide clues in the future regarding the violence of the rotational fission process (*Polishook et al.*, 2014b).

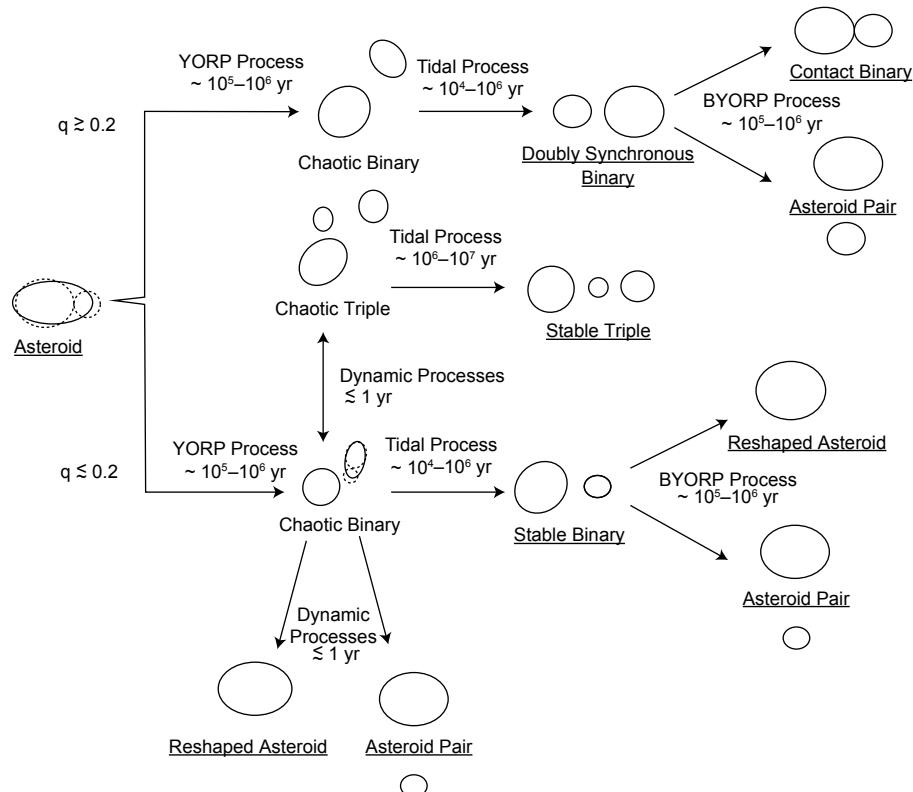

### 4.3. Binary and Triple Systems

*Jacobson and Scheeres* (2011b) showed that after rotational fission there are a number of possible outcomes. Their numerical studies produced the evolutionary flow chart shown in Fig. 11; many of these outcomes were also found by *Fang and Margot* (2012c). The high- and low-mass-ratio distinction for rotational fission emphasized above plays

an important role in distinguishing the two evolutionary pathways. Along the high-mass-ratio pathway, both binary members tidally synchronize and then evolve according to the BYORP effect.

Along the low-mass-ratio pathway, the binary system is unbound. Since these systems are chaotic, many are disrupted and become asteroid pairs. During this chaotic binary state, the secondary can often go through rotational fission itself, although this rotational fission is torqued by spin-orbit coupling (Fig. 10) rather than the YORP effect. Loss of material from the secondary stabilizes the remaining orbiting components. The lost mass may reaccrete onto the primary, perhaps contributing to the observed equatorial ridges, or may escape from the system. In these cases, the system undergoes another chaotic binary episode with three possible outcomes: a reshaped asteroid, an asteroid pair, or a stable binary. These binaries still possess positive free energy such that they may disrupt if disturbed. In other cases, the system retains three components after secondary fission. While the numerical simulations of *Jacobson and Scheeres* (2011b) did not yield this latter outcome, it is possible that this pathway explains the existence of stable triple systems.

After stabilization of the low-mass-ratio binary system, the secondary synchronizes due to tides (e.g., *Goldreich and Sari*, 2009), although some satellites may be trapped in a

**Fig. 11.** Flowchart showing the possible evolutionary paths for an asteroid after it undergoes rotational fission. Each arrow is labeled with the dominant process and an estimated timescale for this process. Underlined states are nominally stable for a YORP effect timescale. Figure from *Jacobson and Scheeres* (2011b).

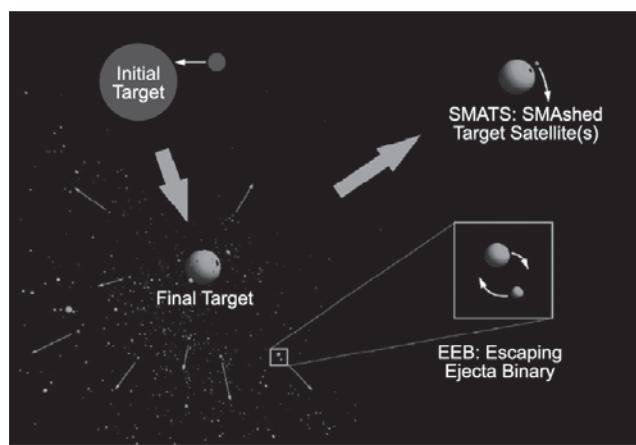

chaotic rotation state for durations that exceed the classic spin synchronization timescales (Naidu and Margot, 2015). Then the system evolves according to the BYORP effect and tides. These binary evolutionary processes and their outcomes are discussed in the chapter by Walsh and Jacobson in this volume. As shown in Fig. 11, these evolutionary paths include each of the binary morphologies identified in this chapter and by other teams (Pravec and Harris, 2007; Fang and Margot, 2012c). In particular, the formation of wide asynchronous binaries such as (1509) Esclangonga, (4674) Pauling, (17246) 2000 GL<sub>74</sub>, and (22899) 1999 TO<sub>14</sub> is best explained by a rotational fission mechanism (Polishook et al., 2011) followed by BYORP orbital expansion (Jacobson et al., 2014b).

An alternative formation mechanism for triples such as (153591) 2001 SN<sub>263</sub> and (136617) 1994 CC is that after creating a stable binary system, the primary undergoes rotational fission a second time. As long as the third component is on a distant enough orbit, then this process may result in a stable triple system (Fang et al., 2011; Fang and Margot, 2012c; Jacobson et al., 2014b).

## 5. LARGE ASTEROIDS: SYNTHESIS

The primaries of most known binary and triple asteroids greater than 20 km have spin periods in the range of 4 h to 7 h (Fig. 7). While these spin rates are not near the disruption spin limit, they are typically faster than the mean spin rates for asteroids of similar sizes. The total angular momentum content, however, is well below that required for rotational fission. The secondary-to-primary mass ratios in these systems range from 10<sup>-6</sup> to 10<sup>-2</sup>. These properties are consistent with satellite formation during large collisions (Fig. 12). Durda et al. (2004) have shown in numerical simulations that impacts of 10- to 30-km-diameter projectiles striking at impact velocities between 3 km s<sup>-1</sup> and 7 km s<sup>-1</sup> can produce satellites that match observed properties. Multiple asteroid systems, e.g., (45) Eugenia (Merline et al., 1999; Marchis et al., 2007) and (87) Sylvia (Margot and Brown, 2001; Marchis et al., 2005a), can also plausibly form through collisions.

There is more uncertainty related to the formation of (90) Antiope and (617) Patroclus, which are both too large to be substantially affected by YORP. Hypotheses for the formation of (90) Antiope include primordial fission due to excessive angular momentum (Pravec and Harris, 2007), an improbable low-velocity collision of a large impactor (Weidenschilling et al., 2001), or shrinking of an initially wide binary formed by gravitational collapse (Nesvorný et al., 2010). Gravitational collapse in a gas-rich protoplanetary disk has been invoked to explain the formation of numerous binaries in the transneptunian region. (617) Patroclus may be a primordial TNO that avoided disruption during emplacement in the Trojan region (Nesvorný et al., 2010). Wide TNO binaries would not be expected to survive this process, but encounter calculations (e.g., Fang and Margot, 2012a) show that tight binaries would.

**Fig. 12.** Numerical simulations show that binaries can form as a result of large impacts between asteroids. In some scenarios, impact debris can remain gravitationally bound to the target body, forming a satellite (SMATs). This process likely explains the formation of large MBA binaries. In other scenarios, two fragments from the escaping ejecta have sufficiently similar trajectories, such that they become bound to one another (EEBs). Figure from Durda et al. (2004).

## 6. CONCLUSIONS

Studies of binaries, triples, and pairs remain a fertile ground for observing processes that are important in planet formation and for measuring quantities that are difficult to obtain by other means. These include masses and densities as well as thermal, mechanical, and interior properties. Binaries or triples have been found in ~50 NEAs, ~50 small MBAs, ~20 large MBAs, and 2 Trojans. A unifying paradigm based on rotational fission and post-fission dynamics explains the formation of small binaries, triples, and pairs. Because the Sun-powered rotational fission process is unrelenting, and because the production of pairs is a frequent outcome of this process, a substantial fraction of small bodies likely originated in a rotational disruption event. This origin affects the size distribution of asteroids and may explain the presence of single NEAs with equatorial bulges observed with radar. Small satellites of large MBAs are likely formed during large collisions. Advances in instrumentation, observational programs, and analysis techniques hold the promise of exciting findings in the next decade.

# Formation and Evolution of Binary Asteroids

Kevin J. Walsh

*Southwest Research Institute*

Seth A. Jacobson

*Observatoire de la Côte d'Azur and University of Bayreuth*

Satellites of asteroids have been discovered in nearly every known small-body population, and a remarkable aspect of the known satellites is the diversity of their properties. They tell a story of vast differences in formation and evolution mechanisms that act as a function of size, distance from the Sun, and the properties of their nebular environment at the beginning of solar system history and their dynamical environment over the next 4.5 G.y. The mere existence of these systems provides a laboratory to study numerous types of physical processes acting on asteroids, and their dynamics provide a valuable probe of their physical properties otherwise possible only with spacecraft. Advances in understanding the formation and evolution of binary systems have been assisted by (1) the growing catalog of known systems, increasing from 33 to ~250 between the Merline *et al.* (2002) chapter in *Asteroids III* and now; (2) the detailed study and long-term monitoring of individual systems such as 1999 KW<sub>4</sub> and 1996 FG<sub>3</sub>, (3) the discovery of new binary system morphologies and triple systems, (4) and the discovery of unbound systems that appear to be end-states of binary dynamical evolutionary paths. Specifically for small bodies (diameter smaller than 10 km), these observations and discoveries have motivated theoretical work finding that thermal forces can efficiently drive the rotational disruption of small asteroids. Long-term monitoring has allowed studies to constrain the system's dynamical evolution by the combination of tides, thermal forces, and rigid-body physics. The outliers and split pairs have pushed the theoretical work to explore a wide range of evolutionary end-states.

## 1. INTRODUCTION

There have been considerable advances in the understanding of the formation and evolution of binary systems since the *Asteroids III* review by Merline *et al.* (2002) and a subsequent comprehensive review by Richardson and Walsh (2006). The current properties of this population are detailed in the chapter in this volume by Margot *et al.*, and this review will rely on their analysis in many places as we review work on the formation and dynamics of these systems. While the inventory of known binary systems in all populations has increased, for some populations the understanding of dynamics and formation have advanced only minimally, while in others areas research has moved rapidly. Therefore this chapter will not be evenly weighted between different populations; rather there will be substantial discussion of small asteroids and the Yarkovsky-O'Keefe-Radzievskii-Paddack (YORP) effect.

The scope of this chapter will be different from that of the *Asteroids III* chapter by Merline *et al.* (2002). Thanks to an excellent review of binary systems in the Kuiper belt by Noll *et al.* (2008) in the *Solar System Beyond Neptune* book, and the apparent physical, dynamical, and evolutionary differences between binary minor planets in the outer

and inner regions of the solar system, we will exclude the Kuiper belt population from our discussion here.

### 1.1 The Known Population of Binary Minor Planets

The known population of asteroid satellites has increased from 33 to ~244 between the time of the Merline *et al.* (2002) *Asteroids III* chapter and now: 49 near-Earth, 19 Mars-crossing, and 93 main-belt asteroids (MBAs) (Pravec and Harris, 2007; Johnston, 2014). As noted in 2002, the binary systems found among near-Earth asteroids (NEAs) have only a subset of the properties of those found among the MBAs. While the orbital and collisional dynamics differ substantially in these two populations, further study has found that the variation and similarities between binary properties is most strongly dependent on size.

The known binary systems among NEAs have primary component diameters exclusively less than 10 km. These small systems typically have moderately sized secondaries between 4% and 58% the size of the primary — corresponding to a mass ratio range of  $6.4 \times 10^{-5}$ – $2.0 \times 10^{-1}$  assuming equal densities, are on tight orbits with typically 2.5–7.2 primary radii separation, and have a fast-spinning primary with rotation period between 2.2 and 4.5 h — all are below

twice the critical disruption spin period of 2.3 h for a sphere with a density of 2 g cm<sup>-3</sup>. The data for these systems is presented in Fig. 1. When lightcurve surveys probed similar-sized asteroids in the main belt, they found systems with the same characteristics existing at roughly the same proportion of the population (Warner and Harris, 2007).

The known binary systems among MBAs have properties that vary with their size. The small population [ $D < 15$  km; (4492) Debussy is the largest] look similar to the various morphologies found among NEAs, including a few that appear similar to (69230) Hermes, while asteroid satellites around large asteroids [ $D > 25$  km; (243) Ida is the smallest of this group] fall into other categories. These larger asteroid systems have by comparison much smaller satellites on much more distant orbits. While a number of the large asteroids with satellites have rotation periods lower than the average asteroids of these sizes [geometric means and 1 $\sigma$  deviations are  $7.6 \pm 0.4$  h vs.  $12.2 \pm 0.5$  h (Warner *et al.*, 2009; Pravec *et al.*, 2012)], their rotation periods are all more than twice the critical disruption spin period of 2.3 h for a sphere with a density of 2 g cm<sup>-3</sup>, with the exception of (22) Kalliope (Pravec *et al.*, 2012; Johnston, 2014).

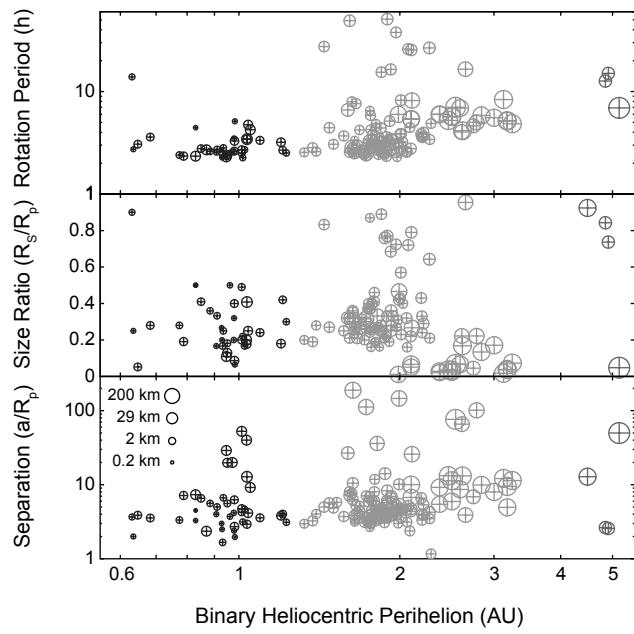

The techniques used to increase this database of known systems over time are important as they define any biases of our knowledge of each population. Lightcurve techniques, which are important for finding close companions around

small asteroids, are strongly biased against finding distant companions. Meanwhile, radar can discover satellites widely separated from their primaries, but is ineffective for observing distant MBAs (Ostro *et al.*, 2002). Direct high-resolution imaging is best for finding distant companions of large MBAs (Merline *et al.*, 2002). The size of the known population of small binary asteroid systems has increased substantially owing to the ready availability of small telescopes to survey asteroid light curves and the increased frequency of radar observations. Meanwhile, many large MBAs have been surveyed with groundbased telescopes with far fewer recent discoveries — although new adaptive optics (AO) technologies may uncover previously unseen satellites at previously studied asteroids (Marchis and Vega, 2014).

## 1.2. The YORP Effect

The largest shift in the understanding of binary formation and evolution has come from studies of thermal forces that can affect a single body or a binary system. The reflection and reemission of solar radiation can produce a torque that changes the rotation rate and obliquity of a small body. This effect is referred to as the YORP effect, coined by Rubincam (2000), and evolved out of the work of many researchers on similar topics (Radzievskii, 1952; Paddock, 1969; Paddock and Rhee, 1975; O'Keefe, 1976). We only provide a brief summary here [see Bottke *et al.* (2006) and the Vokrouhlický *et al.* chapter in this volume for a detailed discussion of the effect].

The YORP effect has been directly detected for several asteroids through observed rotation-rate changes (Taylor *et al.*, 2007; Lowry *et al.*, 2007; Kaasalainen *et al.*, 2007; Ďurech *et al.*, 2008a,b, 2012). These rotation-rate changes match the predicted magnitude of the effect from theoretical predictions (Rubincam, 2000; Bottke *et al.*, 2002; Vokrouhlický and Čapek, 2002; Čapek and Vokrouhlický, 2004; Rozitis and Green, 2013b). The YORP effect has a straightforward dependence on asteroid size (timescales increase with  $R^2$ ) and distance from the Sun (timescales increase with  $a^2$ ), but a complicated relationship with shape (Nesvorný and Vokrouhlický, 2007; Scheeres, 2007b). This shape dependence is characterized by a YORP coefficient, which measures the asymmetry of the body averaged about a rotation state and a heliocentric orbit. While instantaneous estimates of the YORP coefficient are available from astronomical measurements of the radial accelerations of asteroids, theoretical models of long-term averaged values are stymied by a sensitive dependence on small-scale topography (Statler, 2009; McMahon and Scheeres, 2013a; Cotto-Figueroa *et al.*, 2015) and regolith properties (Rozitis and Green, 2012, 2013a). NEAs and MBAs with diameters below about 20 km are likely to be affected on solar system timescales (Bottke *et al.*, 2006; Jacobson *et al.*, 2014b). Kilometer-sized NEAs can have rotation-rate-doubling timescales shorter than their dynamical lifetime of ~10 m.y. and MBAs shorter than their collision lifetime of ~100 m.y. (Bottke *et al.*, 2006; Jacobson, 2014).

**Fig. 1.** The known population of binary asteroids. The three panels show (bottom) the component separation in terms of the primary radius, (middle) the size ratio of the two components, and (top) the rotation period of the primary, all plotted as a function of the system's heliocentric orbit's pericenter (Johnston, 2014). The size of the symbol indicates the size of the primary body, with the scale being on the left side of the bottom panel.

The distribution of spin rates observed for bodies smaller than 40 km in size show excesses of very fast and slow rotators (Pravec and Harris, 2000; Warner and Harris, 2007), which is matched very well by a spin-distribution model that includes the YORP effect (Pravec *et al.*, 2008; Rossi *et al.*, 2009; Marzari *et al.*, 2011), as suspected in the *Asteroids III* chapter by Pravec *et al.* (2002). Note that the very large asteroid lightcurve survey of Masiero *et al.* (2009) found a more Maxwellian distribution of spin rates among small asteroids, although it is not necessarily incompatible with YORP spin evolution. Among larger bodies, a subset of the Koronis asteroid family was found to have aligned obliquity and clustered spin rates (Slivan, 2002), which is due to the YORP effect driving them into spin-orbit resonances (Vokrouhlický *et al.*, 2003). Among asteroid families, whose spreading is controlled by the Yarkovsky drift of family members, there are clear signatures of the YORP effect changing the obliquity of smaller bodies and in turn changing their Yarkovsky drift rates (Vokrouhlický *et al.*, 2006; Bottke *et al.*, 2006, 2015).

Morning and evening thermal differences across regolith blocks torque the asteroid similarly in magnitude to the “normal” YORP effect. Unlike the effect described above, this “tangential” YORP effect does depend on the rotation rate, material properties of the regolith, and size distribution of the blocks (Golubov and Krugly, 2012; Golubov *et al.*, 2014). Furthermore, the tangential YORP effect has a prograde bias unlike the normal YORP effect, which is unbiased. This additional torque may explain the difference between the predicted rotational deceleration of (25143) Itokawa (Scheeres *et al.*, 2007; Ďurech *et al.*, 2008b; Breiter *et al.*, 2009) and the observed acceleration by the Japanese space mission Hayabusa (Lowry *et al.*, 2014; Golubov *et al.*, 2014). Similarly, a preference for spinning up may be necessary to explain the large fraction of observed binary systems, ~15% of small asteroids, which are presumed to be formed from rotational disruption caused by continued YORP spinup (discussed in detail below).

As mentioned as early as the Vokrouhlický and Čapek (2002) and Bottke *et al.* (2002) works on the YORP effect, this effect was a very good candidate to rotationally disrupt rubble-pile asteroids. As the catalog of known systems has grown, and the subpopulations of binary systems became more defined, rotational disruption by the YORP effect emerged as the primary candidate as the dominant formation mechanism. Much of the recent research, and the discussion below, is focused on the step(s) between when the YORP effect starts increasing the angular momentum of an asteroid and when we observe the diverse catalog of systems today. Some subpopulations may emerge directly from YORP-induced rotational disruption, while others seem to demand further evolutionary forces.

## 2. BINARY SUBPOPULATIONS

With over 100 systems spread between NEAs and MBAs, clear subpopulations of binary systems have emerged.

Pravec and Harris (2007) compiled the parameters for the catalog of known binary systems, including a calculation of the total angular momentum of each system. They used this data to create a classification system of the known inner solar system binary systems that is well suited for the topics in this chapter (most of these populations are clear in Figs. 1 and 2), and we update it below:

**Group L:** Large asteroids (diameter:  $D > 20$  km) with relatively very small satellites (secondary to primary diameter ratio:  $D_2/D_1 \leq 0.2$ ). We identify 11 members.

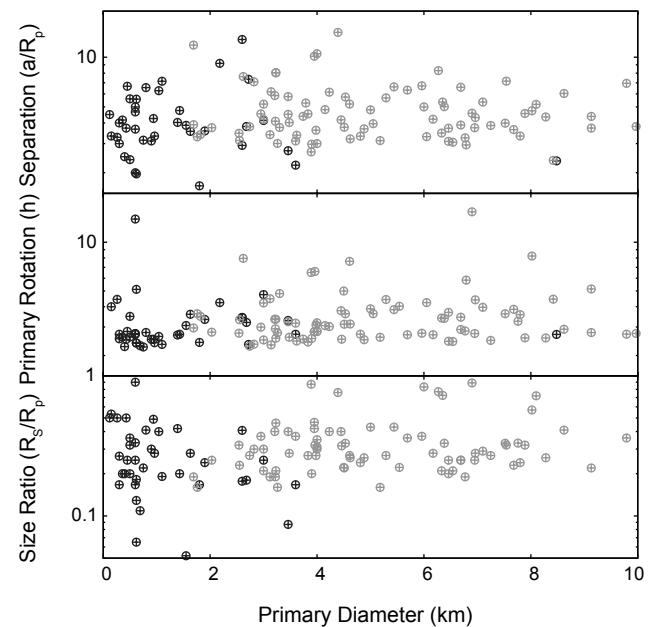

**Group A:** Small asteroids ( $D < 20$  km) with relatively small satellites ( $0.1 \geq D_2/D_1 \leq 0.6$ ) in tight mutual orbits (semimajor axis,  $a$ , less than 9 primary radii,  $R_p$ ). We identify 88 members.

**Group B:** Small asteroids ( $D < 20$  km) with relatively large satellites ( $0.7 \geq D_2/D_1$ ) in tight mutual orbits ( $a \leq 9 R_p$ ). We identify 9 members.

**Group W:** Small asteroids ( $D < 20$  km) with relatively small satellites ( $0.2 \geq D_2/D_1 \leq 0.7$ ) in wide mutual orbits ( $a \geq 9 R_p$ ). We identify 9 members.

**Three outliers:** Two would-be Group L members [(90) Antiope and (617) Patroclus] have the Group B characteristic of similar-sized components but are much larger than the other Group B members ( $D \sim 87$  and 101 km, respectively), and a would-be Group W member [(4951) Iwamoto] has the Group B characteristic of similar-sized components but a much wider mutual orbit ( $a \sim 17 R_p$ ).

**Split pairs:** These are inferred systems due to dynamical models that very closely link their heliocentric orbits.

**Fig. 2.** The population of small binary systems, showing their (bottom) size ratio, (middle) primary rotation period, and (top) component separation, all plotted as a function of their primary diameter (Pravec and Harris, 2007; Johnston, 2014). The NEAs are black symbols and MBAs are gray symbols.

Therefore they are not actual binaries, but are rather inferred dynamical end-states. Some pair members are binaries themselves.

The principal change in this classification scheme from *Pravec and Harris* (2007) is the size — splitting “large” and “small” asteroids. Previously, “large” was defined to be asteroids with diameters larger than 90 km, but from more recent binary asteroid observations and YORP theory, a more natural boundary between “large” and “small” is 20 km (*Pravec et al.*, 2012; *Jacobson et al.*, 2014a). The boundaries between the various defining characteristics appear robust in Fig. 1, where adjustments on the order of 10% lead to the creation of no or only a few new outliers. The data in the paragraphs above come from P. Pravec’s binary catalog (*Pravec et al.*, 2012).

## 2.1. Large Systems: Group L

Group L members are distinct in the bottom two panels of Fig. 1, and are defined by having large primaries with  $D > 20$  km (large symbols), and relatively smaller size ratios ( $D_2/D_1 \leq 0.2$ ). These size ratios range from 0.03 to 0.2 with the lowest mean of any group:  $0.08 \pm 0.06$  ( $1\sigma$ ) (*Pravec et al.*, 2012). They are typically discovered with groundbased high-resolution imaging with (243) Ida a notable exception, whose satellite was discovered by the Galileo space mission (*Belton and Carlson*, 1994). There are 11 known systems, with the largest being (87) Sylvia ( $D \sim 256$  km) with its satellites Romulus and Remus (*Brown et al.*, 2001; *Marchis et al.*, 2005) and the smallest being (243) Ida ( $D \sim 32$  km) with its satellite Dactyl (*Belton and Carlson*, 1994). None of the eight asteroids larger than (87) Sylvia have been reported to have satellites, but there are likely many satellites among the asteroids with sizes near that of (243) Ida and up to that of (87) Sylvia since severe biases limit detection in that population.

The rotation periods of these large asteroids range from 4.1 to 7.0 h with a geometric mean:  $5.6 \pm 0.8$  ( $1\sigma$  h) (*Pravec et al.*, 2012). With the exception of (22) Kalliope, all the Group L members rotate at less than half the critical disruption rate for a spherical body with a density of  $2 \text{ g cm}^{-3}$  (2.3-h rotation period). As discussed in *Descamps et al.* (2011), the lower than typical rotation periods [asteroids of similar sizes have  $12.2 \pm 0.5$ -h rotation periods (*Warner et al.*, 2009)] and the elongated shapes of the primaries [e.g., the bean-shape of (87) Sylvia (*Marchis et al.*, 2005)] are suggestive of a violent disruption process, with the reaccumulation of the parent body into high-angular-momentum shape and spin configurations. However, previous numerical models of asteroid disruptions did not retain shape and spin information of the reaccumulated remnants (*Durda et al.*, 2007), except in the case of (25143) Itokawa (*Michel and Richardson*, 2013), so this has not been explicitly tested.

It is important to note that due to an increase of YORP timescales with surface area, YORP cannot play a role for these large systems.

## 2.2. Small Systems: Groups A, B, and W

Systems with small primary bodies ( $D < 20$  km) almost all fit in the subpopulation of Group A, and are found among NEAs, small MBAs and Mars crossers. Members of Group A have diameters between 0.15 and 11 km (*Pravec et al.*, 2012). Their mutual orbits are within 2.7 and 9.0 primary radii (mean statistics:  $4.8 \pm 1.3 R_p$ ), and the satellites are between 0.09 and 0.58 the size of the primary (mean statistics:  $0.3 \pm 0.1$ ).

Group A members have similar amounts of angular momentum relative to their critical values (where critical is enough to break up the combined masses if in a single body). Typically this is due to the rapidly rotating primary with a period between 2.2 and 4.4 h (*Margot et al.*, 2002; *Pravec et al.*, 2006, 2012) — always within a factor of 2 of the critical disruption rate for a spherical body with a density of  $2 \text{ g cm}^{-3}$  (2.3-h rotation period). The geometric mean of their rotation periods is  $2.9 \pm 0.8$  ( $1\sigma$ ) h compared to  $7.4 \pm 0.3$  h for asteroids in the same size range (*Pravec et al.*, 2012; *Warner et al.*, 2009).

While the orbit period is never synchronous with the very fast primary rotation (see Figs. 1 and 2), the synchronicity of the satellite rotation with the orbit period divides Group A into two distinct subgroups. Most belong to the synchronous satellite subgroup [ $\sim 66\%$  (*Pravec et al.*, 2012)], although it is possible that these satellites have chaotic rotation but appear nearly synchronous (*Naidu and Margot*, 2015). The rest of the asteroids have satellites that are asynchronous, and have rotation periods between the primary rotation period and the orbit period (*Pravec et al.*, 2012).

There are very few well-characterized mutual orbits — only seven binary and two triple systems (*Fang and Margot*, 2012b). Among these, there is a trend between their measured orbital eccentricity and the synchronicity of the satellites’ rotation and orbit periods [see Fig. 1 of *Fang and Margot* (2012b)], where synchronous satellites are generally less eccentric. This trend is consistent with limits on the eccentricity determined by lightcurve studies (*Pravec and Harris*, 2007). Some asynchronous satellites on eccentric orbits may be in chaotic rotation as a result of torques on their elongated shapes [e.g., 1991 VH (*Naidu and Margot*, 2015)]. This could explain the high frequency ( $\sim 33\%$ ) of asynchronous satellites in light of possibly rapid theoretical despinning timescales — around  $10^2$ – $10^8$  yr [the tidal parameters are very uncertain (*Goldreich and Sari*, 2009; *Jacobson and Scheeres*, 2011c; *Fang and Margot*, 2012b)], compared to a  $\sim 10^7$ -yr dynamical lifetime in the NEA population or a  $\sim 10^8$ -yr collisional lifetime in the MBA population.

The Group B members have nearly equal-sized components (mean  $D_2/D_1$  is  $0.88 \pm 0.09$ ; they stand out in the middle panel of Fig. 1). There is a break among the small binary population between Group A and Group B, suggesting an alternate evolutionary route (*Scheeres*, 2004; *Jacobson and Scheeres*, 2011a). These systems are in a doubly synchronous state with synchronized rotation and orbital periods (*Pravec*

and Harris, 2007). Orbital periods extend from 13.9 h to 49.1 h, similar to the Group A binaries [11.7 h to 58.6 h (Pravec et al., 2012)]. Nearly all this population is found in the main belt and discovered by lightcurve observations with the exception of the NEA (69230) Hermes. Hermes is decidedly smaller [ $D \sim 0.6$  km (Margot et al., personal communication)] than the next smallest confirmed Group B member [(7369) Gavrilin,  $D \sim 4.6$  km (Pravec and Harris, 2007)], but an unconfirmed member of Group B, 1994 CJ<sub>1</sub>, is even smaller [ $D < 0.15$  km (Taylor et al., 2014)]. The mean size D is  $7 \pm 3$  km, and the largest, (4492) Debussy, is 12.6 km (Pravec et al., 2012). Because these systems are doubly synchronous, there are strong biases against discovery; only mutual events reveal the presence of the satellite. Furthermore, they are not typically separated enough to be detected by high-resolution imaging [the widest is (854) Frostia, with a component separation of only 36.9 km], and too distant and small for radar detection in the main belt. Thus they are possibly significantly underrepresented among known asteroid binaries.

Group W binary members have very large separations (between 9 and 116  $R_p$ ), and are typically detected by the Hubble Space Telescope or AO observations from ground-based telescope observatories. The existence of some of this group in the main belt defies formation only from planetary encounters (Fang and Margot, 2012a). Like Group A and B members, they are small [mean size D is  $4.8 \pm 2.3$  km (Pravec et al., 2012)], so radiative torques like the YORP effect are important. Like Group A members, they are rapidly rotating [geometric mean primary rotation period  $3.3 \pm 0.8$  hr; Polishook et al., 2011] and have moderate size ratios [mean size ratio  $D_2/D_1$  is  $0.4 \pm 0.2$  (Pravec et al., 2012)]. They follow the pattern of the asynchronous subgroup of Group A and all their satellites have rotation periods that are between that of the primary's rotation and the satellite's orbital period. The links between Group A and Group W are strong, and Jacobson et al. (2014b) developed an evolutionary pathway from the former to the latter. Previously, Group W members have been suspected to be debris from catastrophic collisions [dubbed escaping ejecta binary systems (EEBs) in Durda et al. (2004)], but further study consistently finds rapidly rotating primaries (Polishook et al., 2011).

Many of these systems were discovered and characterized by lightcurve observations, which produce rotation periods as well as some information on shape from the amplitude of the light curve (Pravec and Harris, 2007). The lightcurve amplitude principally constrains two of the axes of the body, the long a and intermediate b axis (for principal axis rotation about its shortest c principal axis). It can constrain the other axis ratio if there are multiple observing geometries. The lightcurve amplitude can be converted to determine the a/b relationship, which roughly describes the shape of the body's equatorial cross-section. Group A, B, and W members have a/b from 1.01 to 1.35 with an average value of  $1.13 \pm 0.07$  (Pravec et al., 2012) — nearly circular equatorial cross-

sections. Meanwhile, the satellites of Group A, B, and W members have a/b from 1.06 to 2.5 with an average value of  $1.44 \pm 0.24$  (Pravec et al., 2012). Thus satellites represent a much larger variety of equatorial cross-sections.

Finally, some primary members of Group A and W have a characteristic spheroidal “top” shape due to a pronounced deviation from a sphere along an equatorial ridge. This radar-derived shape was made famous by 1999 KW<sub>4</sub> (Ostro et al., 2006), but has been found for many other binary and single asteroids [(29075) 1950 DA (Busch et al., 2007); 2004 DC (Taylor et al., 2008); 2008 EV<sub>5</sub> (Busch et al., 2011); (101955) Bennu (Nolan et al., 2013); (136617) 1994 CC (Brozović et al., 2011); (153591) 2001 SN<sub>263</sub> (Becker et al., 2015)]. This ridge preserves a low a/b ratio, i.e., a circular equatorial cross-section, but due to the confluence of rotation and shape, this reduces the gravitational binding energy of material on the ridge (Ostro et al., 2006; Busch et al., 2011; Scheeres, 2015). At high rotation rates, the entire mid-latitudes obtain high slopes and therefore disturbed loose material would naturally move toward the potential low at the equator; this material upon reaching the equator may move off the surface entirely and enter into orbit (Ostro et al., 2006; Walsh et al., 2008; Harris et al., 2009). This discovery has driven studies of asteroid reshaping focusing on the granular and cohesive properties of the surface material and possible secondary fragmentation and infall of orbital material (Ostro et al., 2006; Walsh et al., 2008; Harris et al., 2009; Holsapple, 2010; Jacobson and Scheeres, 2011a; Scheeres, 2015).

### 2.3. Triples

The first discovered triple in the main belt was (87) Sylvia, with two small satellites orbiting its beanshaped primary body (Marchis et al., 2005). More triples have since been found, with (45) Eugenia (Marchis et al., 2007), (93) Minerva (Marchis et al., 2009), and (216) Kleopatra joining the list (Marchis et al., 2008). As discussed below, this is believed to be a natural outcome of formation via asteroid collisions.

There are also a few confirmed and suspected small asteroid triple systems: (136617) 1994 CC, (153591) 2001 SN<sub>263</sub>, 2002 CE<sub>26</sub>, (3749) Balam, and (8306) Shoko (Brozović et al., 2009; Nolan et al., 2008; Shepard et al., 2006; Marchis et al., 2008; Pravec et al., 2013). All have rapidly rotating primaries (2001 SN<sub>263</sub> is the lowest at 3.425 h) and low size ratios between the smaller two members and the primary (Balam has the largest measured satellite at 46.6% its size). For the two triple systems with known primary shapes [(136617) 1994 CC, (153591) 2001 SN<sub>263</sub>], both have the typical “top” shape described above (Brozović et al., 2011; Becker et al., 2009).

Both Balam and Shoko are also members of split pairs, and the other members are 2009 BR<sub>60</sub> and 2011 SR<sub>158</sub>, respectively (Vokrouhlický, 2009; Pravec et al., 2013). As explained in the next subsection, split pairs have a dynamical

age that is interpreted as the rotational fission formation age. Since it is unlikely that the split pair member could have formed without significantly affecting the triple system, it is possible that all components were created at the same time from a single rotational fission event (*Jacobson and Scheeres*, 2011b).

#### 2.4. Outliers

Large double asteroids such as the MBA (90) Antiope and Trojan (617) Patroclus appear unique in the inner solar system. These are too large, with diameters greater than 100 km, to have gained angular momentum from thermal effects, and collision simulations do not typically create such systems (*Durda et al.*, 2004). They have very large angular momentum content, owing to the similar-sized components (*Pravec and Harris*, 2007; *Descamps et al.*, 2007; *Michałowski et al.*, 2004). Antiope is notable as it is among the largest fragments in an asteroid family, owing to the exceptional size of Themis and its family. Meanwhile, Patroclus is a Trojan, and solar system formation models suggest that many or all of them may have been implanted from the primordial Kuiper belt region (*Morbidelli et al.*, 2005; *Nesvorný et al.*, 2013). Thus this system may share a common origin with the systems found in the Kuiper belt (see *Noll et al.*, 2008; *Nesvorný et al.*, 2010).

The other outlier, (4951) Iwamoto, has a much wider mutual orbit than other Group B members, but this may be explained by orbit expansion due to the BYORP effect as discussed below (*Ćuk*, 2007; *Jacobson and Scheeres*, 2011b).

#### 2.5. Split Pairs

An important discovery related to the dynamics of binary systems is the existence of individual asteroids that are not bound to each other but instead show convincing signs of being split pairs (*Vokrouhlický and Nesvorný*, 2008, 2009; *Pravec and Vokrouhlický*, 2009; *Pravec et al.*, 2010). These were found using dynamical studies similar to those that search for families of asteroids, but here pairs were found to be closely linked dynamically.

Follow-up observations have found convincing links in both size and rotation of the pairs (*Pravec et al.*, 2010) as well as photometric appearance (*Moskovitz*, 2012; *Duddy et al.*, 2012). Their sizes and rotation make a very strong case that the smaller member of the pair was ejected during a rotational fission event, with the signature of this in the slow rotation of the larger object as a function of the size of the smaller object. The latter work finds similar photometric colors for the pairs, supporting the dynamical links between them. The dynamical models suggest that some of these pairs separated less than just  $\sim$ 17 k.y. ago, and hence the photometric colors have not had time to evolve significantly due to space weathering or other effects (*Vokrouhlický and Nesvorný*, 2009; *Vokrouhlický et al.*, 2011).

### 3. FORMATION

While the community and the literature largely agree on the collisional origin of the satellites of large asteroids (Group L), there is continued work on the details of how the small systems (Groups A, B, W) form and evolve. An important part of understanding the formation of the small systems concerns both the properties and variety of outliers and the possible complicated evolutionary paths for satellites or building blocks of satellites once in orbit around a rubble-pile asteroid.

#### 3.1. Large Systems: Collision

Collisions were proposed as a potentially important formation mechanism even before the discovery of Ida's moon Dactyl in 1993. Most works focused on ejecta from a collision becoming mutually bound, becoming bound around the largest remnant, or rotational fission due to a highly oblique or glancing impact (*Weidenschilling et al.*, 1989; *Merline et al.*, 2002; *Richardson and Walsh*, 2006). Both *Weidenschilling et al.* (1989) and *Merline et al.* (2002) found that complete disruption is a far more likely outcome than collisionally induced rotational fission, and there are no observed systems that can be clearly attributed to this latter process.

The study of the other collisional mechanisms first focused on cratering events on the asteroid Ida, numerically tracking the evolution of ejected debris in order to form its small satellite Dactyl (*Durda*, 1996; *Doressoundiram et al.*, 1997). Studies of asteroid impacts gained a numerical boost by combining smoothed particle hydrodynamics models of asteroid fragmentation with N-body models of their gravitational reaccumulation (*Michel et al.*, 2001, 2002, 2003, 2004; *Durda et al.*, 2004, 2007). These models were more capable of modeling the physics of catastrophic collisions and maintaining high-resolution models of the fragments' long-term gravitational interactions and reaccumulation. They found that the formation of satellites is a natural outcome in an asteroid disruption.

*Durda et al.* (2004) further explored the different types of systems formed during a collision. This large suite of 161 impact simulations studied 100-km basalt targets being impacted by objects of various sizes hitting at a range of velocities and angles. In their suite of collision and reaccumulation simulations they observed, and named, the two previously proposed types of systems: escaping ejecta binary systems (EEBs) and smashed target satellites (SMATS). The SMATS generally featured small satellite(s) orbiting the reaccumulated target body. The known satellites around large ( $D > 10$  km) MBAs share similar properties: extreme size ratio between primary and secondary and large orbital separation (where the orbital separations are too large to be explained by tides; see section 4.2). They predicted a formation rate that should roughly produce the observed number of satellites detected around very large asteroids ( $D > 140$  km), accounting for their production due to colli-

sions, satellites destroyed by collisions, and the very early clearing of the asteroid belt.

Meanwhile, they proposed that some small main-belt systems featuring two small components of roughly similar size on distant orbits are possibly EEBs. Their examples were (3749) Balam and (1509) Esclangona, and while at the time both were interesting candidates, (3749) Balam has been discovered to have a third component and a split pair and (1509) Esclangona has been found to have a very rapid rotation period similar to that found among many of the binary systems formed by the YORP effect (Warner *et al.*, 2010). The best remaining candidates are (317) Roxane because of its slow primary rotation [8.2 h (Harris *et al.*, 1992; Polishook *et al.*, 2011; Jacobson *et al.*, 2014b)] and (1717) Arlon because of its slow primary rotation [5.1 h (Cooney *et al.*, 2006)] and high size ratio [ $>0.22$  (Cooney *et al.*, 2006; Jacobson *et al.*, 2014b)]. The lack of EEBs in the known catalog is curious, as the simulations of Durda *et al.* (2004) formed hundreds of systems immediately after a collision, although the stability of these binaries was not thoroughly examined. This is an important avenue for future work, especially given the importance of spin-orbit coupling for binaries after rotational fission (Jacobson and Scheeres, 2011a). Tens of asteroid families are known (see the chapter by Nesvorný *et al.* in this volume) and there is evidence for even very recent impacts throughout the solar system (Nesvorný *et al.*, 2002; Vokrouhlický and Nesvorný, 2009). However, small and wide binary systems are difficult to find, and small components are more susceptible to collisional grinding (see the chapter by Bottke *et al.* in this volume), which may explain the lack of discoveries of this type of system. Meanwhile, the known systems need substantial characterization (rotation periods, etc.) to try to distinguish between possible EEBs and end-states of YORP/BYORP evolution processes (see below).

All the numerical work to understand formation of satellites during collisions have found triple and multiple systems in their simulations. Durda *et al.* (2004) reported temporary multiple systems, and Leinhardt and Richardson's (2005) reanalysis of a single simulation found 10% triples and 3% quadruple systems that lasted the length of the simulations (days). While triples have now been found among some large systems, longer-term dynamical simulations of their formation and evolution following large impacts would be needed to quantify the match between observations and models.

Catastrophic impact modeling has generally relied on very similar collision scenarios (impact speeds and angles, etc.) to model both the formation of satellites and asteroid families (Michel *et al.*, 2001, 2003; Durda *et al.*, 2004, 2007). While asteroid families are strictly correlated with collisions, it does not mean that the presence of a family demands satellites, as not every collision forms satellites, and small satellites themselves are susceptible to collisional evolution/destruction on timescales shorter than the age of many observed asteroid families (Durda *et al.*, 2004).

### 3.2. Small Systems: Rotational Disruption

Even before the discovery of small binary systems, the doublet craters found on the terrestrial planets (Melosh and Stansberry, 1991; Bottke and Melosh, 1996) and crater chains on the Moon (see Richardson *et al.*, 1998) suggested that there were mechanisms to disrupt small asteroids. The demonstration provided by Comet Shoemaker-Levy 9 and its tidal disruption at Jupiter further instigated models of “rubble-pile” interiors and their tidal disruptions while encountering planetary bodies (Asphaug and Benz, 1996; Richardson *et al.*, 1998).

Bottke and Melosh (1996) suggested that searches for asteroid satellites “place emphasis on kilometer-sized Earth-crossing asteroids with short-rotation periods,” and lightcurve surveys found many interesting targets in this sample. Observations of multi-frequency light curves and possible eclipse/occultation events became common, and gave very strong indications of possible satellites (Pravec and Hahn, 1997; Pravec *et al.*, 1998, 2000; Mottola and Lahulla, 2000). The radar imaging of NEA 2000 DP<sub>107</sub> confirmed that the lightcurve observations were detecting actual satellites (Margot *et al.*, 2002). Combining all possible detections, Margot *et al.* (2002) suggested that up to 16% of the population were binaries and that rotational disruption was a primary culprit (Pravec *et al.*, 1999; Margot *et al.*, 2002; Pravec and Harris, 2007).

Rubble-pile asteroids encountering Earth were studied with a granular dynamics code by Richardson *et al.* (1998) and again by Walsh and Richardson (2006). While both groups found that binaries are at least initially formed following some disruptive tidal event, Walsh and Richardson (2006) found that the primary bodies were typically elongated, the secondaries were on very eccentric orbits, and the primary rotated with a period around 3.5–6 h, rather than the near-critical 2–4-h periods. Walsh and Richardson (2008) took the resulting simulation outcomes and built a Monte Carlo model including the expected time between planetary encounters, expected encounter outcomes, nominal tidal evolution of orbits and primary spin, and observed asteroid shape and spin characteristics. They found that the produced systems are not expected to survive very long, owing to the large semimajor axes and high eccentricities. These works, and the discovery of small binary systems in the main belt (Warner and Harris, 2007) where there is no planetary body to tidally disrupt an asteroid, strongly suggested that tidal disruption is not a primary mechanism. Tidal disruption of NEAs could still account for a small subset of the population, although it is not clear if the elongated primaries and eccentric secondaries could survive long enough to be observed (Walsh and Richardson, 2008).

A more ubiquitous method for rotational disruption of small asteroids is the YORP effect. Rubincam (2000) proposed that the YORP effect could spin centimeter-sized objects so fast that they would eventually burst. Vokrouhlický and Čapek (2002) pointed out that this effect will likely drive asteroids to  $0^\circ/180^\circ$  obliquity end-states and then in many cases of

continued spinup could drive them to “rotational fission.” YORP was connected directly with binary formation in *Asteroids III* (Bottke et al., 2002), where it was proposed as a possible means for forming small binary asteroids and inducing reshaping.

*Ostro et al.* (2006) observed NEA 1999 KW<sub>4</sub> with radar and produced an incredibly detailed shape model of the primary, while *Scheeres et al.* (2006) analyzed the dynamics of the system (see *Fahnestock and Scheeres*, 2008). This system was similar to previously discovered NEA systems — it featured a rapidly rotating primary (essentially at critical rotation rate) and a small secondary on a close orbit just beyond its Roche limit. However, owing to the exceptional resolution of these radar observations, the derived shape model was found to have a bulging equatorial ridge (see Fig. 3).

As part of the dynamical analysis of the system, *Scheeres et al.* (2006) hypothesized that the system disrupted and shed mass due to tidal torques from a planetary flyby or the YORP effect. The primary would have evolved to build the ridge and reach the very rapid rotation rate due to the infall of material that was not accreted/incorporated in the satellite.

Starting with the *Scheeres et al.* (2006) work on the state of the 1999 KW<sub>4</sub> system, and their suggestion that the equatorial ridge could have been formed by the infall of material, this started one of two tracks of thought about the ridge and its formation that were followed up in a number of works (*Scheeres*, 2007b; *Jacobson and Scheeres*, 2011a). These works posited that the mass loss was a more singular catastrophic event — a fission event — and that later processing of this lost mass accounts for the equatorial ridge and other widely observed system properties. At the other end of the discussion, *Walsh et al.* (2008) modeled YORP-spinup of rubble piles made of thousands of constituent particles and

proposed that the equatorial ridge was caused by reshaping of the primary rubble-pile asteroid as a result of spinup and consequent mass loss. In this model the satellite was slowly built in orbit by repeated mass-shedding events.

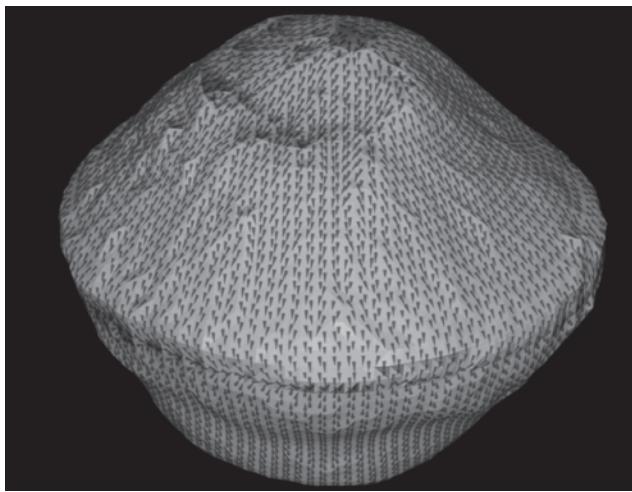

These models in some ways were working from opposite ends of a spectrum of model resolution and techniques. The *Scheeres* (2007b) work focused on the rigid body dynamics of separated contact binaries, and *Jacobson and Scheeres* (2011a) extended this to consider what might happen if the ejected fragment itself was allowed to fragment once in orbit, which is critical to prevent rapid ejection of the fragment, and also whether the infall of some of the material could explain the ubiquitous top-shape primaries. Meanwhile, *Walsh et al.* (2008, 2012) started with model asteroids constructed of thousands of individual solid spherical particles interacting through their gravity and through mutual collisions. While the gravity and collisions of the particles are efficiently modeled throughout the simulations, the timescales for spinup were necessarily shortened for computational reasons and the structure of the body consisted of different, but very simple, size distributions of spherical particles. A valuable test of these different ideas may occur when NASA’s Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) space mission reaches asteroid (101955) Bennu, which shows signs of having an equatorial ridge (*Nolan et al.*, 2013; *Lauretta et al.*, 2014).

All scenarios suffer confusion from new studies of the sensitivity of the YORP effect to very small changes in an asteroid’s shape. Model asteroids were generated, inclusive of small features such as boulders and small craters, and when YORP evolutions were calculated it was found that very small changes on the surface of a small body can dramatically change its YORP behavior (*Statler*, 2009; *Cotto-Figueroa et al.*, 2015). The changes could be so dramatic that nearly any reshaping of a body during its YORP spinup could essentially result in a completely different YORP state. Essentially each shape change, no matter the scale, results in a coin-flip outcome to determine if the body continues spinning up or reverses and spins down.

The population of asteroids with secondaries is ~15% (*Pravec and Harris*, 2007), and so the rotational disruption mechanism appears to be quite efficient. If each movement on the surface of an asteroid results in a coin-flip to determine spinup or spindown, then seemingly bodies would never spin up enough to rotationally disrupt. This perplexing issue may demand some underlying tendency for small bodies to “spin up” by the YORP effect. It is possible that the YORP effect could actually induce preferential spinup for even a symmetrically shaped asteroid, following the “tangential YORP effect,” which may play a big role in understanding these issues (*Golubov and Krugly*, 2012; *Golubov et al.*, 2014).

### 3.3. Split Pairs

The rotational fission hypothesis states that at a critical spin rate an asteroid’s components enter into orbit about

**Fig. 3.** The radar-derived shape model of 1999 KW<sub>4</sub>. The shading indicates local gravitational slopes, with the majority being near 30–40 and the lighter and darker shades at the equator and poles near zero (*Ostro et al.*, 2006; *Scheeres et al.*, 2006).

each other from a state of resting on each other (*Jacobson and Scheeres*, 2011a). The spin energy of the asteroid at this critical spin and any released binding energy is the free energy available to disrupt the asteroid system. Therefore, there is a direct energy and angular momentum relationship between the spin states of the newly formed components and the mutual orbit. From these considerations and some simple assumptions, this theory predicts a relationship between the sizes of the two components and the rotation rate of the larger component. Observations of split pairs directly confirm this theoretical prediction (*Pravec et al.*, 2010). This is powerful evidence that the rotational fission hypothesis is correct for split pairs.

Further observations of split pairs confirm that each member is a good spectroscopic match to the other (*Moskovitz*, 2012; *Duddy et al.*, 2012; *Polishook et al.*, 2014a). Interesting observations that there is no significant longitudinal spectroscopic variations and that the spin axes between members are identical are interesting twists that future theory must account for (*Polishook et al.*, 2014a,b).

#### 4. EVOLUTION OF BINARY SYSTEMS

There are a number of different binary evolution mechanisms. Classical solid body tides are long studied and binary asteroids provide useful test cases. Meanwhile, thermal effects can affect a single body in the system or the pair of bodies. A single body having its spin state changed by a thermal effect can possibly reshape due to its angular momentum increase. Binaries on near-Earth orbits can encounter the terrestrial planets, which can destabilize or otherwise alter a system's mutual orbit, while also distorting or disrupting either component. Finally, an impact can destroy a satellite, remove it from a system, or simply perturb its orbit.

The small number of known large systems are unaffected by many of these evolutionary mechanisms: Their satellites are typically too distant for tides and their sizes too large for thermal effects, and there are no planets in the main belt to perturb them. Meanwhile, the known small systems may be affected by multiple effects simultaneously in ways that are difficult to disentangle. Therefore, the primary set of data used to understand evolutionary effects are the large number of small systems — Groups A, B, and W. The majority of all systems (Group A) look quite similar — they have rapidly rotating primaries, their secondaries just beyond the nominal Roche limit at  $\sim 2.5$   $a/R_p$  (where  $a$  is the semimajor axis and  $R_p$  is the primary radius), and they are between 9% and 58% the size of the primary (typically less than 2–3% of the primary mass). The outliers are a minority, but they and the split pairs point to important evolutionary end-states of the small systems.

##### 4.1. Binary YORP

The theory of binary YORP (BYORP) is a direct extension of the Yarkovsky and YORP effects; instead of modifying the spin state of an asteroid, the BYORP effect modifies the mutual orbit of a double asteroid system in a spin-orbit

resonance, typically the synchronous 1:1 spin-orbit resonance (*Ćuk and Burns*, 2005). Similar to YORP, the back-reaction force from the photon causes a torque, but here the lever arm connects the center of mass of the binary system to the emitting surface element. The back-reaction torques the satellite about this mass center, changing the mutual orbit. Unlike the YORP effect, the relative position and orientation of the emitting surface element can change the mutual orbit's semimajor axis  $a$  with respect to the center of mass of the binary system (unlike a rigidly rotating asteroid in the case of the YORP effect), so only binary members that occupy a spin-orbit resonance have nonzero cumulative BYORP effects; the torques on all binary members outside of spin-orbit resonances cancel out over time.

*Ćuk and Burns* (2005) recognized that this effect could be significant for small asteroids found throughout the binary asteroid population. Most discovered binaries in the near-Earth and main-belt populations have small (radius  $< 10$  km) secondaries, which are tidally locked in a synchronous spin-orbit resonance (*Richardson and Walsh*, 2006; *Pravec et al.*, 2006). From these characteristics and shape estimates, simple estimates scaled from the YORP effect concluded that the BYORP effect is able to significantly modify an orbit in as little as  $\sim 10^5$  yr (*Ćuk and Burns*, 2005; *Ćuk*, 2007; *Goldreich and Sari*, 2009). Secular averaging theory has agreed with these short timescale estimates (*McMahon and Scheeres*, 2010b,a; *Steinberg and Sari*, 2011).

Assuming the smaller secondary is synchronously rotating and expanding the solution to only first order in eccentricity, the secular evolution of the mutual orbit's semimajor axis  $a$ , measured in primary radii  $R_p$ , and eccentricity  $e$  are (equations (93) and (94) from *McMahon and Scheeres*, 2010a, with redefined variables)

$$\frac{da}{dt} = \frac{3H_{\odot}B_s a^{3/2} \sqrt{1+q}}{2\pi\rho\omega_d R_p^2 q^{1/3}} \quad (1a)$$

$$\frac{de}{dt} = -\frac{3H_{\odot}B_s a^{1/2} e \sqrt{1+q}}{8\pi\rho\omega_d R_p^2 q^{1/3}} = -\frac{e}{4a} \frac{da}{dt} \quad (1b)$$

where  $q$  is the mass ratio between the secondary and the primary,  $\rho$  is the density of both asteroids assumed to be the same since they are likely to be of common origin,  $\omega_d = \sqrt{4\pi\rho G/3}$  is the critical rotational disruption rate for a sphere of density  $\rho$ ,  $G$  is the gravitational constant,  $H_{\odot} = F_{\odot}/(a_{\odot}^2 \sqrt{1-e_{\odot}^2})$  is a heliocentric orbit factor,  $F_{\odot}$  is the solar radiation constant, and  $a_{\odot}$  and  $e_{\odot}$  are the heliocentric semimajor axis and eccentricity of the binary asteroid system. Finally,  $B_s$  is the BYORP coefficient of the secondary.

As defined here,  $B_s$  does not depend on the size of the secondary, only its shape relative to its orientation (see *McMahon and Scheeres*, 2010a). The BYORP coefficient can be positive corresponding to outward expansion of the mutual orbit or negative corresponding to inward shrinking. (66391) 1999 KW<sub>4</sub> has the only existing detailed secondary shape model (*Ostro et al.*, 2006), and it has an

estimated magnitude of  $|B_s| \sim 0.04$  (*McMahon and Scheeres*, 2010a, 2012b). Estimates of  $B_s$  from other asteroid shape models and Gaussian ellipsoids suggest that the BYORP coefficients are typically  $|B_s| < 0.05$  (*McMahon and Scheeres*, 2012a). Scaling the (66391) 1999 KW<sub>4</sub> estimate to other binary asteroid systems, *Pravec and Scheirich* (2010) calculated mutual orbit evolution predictions for seven observable binaries: (7088) Ishtar, (65803) Didymos, (66063) 1998 RO<sub>1</sub>, (88710) 2001 SL<sub>9</sub>, (137170) 1999 HF<sub>1</sub>, (175706) 1996 FG<sub>3</sub>, and (185851) 2000 DP<sub>107</sub>. First results regarding (175706) 1996 FG<sub>3</sub> have been reported in *Scheirich et al.* (2015) and are discussed below. Close observations of these candidates over the next few years will test the nascent BYORP theories.

As noticed initially by *Ćuk and Burns* (2005), outward BYORP expansion of the mutual orbit damps the eccentricity. This potentially provides a disruption pathway for binary asteroids. Their orbit can expand until the semimajor axis reaches their Hill radii since outward expansion is a runaway process. If so, then these binaries would become unbound by three-body interactions with the Sun and create asteroid pairs. Unlike most observed asteroid pairs, these would not follow the rotation-size ratio relationship set by immediate disruption after rotational fission (*Scheeres*, 2004; *Pravec et al.*, 2010). No such pairs have yet been identified; however, the expected ratio between pairs formed from fission to those formed from BYORP expansion is high (*Jacobson and Scheeres*, 2011a).

BYORP expansion of the orbit of the secondary will only continue if the rotation of the secondary remains synchronous with its orbital period. However, a numerical experiment by *Ćuk and Nesvorný* (2010) found that the eccentricity may actually increase. Eccentricity growth induces chaotic rotation that is then halted by the BYORP effect, and if the orientation of the secondary is reversed, then the mutual orbit will contract. *Ćuk and Nesvorný* (2010) rule out the role of the evection resonance for responsibility of this eccentricity increase and attributes it to spin-orbit coupling. This disagrees with evolution resulting from the force decomposition and averaged equations (*Ćuk and Burns*, 2005; *Goldreich and Sari*, 2009; *McMahon and Scheeres*, 2010b; *Steinberg and Sari*, 2011). Future work directly comparing long-term evolution of a *Ćuk and Nesvorný* (2010)-type model and the secular evolution equations is needed to determine resolutely the consequences of outward BYORP evolution on eccentricity.

Using the secular evolution equations and including mutual tides, *Jacobson et al.* (2014b) found that outward expansion can be interrupted by an adiabatic invariance between the mutual semimajor axis and libration state of the secondary. As the mutual orbit expands, a small libration can grow until the rotation of the secondary desynchronizes and begins to circulate. This has been proposed as the mechanism by which to explain the small known population of wide binary asteroid systems that are found among NEAs and in the main belt, as this process can leave secondaries stranded so far from the primary to make tidal synchronization timescales very long (*Jacobson et al.*, 2014b). As observations continue

to be made of wide and possibly expanding binaries such as (185851) 2000 DP<sub>107</sub>, the theories regarding expansion due to the BYORP effect will continue to be tested.

The BYORP effect can also shrink orbits and simultaneously increase eccentricity (*Ćuk and Burns*, 2005; *Goldreich and Sari*, 2009; *McMahon and Scheeres*, 2010b; *Steinberg and Sari*, 2011). This will be discussed after describing tides, which are important when considering very tight binary asteroid systems.

## 4.2. Tides

The evolutionary consequences of mutual body tides have been considered for the evolution of asteroids since the discovery of the first asteroid satellite, Dactyl, about (243) Ida (*Petit et al.*, 1997; *Hurford and Greenberg*, 2000). These body tides are the result of the asteroid's mass distribution chasing an ever-changing equilibrium figure determined by the asteroid's spin state and the gravitational potentials of both binary members. Since the relaxation toward this figure is dissipative, energy is lost in the form of heat and removed from the rotation state of the asteroid. The difference in potential between the delayed figure and the theoretical equilibrium figure is referred to as the tidal bulge. This tidal bulge torques the mutual orbit, ensuring conservation of angular momentum within the asteroid system. Unlike lunar tides on Earth, where most of the energy is dissipated at the ocean-seabed interface and in the deep ocean itself (*Taylor*, 1920; *Jeffreys*, 1921; *Egbert and Ray*, 2000), the mutual tides between asteroids do not dissipate energy along an interface or in a fluid layer but rather throughout the solid body. However, new results indicate that tidal dissipation in rubble piles may be much higher (*Scheirich et al.*, 2015) than previously expected (*Goldreich and Sari*, 2009), so where and how tidal energy is dissipated must be examined much more thoroughly in the future.

Under most proposed formation circumstances and observed in nearly all small systems, except for those with synchronous rotations, asteroids rotate at rates greater than their mutual orbit mean motion (*Pravec et al.*, 2006). In this case, the tidal bulge lags behind the line connecting the mass centers of the binary members, and the binary's primary is rotationally decelerated. In this case, the mutual orbit expands, similar to the Earth-Moon system. Alternatively, the tidal bulge precedes the line connecting the two asteroids, and the binary's primary is rotationally accelerated. In this case, the mutual orbit shrinks, similar to the Mars-Phobos system. No observed binary asteroids currently occupy this state. A third tidal state also exists: Librational tides can oscillate through tidally locked binary members. This tide is responsible for removing libration from synchronous satellites. The tidal bulge oscillates from the trailing to leading hemisphere as the secondary librates, so the torque on the orbit cancels out and the orbit does not evolve.

Formally deriving an explicit set of equations to describe these torques has been a focus of research for over a century (*Darwin*, 1879). Historically, most theoretical descriptions

of tides have fallen into two camps, split by their assumptions regarding the relationship between the tidal bulge and the line connecting the mass centers of the two asteroids: (1) Some assume a constant lag angle (*Goldreich*, 1963; *Kaula*, 1964; *MacDonald*, 1964; *Goldreich and Soter*, 1966; *Taylor and Margot*, 2010), and (2) some assume a constant lag time (*Singer*, 1968; *Mignard*, 1979, 1980; *Hut*, 1980, 1981). Neither relationship is expected to accurately reflect potential asteroid rheology (*Efroimsky and Williams*, 2009; *Greenberg*, 2009; *Goldreich and Sari*, 2009; *Jacobson and Scheeres*, 2011c; *Ferraz-Mello*, 2013). Although the constant lag angle is believed to better represent circulating tides through solid bodies, *Greenberg* (2009) describes its shortcomings in vivid starkness. For the sake of this review, we will consider using the theory only for nearly circular orbits and will be careful to state when we feel that this theory may not be adequate. If systems have a nonnegligible eccentricity, the tidal despinning calculated by the first-order theory will be a lower bound, but the effects on the orbital evolution, particularly the eccentricity, are more difficult to determine. For instance, the theories in *Goldreich* (1963) and *Hut* (1981) give different predictions regarding the orbital evolution of asynchronous asteroids depending on orbital parameters.

Constant lag angle tidal theory assumes that the tidal bulge raised by an orbiting companion lags the line connecting the bodies' centers by a constant angle  $\epsilon$ , which is related to a tidal dissipation number  $Q$  via  $Q = 1/2\epsilon$ . The tidal dissipation number quantifies the amount of energy dissipated each tidal frequency cycle over the maximum energy stored in the tidal distortion [for further discussion, see *Goldreich and Soter* (1966), *Greenberg* (2009), and *Efroimsky and Williams* (2009)]. This theory is appropriate for determining the tidal torque on a circulating body, but as the body approaches synchronization and when the body is librating, this theory likely overestimates the actual tidal torque. The circulating tidal torque on a spherical asteroid with radius  $R$  from a perturbing binary member with a mass ratio of  $q$  is

$$\Gamma_C = \frac{2\pi k_2 \omega_d^2 \rho R^5 q^2}{Q a^6} \left( \frac{\omega - n}{|\omega - n|} \right) \quad (2)$$

where the semimajor axis  $a$  is measured in asteroid radii  $R$ ,  $(\omega - n)/|\omega - n|$  indicates the direction of the torque given the spin rate of the asteroid  $\omega$  and the mean motion of the mutual orbit  $n$ , and  $k_2$  is the second-order Love number of the asteroid. The potential Love number  $k$  quantifies the additional gravitational potential produced by the tidal bulge over the perturbing potential. In other words, it captures how much the tidal bulge responds to the deforming potential. We are currently considering only the lowest-order relevant surface harmonic, namely the second [for further discussion of the perturbing potential and its expansion, see *Ferraz-Mello et al.* (2008)]. A perfectly rigid asteroid would have a tidal Love number of 0, whereas a inviscid fluid would have a Love number of 3/2 according to its definition (*Goldreich and Sari*, 2009).

This tidal torque is most applicable to the primary, which is often rapidly rotating compared to the mean motion of the mutual orbit (*Pravec et al.*, 2006; *Richardson and Walsh*, 2006). In the most common case, the secondary is tidally locked and so does not contribute to the evolution of the semimajor axis of the mutual orbit. Given the torque above, the semimajor axis  $a$ , measured in primary radii  $R_p$ , and the primary spin rate  $\omega_p$  evolution are (*Goldreich and Sari*, 2009)

$$\frac{da}{dt} = \frac{3k_{2,p}\omega_d q \sqrt{1+q}}{Q_p a^{11/2}} \quad (3a)$$

$$\frac{d\omega_p}{dt} = -\frac{15k_{2,p}\omega_d^2 q^2}{4Q_p a^6} \quad (3b)$$

where  $k_{2,p}$  and  $Q_p$  are the tidal Love and dissipation numbers for the primary [for higher-order expansions, see *Taylor and Margot* (2010)].

The ratio of tidal despinning timescales for the primary and secondary are

$$\frac{\tau_s}{\tau_p} = \frac{k_{2,p} Q_s}{k_{2,s} Q_p} q^2 \quad (4)$$

where  $k_{2,s}$  and  $Q_s$  are the tidal Love and dissipation numbers for the secondary. Since the mass ratio is often on the order of  $q \sim 0.01\text{--}0.1$ , it is immediately clear that the secondary tidally locks first. It is possible that the ratio of tidal parameters could counteract this; however, both the tidal parameters derived from a modified continuum tidal theory (*Goldreich and Sari*, 2009) and the observed parameters from a hypothetical tidal-BYORP equilibrium (*Jacobson and Scheeres*, 2011c) are consistent with faster tidal synchronization of the secondary,  $\tau_s/\tau_p \propto q^{3/2}$  and  $\tau_s/\tau_p \propto q^{5/2}$ , respectively.

When the mass ratio is nearly equal, tides drive both bodies to synchronization in nearly the same timescale (*Jacobson and Scheeres*, 2011a). From this configuration, where both members are tidally locked, the BYORP effect can expand or shrink the mutual orbit to great affect. Acting independently on each body, in addition to the YORP effect acting on each component, BYORP can effectively transfer angular momentum to the orbit (*Taylor and Margot*, 2014). This could lead to rapid separation (*Jacobson and Scheeres*, 2011a), inward drift leading to unstable configurations (*Bellerose and Scheeres*, 2008; *Scheeres*, 2009; *Taylor and Margot*, 2014), or gentle collisions and contact binaries (*Scheeres*, 2007a; *Jacobson and Scheeres*, 2011a).

Although circulating tides drive the secondary to synchronous rotation, the secondary still has significant tidal dissipation occurring within it due to librational tides. The circulating theory is inappropriate for libration since according to this theory the tidal bulge instantaneously moves across the body. *Mignard* (1979) developed an alternative approach that assumes that the phase lag is proportional to the frequency of the tidal forcing. Here  $\lambda_0$  is the characteristic spin rate at which the body transitions from a circulation torque to the

libration torque or vice versa [where  $\lambda_0$  is related to tidal lag time  $\Delta t$  by  $2Q|\lambda_0|\Delta t = 1$  (*Mignard*, 1979)]. In the tidal torque,  $\lambda_0$  takes the place of  $|\omega - n|$  in the denominator of equation (2). The libration torque is not only appropriate when the system is librating, but also when the system is circulating slowly compared to  $\lambda_0$ . However, this torque becomes inappropriate as the body begins to circulate quickly since the tidal bulge could wrap about the body.

These two theories are actually one and the same if  $\lambda = \omega - n$  when  $\omega - n > \lambda_0$  and if  $\lambda = \lambda_0$  when  $\omega - n \leq \lambda_0$ , in which case  $\lambda$  replaces  $\lambda_0$  in equation (2). This approximate tidal torque can handle both libration and circulation for nearly circular and non-inclined systems (*Jacobson and Scheeres*, 2011a).

### 4.3. BYORP Effect and Tides

The leading hypothesized formation mechanism for Group A binary asteroids is by rotational disruption, which is observed to produce a rapidly rotating primary and a secondary that is quickly tidally locked — the secondary is even predicted to begin rotating more slowly (*Scheeres*, 2007a; *Walsh et al.*, 2008; *Jacobson and Scheeres*, 2011a). When considering this configuration for nearly circular orbits, circulating tides on the primary and librational tides on the secondary contribute to the change in eccentricity of the mutual orbit. Since the libration of the secondary and the mutual eccentricity are coupled (*McMahon and Scheeres*, 2013b), the librational tides on the secondary are often broken into direct librational and radial components (*Murray and Dermott*, 2000). The sum effect of all these tides on the mutual eccentricity is that the eccentricity is always being damped due to the dominance of the librational tides on the secondary, for a wide range of tidal parameters considered (*Goldreich and Sari*, 2009; *Jacobson and Scheeres*, 2011c).

In the singly synchronous configuration — rapidly rotating primary and tidally locked secondary — the mutual orbit of a small binary asteroid can evolve according to both the BYORP effect and tides. While tides in synchronous binary asteroids systems act only to expand the semimajor axis and decrease eccentricity, the BYORP effect can expand or shrink the semimajor axis depending on the shape and orientation of the secondary. In the case of BYORP effect driven expansion, both processes are growing the semimajor axis and both are reducing the eccentricity. As discussed above, this process can lead to disruption at the Hill radius or desynchronization of the secondary, which can strand the mutual orbit at a wide semimajor axis. Alternatively, the BYORP effect and tides can act in opposite directions. These effects drive the semimajor axis to an equilibrium location

$$a^* = \left( \frac{2\pi k_{2,p} \omega_d^2 \rho R_p^2 q^{4/3}}{B_s H_\odot Q_p} \right)^{1/7} \quad (5)$$

This semimajor axis location depends directly on the tidal parameters and the BYORP coefficient. If this location is dis-

tant, then secondaries could be rapidly lost (*Cuk and Burns*, 2005; *Cuk*, 2007; *Goldreich and Sari*, 2009; *McMahon and Scheeres*, 2010a), and the binary formation rate would have to be significant to account for the observed ~15% fraction (*Cuk*, 2007). Alternatively, the proposed equilibrium of tides and BYORP prevents this rapid destruction of systems and no longer requires binary formation rates to match potentially very fast BYORP disruption rates (*Jacobson et al.*, 2014c).

A prediction for occupying this equilibrium is that the semimajor axis should not be changing significantly. While measured changes in the semimajor axis or orbital period require precision that is currently unobtainable, a change in the semimajor axis does lead to a quadratic drift in the mean anomaly (*McMahon and Scheeres*, 2010a), which can be measured very precisely through the timing of mutual events in photometric light curves. A large survey has been undertaken to examine whether these drifts occur (*Scheirich and Pravec*, 2009). The first results from this survey find no drift in mean anomaly for NEA binary (175706) 1996 FG<sub>3</sub> (*Scheirich et al.*, 2015), which may point to this equilibrium.

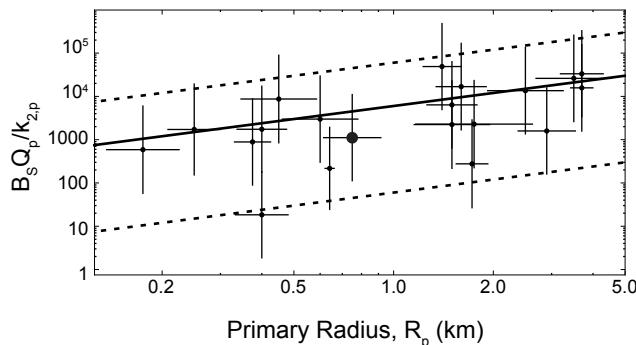

If the singly synchronous binary population occupies this equilibrium, then we are able to learn about the internal properties of asteroids only from remote sensing measurements (*Jacobson and Scheeres*, 2011c); however, the tidal and BYORP coefficients are degenerate

$$\frac{B_s Q_p}{k_{2,p}} = \frac{2\pi \omega_d^2 \rho R_p^2 q^{4/3}}{H_\odot a^7} \quad (6)$$

This parameter relationship is shown in Fig. 4 along with a fit to the data:  $B_s Q_p / k_{2,p} = 6 \times 10^3$  (R<sub>p</sub>/1 km). As discussed above, estimates for the BYORP coefficient are around  $B_s \sim 0.01$  (*Cuk and Burns*, 2005; *Goldreich and Sari*, 2009; *McMahon and Scheeres*, 2010a, 2012a). From the data, the tidal parameters then follow:  $Q/k_2 = 6 \times 10^5$  (R<sub>p</sub>/1 km), very different than the  $Q/k_2 \gtrsim 10^7$  (1 km/R<sub>p</sub>) predicted from a modification of the continuum theory for rubble-pile asteroids (*Goldreich and Sari*, 2009).

*Taylor and Margot* (2011) predict tidal properties by assuming a tidal evolutionary path from twice the primary radius to the current orbital separation in under a certain timescale. For (175706) 1996 FG<sub>3</sub>, they estimate that  $Q/k_2 \approx 2.7 \times 10^7$  in order to migrate from 2 to 3.6 primary radii in 10 m.y. Using the new estimate of the tidal parameters from *Scheirich et al.* (2015),  $Q/k \approx 2.4 \times 10^5$  and this same tidal migration (assuming no influence from the BYORP effect) could take place in  $5.6 \times 10^4$  yr. This much higher rate of tidal dissipation or much larger tidal Love number can only be consistent with a tidal rheology very different than that for terrestrial planets and moons. Furthermore, the equations that convert the tidal Love number to a rigidity or elastic modulus, often denoted  $\mu$ , assume a continuum model that may not apply for this rubble-pile tidal rheology.

So far, the discussed tidal theory assumes that all the rotation axes are aligned and that the mutual orbit is nearly circular. If this is not the case, then the tidal bulge can have a

**Fig. 4.**  $B_s Q_p / k_{2,p}$  were calculated directly from observed quantities according to equation (6) for each known synchronous binary, and plotted as a function of primary radius  $R_p$  along with  $1\sigma$  uncertainties. The large circle in the center highlights the binary (175706) 1996 FG<sub>3</sub>. All the data is from <http://www.asu.cas.cz/asteroid/binastdata.htm>, maintained by P. Pravec according to Pravec et al. (2006). The solid line is a fitted model to the data:  $B_s Q_p / k_{2,p} = 6 \times 10^3 R_p$ . The dashed lines indicate the range of predicted scatter in the model due to the BYORP coefficient (possibly 10x stronger or 100x weaker). Reproduced with some updated binary parameters from Jacobson and Scheeres (2011c).

significant effect on the mutual orbit and rotation state of the asteroid. The differences between the different tidal theories become more extreme, and they differ by more than a matter of magnitudes, but also of direction. This is an ongoing area of active research, with new tidal theories being developed to eventually accurately describe asteroid lithologies (Goldreich and Sari, 2009; Efroimsky and Williams, 2009).

A separate tidal effect relies on “tidal saltation,” or the physical lofting of material off the surface of the primary. The very rapid, near critical, rotation of the primary permits the very small perturbations of the secondary to loft debris off the primary’s equator (Fahnestock and Scheeres, 2009; Harris et al., 2009), and during flight angular momentum is transferred from the debris to the orbit of the secondary. This expands the orbit of the secondary at rates that could potentially compete with tidal forces. Given the direct physical alteration of the primary by the repeated lofting and landing of particles on the equator, this theory provides an interesting observational test for future observations of equatorial ridges on NEAs.

#### 4.4. Asteroid Reshaping

If the asteroids were simply fluids, then they would follow permissible shape and spin configurations that have been studied by many, including Newton, Maclaurin, Jacobi, Poincaré, Roche, and Chandrasekhar. Observations of asteroids clearly show that they are not fluids, and their distribution of shape and spin configurations agree (Pravec et al., 2002). Observations also suggest that they are not simply monolithic rocks.

Rather, the population of small asteroids ( $D < 10$  km) are thought to be primarily gravitational aggregates consisting

of small bodies held together almost strictly by their self-gravity. Numerous observations and models contribute to this line of thought, including not only their spin and shape distributions, but also observations of crater chains on the Moon, the breakup of Comet Shoemaker-Levy 9, the very large observed impact crater on the large primitive asteroid (253) Mathilde, and, of course, the striking images of the small asteroid (25143) Itokawa. These arguments were last summarized in *Asteroids III* by Richardson et al. (2002), and the chapter by Scheeres et al. in this volume reviews our general knowledge of asteroid interiors.

Efforts to understand asteroid shape and spin configurations borrow cohesionless elastic-plastic yield criteria from soil mechanics (Holsapple, 2001, 2004; Sharma, 2009). These formulations calculate envelopes of allowable spin and shape configurations as a function of the material properties — typically relying on an angle of friction as the critical parameter. Neither cohesion nor tensile strength is required to explain the shapes and spins of nearly all large ( $D > 200$  m) observed asteroids (Holsapple, 2001, 2004), although the spins and shapes do not rule out any material strength either.

What about cohesion? Multiple recalculations of allowable spin rates as a function of cohesive forces find that even very small amounts of cohesion can dramatically change the allowable spin rates for a body. Even amounts as low as 100 Pa allow for kilometer-sized asteroids to rotate much faster than the observed 2.3–4-h limit (Holsapple, 2007; Sánchez and Scheeres, 2014). Only a single body is observed to be larger than 200 m and rotate faster than 2.3–4 h (Warner et al., 2009).

Rozitis et al. (2014) combined measurements of Yarkovsky drift and thermal properties to estimate the density of a kilometer-sized NEA, 1950 DA. Measurements of this asteroid’s spin rate find that it is rotating faster than what simply gravity and friction would allow, and thus it must have nonzero cohesive strength to prevent disruption. As pointed out by Holsapple (2007), very small amounts of cohesive strength are needed to allow bodies to rotate faster than the classical spin limits. Hirabayashi et al. (2014) estimated between 40 and 210 Pa for the cohesive strength of main-belt comet P/2013 R3, and Rozitis et al. (2014) estimated only  $64^{+12}_{-20}$  Pa of cohesive strength of (29075) 1950 DA. This amount of cohesion is in line with the predictions for cohesion produced by fine grain “bonding” larger constituent pieces of an asteroid (Scheeres et al., 2010; Sánchez and Scheeres, 2014), and would be similar to what is found in weak lunar regolith (see the chapter by Scheeres et al. in this volume).

The exciting radar-produced shape model of 1999 KW<sub>4</sub> showed that the asteroid shape held more information than could be contained in a simple triaxial ellipsoid model (Ostro et al., 2006). The equatorial bulge seen in those radar shape models became ubiquitous among primaries of other rapidly rotating asteroids (see the chapter by Margot et al. in this volume). A simple rigid ellipsoid that increases its angular momentum will drive surface material toward its equator, and this happens before the material would simply become

unbound (*Guibout and Scheeres*, 2003). This suggests that shape change would precede mass loss if there is loose material available.

Basic granular flow models can estimate what shapes the body might actually take. As the spin rate increases, the effective slope angle on the surface changes owing to the increased centrifugal force, and as slopes become higher on certain regions of the surface they can surpass critical values (angle of repose or angle of friction) and fail. After failing, material will flow “down” to the potential lows near the equator, settling in at lower slopes. This model found a surprisingly good match for the equatorial ridge shape of 1999 KW<sub>4</sub>, using an angle of failure of 37° (*Harris et al.*, 2009). The failure causes very regular slopes through mid-latitudes on nearly circular bodies, a trait clearly observed in the shape of 1999 KW<sub>4</sub> (*Harris et al.*, 2009; *Sánchez and Scheeres*, 2014; *Scheeres*, 2015).

Discrete particle approaches to modeling rubble-pile interior structure and evolution rely on N-body billiard-ball-style granular mechanics. Many of the first models of rubble-pile dynamics, tidal disruption, and spin/shape configurations relied on hard spherical particles that never overlap or interpenetrate (*Richardson et al.*, 1998, 2005). While these “hard-sphere” incarnations of the models did not directly account for friction forces, *Richardson et al.* (2005) showed that standard hexagonal closest packing configurations of the spheres produce enough shear strength so that modeled bodies can maintain spin and shape configurations within ~40° angle-of-friction-allowable envelopes produced by *Holsapple* (2001). While different and more simplistic than the “soft-sphere” representations used to model rubble-pile asteroids (*Sánchez and Scheeres*, 2011, 2012; *Schwartz et al.*, 2012), the modeled aggregates can hold shape and spin configurations similar to those observed on actual asteroids (see Fig. 10 of *Walsh et al.*, 2012). Further detail can be found in the chapter by Murdoch et al. in this volume.

When a rubble-pile asteroid is slowly spun up by the YORP effect, it can eventually be pushed to mass loss (*Rubincam*, 2000; *Vokrouhlický and Čapek*, 2002; *Bottke et al.*, 2002). If the asteroid is made of only a very few constituent pieces than they will reconfigure and eventually separate (*Scheeres*, 2007b). What happens to those two components is a complicated dynamical dance that involves angular momentum transfer due to nonspherical shapes (*Scheeres*, 2007b; *Jacobson and Scheeres*, 2011a).

When the asteroid is made of thousands of particles, different evolutions are found for different particle surface interactions. The “hard-sphere” models include dissipation of energy during collisions, but have to rely on structural packing (crystalline) to provide shear strength rather than surface friction (*Walsh et al.*, 2008, 2012). These models found that model asteroids can maintain oblate shapes at critical rotation rates, which leads to equatorial mass-shedding. While it was hypothesized that this could lead to in-orbit growth of the satellite (*Čuk*, 2007; *Walsh et al.*, 2008), it is clear from the dynamics of such close orbits (*Scheeres*, 2009; *Jacobson and Scheeres*, 2011a) that to avoid almost immediate ejection

from the system, many particles would have to be shed at the same time in order to collide, circularize, and stabilize their orbits beyond the Roche limit.

*Sánchez and Scheeres* (2011, 2012) utilized “soft-sphere” granular models, which allow for more complex surface interactions, including various friction forces and inter-particle cohesion. These works explore a wider range of parameters and find a large variety of outcomes, including “fission” events of bodies splitting into nearly equal parts. There is still a strong dependence on the angle of friction for the outcome, with some of the observed oblate-shaped and critically rotating outcomes observed.

Observed mass-loss events have been associated with YORP-induced rotational fission (*Jewitt et al.*, 2013, 2014, 2015; *Sheppard and Trujillo*, 2015). The rotation period of (62412) 2000 SY<sub>178</sub> is only 3.33 h (*Sheppard and Trujillo*, 2015). Minor components outside of the dust are difficult to observe, and the shape of the primary is impossible to deduce. Future observations are necessary to determine whether the dust is associated only with surface failure or satellite formation in these cases.

#### 4.5. Kozai and Planetary Encounters

Most secondaries in NEA systems are too close to their primary to experience excursions in eccentricity or inclination due to the Kozai effect (*Fang and Margot*, 2012c). For more distant NEA systems, such 1998 ST<sub>27</sub> at a ~16 R<sub>pri</sub>, the Kozai effect could play a role of disrupting systems or driving them to collision and possibly creating contact binaries (*Fang and Margot*, 2012c).

Binary systems in the main belt do not encounter planets, but those on near-Earth orbits can have encounters with terrestrial planets close enough to alter or disrupt their systems (*Farinella*, 1992; *Farinella and Chauvineau*, 1993; *Walsh and Richardson*, 2008; *Fang and Margot*, 2012a). The timescales for encounters close enough to disrupt or disturb a system depend on its heliocentric orbit (how frequently it approaches a planet), and also depend strongly on the system’s properties — primarily the separation of the primary and secondary. Disruption of a typical system with  $a = 4 R_{\text{pri}}$ , where  $a$  is semimajor axis and  $R_{\text{pri}}$  is the primary’s radius, becomes significant (50% of encounters randomized over phasings) at encounters of 3 R<sub>⊕</sub>, which occur on average every 2 m.y. for NEAs (*Walsh and Richardson*, 2008). Planetary flybys may also stymie other evolutionary effects, such as BYORP, by either torquing the secondary and breaking its synchronous rotation, or by exciting its orbital eccentricity (*Fang and Margot*, 2012a). Eccentricity of 0.2 can be excited for a similar  $a = 4 R_{\text{pri}}$  system at only 8 R<sub>⊕</sub>, which happen every ~1 m.y. on average for NEAs (*Walsh and Richardson*, 2008; *Fang and Margot*, 2012a).

### 5. THE FUTURE

The advances made in the last decades have been driven by the increased database of known binary systems and the

mounting evidence and measurements of thermal effects acting widely in the solar system. Naturally, many questions remain, and we are optimistic that the trajectory of current studies is well aligned to answer many of the outstanding questions. We roughly outline the expected progress, discoveries, and events that we think will be the focus of an *Asteroids V* chapter on this topic in a decade.

1. More observations from a variety of sources will help to expand the catalog of rare and outlier populations. Large-scale surveys should provide a flood of data and continue to increase the size of our catalog [e.g., Gaia and the Large Synoptic Survey Telescope (LSST)]. While observations from small telescopes, including significant contributions from amateurs, have been the basis of many lightcurve discoveries of small systems, some of the high-cadence all-sky-survey telescopes may begin to eclipse the production of the network of small telescopes.

2. The nondetection of BYORP at 1996 FG<sub>3</sub> is curious and possibly revealing (Scheirich *et al.*, 2015). While there is a proposed theory to explain why and how the effect may be balanced by tides (Jacobson and Scheeres, 2011a), and other nontidal effects may be similarly important (Fahnestock and Scheeres, 2009; Harris *et al.*, 2009), a nondetection is not a detection, and the community awaits a measurement of this interesting thermal effect. A system with a more distant companion, or perhaps one of the triple systems, may allow for a detection in an environment where tides are small and BYORP is strong (Pravec and Scheirich, 2010). The BYORP effect may be a fundamental and dominating mechanism that is widely shaping the observed population of small binary asteroids — so observing it in action will be a great step forward.

3. There are spacecraft visits planned to asteroids with “top shapes.” The KW<sub>4</sub> shape (or top shape) that is becoming ubiquitous in shape models of the primaries of binary systems was a revealing discovery in this field. Hopefully careful mapping and geologic studies of these systems will reveal how small asteroids become that particular shape. In turn, knowing how the ridge formed might help researchers answer the many remaining questions about the formation and evolution of the satellites that are so often found around these top-shaped bodies. The currently planned space missions from NASA and the Japan Aerospace Exploration Agency (JAXA), OSIRIS-REx and Hayabusa-2 respectively, are each currently seeking to visit primitive NEAs, and each target appears to show some signs of an equatorial ridge (Nolan *et al.*, 2013; Lauretta *et al.*, 2014). It is hoped that the mission surveys of the asteroid surface will elucidate the reshaping histories of these bodies by showing signs of material flow patterns, variations in ages of different surface features, and material differences in different geologic units.

---

Hayabusa was the first asteroid sample return mission. It was launched in May 2003, and arrived at the target asteroid (25143) Itokawa in September 2005. The mission enabled us to see close up a very tiny asteroid in detail for the first time. Hayabusa observed Itokawa with its scientific instruments, and attempted to collect surface material. The mission experienced several serious problems, but successfully returned to Earth in June 2010. After retrieving the capsule, we found thousands of small grains that had been captured from the asteroid. We studied Itokawa in detail with both the remote sensing data and the returned samples, which revealed a great deal of new information to shed light on its origin. In this chapter, we review the Hayabusa mission and summarize the scientific results.

## 1. INTRODUCTION

Hayabusa, the world's first asteroid sample return mission, was built and launched by the Institute of Space and Astronautical Science (ISAS), which was later merged with the Japan Aerospace Exploration Agency (JAXA). The project code name was MUSES-C, and after launch in May 2003 was given the name "Hayabusa," which literally translates to "falcon." Hayabusa arrived at its target asteroid in September 2005, and returned to Earth in June 2010. The main purpose of the mission was to demonstrate the key technologies required for future planetary missions. Hayabusa made a roundtrip flight to a celestial object outside of Earth's gravity sphere. The voyage, however, entailed many hardships, most of which were not anticipated before launch, but Hayabusa successfully returned surface material from the asteroid.

Hayabusa was also the first spacecraft to explore a sub-kilometer-sized asteroid. The target asteroid was the S-type near-Earth asteroid (25143) Itokawa, about 500 m in length. Hayabusa revealed the strange nature of Itokawa by observing it with its remote sensing instruments in 2005. Although the amount of sample from Itokawa was quite small, the analyses of the returned samples have been continued worldwide after the capsule returned to Earth in 2010, and much new information has been gained from this sample analysis.

In this chapter, we first explain the mission description as originally conceived and provide a flight summary, including what anomalies occurred and how the project team coped with those anomalies during the flight. The science results are then summarized in section 3 for remote sensing observations and in section 4 for sample analyses.

## 2. HAYABUSA MISSION DESCRIPTION AND FLIGHT RESULTS

### 2.1. Mission Objectives

The Hayabusa project was primarily a technology demonstration for future sample-return attempts from primitive bodies such as comets and asteroids (Kawaguchi, 1986, 2003; Kawaguchi et al., 2002).

The spacecraft lifted off on May 9, 2003, onboard an M-V vehicle from Uchinoura, Japan. It performed an Earth swing-by the following May. The mission plan adopted by Hayabusa was a little different from that taken by such missions as Rosetta, whose efforts were concentrated on the *in situ* analysis of the surface material of a comet. Instead of delivering the analysis equipment, the Hayabusa project intended to return a small amount of the surface sample to Earth, where large state-of-the-art facilities are available for detailed analysis. According to the original scenario, the spacecraft was to jettison a small reentry capsule in June 2007, when it would have returned back to Earth. The flight period scheduled was approximately four years. However, as this chapter describes later, due to unexpected incidents, the flight was extended and it actually returned home on June 13, 2010, resulting in a flight duration of seven years.

Hayabusa carried five key technology objectives to be demonstrated: (1) interplanetary cruise via ion engines as primary propulsion, (2) autonomous navigation and guidance using optical measurements, (3) sample collection from the asteroid surface under microgravity, (4) direct reentry for sample recovery from interplanetary orbit, and (5) combination of

low thrust and gravity assist. In addition to these, Hayabusa also carried other new technologies, such as a bi-propellant small thrust reaction control system (20N), X-band up/down communication, complete Consultative Committee for Space Data Systems (CCSDS) packet telemetry, duty guaranteed heater control electronics, wheel unloading via ion engines, pseudo-noise (PN) code ranging, lithium ion rechargeable battery, multi-junction solar cell, etc.

The development of Hayabusa was proposed to the government in 1995, and the project began in 1996. The original target asteroid was the near-Earth asteroid (4660) Nereus and the backup target was another near-Earth asteroid, (10302) 1989 ML. However, when the spacecraft development started, the project faced mass capability issues and Nereus was replaced by 1989 ML as the primary target body. In 2000, a launch mishap occurred as the result of a launcher propulsion element flaw. As a result, the launch of MUSES-C was shifted half a year and the target asteroid was again switched to a different object, the near-Earth asteroid (25143) 1998 SF<sub>36</sub>, which was renamed Itokawa after Hayabusa's launch. It should be noted that there were only a very few objects for which sampling and return opportunities were possible. While there were a great number of known asteroids, the number of those for which a low-energy mission scenario could be employed was approximately 10 to 20.

In contrast to Nereus and 1989 ML, the new mission target was found to be accessible only via an Earth gravity assist due to the low thrust propulsion of the spacecraft. This technique is what is known as the Electric Delta-V Earth Gravity Assist (EDVEGA) strategy, and was first devised by the ISAS of JAXA. It is the most efficient way of accelerating a spacecraft from Earth when electric or low-thrust propulsion is used. The Hayabusa spacecraft was the first demonstration of the EDVEGA technology (Kawaguchi *et al.*, 2004). The first year after launch was devoted to acceleration in the vicinity of Earth. The EDVEGA phase was followed by the transfer phase, which took approximately one year, and the spacecraft arrived at asteroid Itokawa in the summer of 2005 (Fig. 1). The spacecraft's return was originally planned to occur in June 2007, and the mission should have been completed in four years. However, as a result of numerous difficulties, the flight was extended to seven years and it finally returned in June 2010.

## 2.2. The Hayabusa Spacecraft System

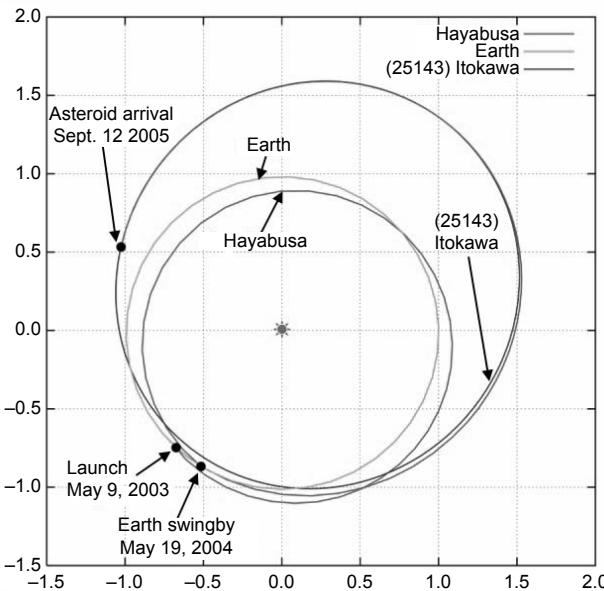

**2.2.1. Configuration.** Hayabusa was a small probe whose dimensions were 1.0 m × 1.6 m × 1.1 m, with a total weight (wet mass) of 510 kg, including 70 kg of chemical fuel for the reaction control system (RCS) and 60 kg of Xe propellant for the ion engines. The relatively large solar array generated 2.6 kW of electric power at Earth. The top and bottom views of the Hayabusa spacecraft are shown in Fig. 2. It was a three-axis stabilized spacecraft with a fixed high-gain antenna (HGA) and solar array panel (SAP). Most of the instruments were on the bottom of the spacecraft so they could be pointed to the asteroid surface when the spacecraft descended and

touched down on the surface. The ion engine thruster apertures were located on a side panel (+X panel), while the reentry capsule and star tracker were on the -X panel.

The ion engine system adopted consisted of four thruster heads located on a two-axis gimbal plate so that the thrust could always penetrate the center of gravity and the attitude could eliminate the disturbance torque. On both ±X panels there were medium-gain antennas (MGA) that enabled the spacecraft to communicate with ground stations while the ion engines were turned on, and the HGA was not pointed to Earth. There was a sample collection horn that extended down from the -Z panel. The -X panel was the surface that was not supposed to be illuminated by the Sun, while the +X panel could be exposed to the Sun to a certain extent. The HGA was basically the same as that on the ISAS Mars Exploration spacecraft Nozomi, and its diameter was 1.6 m. The communication system adopted X-band for both up and down links. During the EDVEGA phase, since the distance from the Sun decreased below 1 AU, the HGA was painted white for thermal control. There was a Sun angle sensor and a low-gain antenna (LGA) at the top of the HGA.

**2.2.2. Special ion engines adopted.** The special characteristics of the ion engines onboard Hayabusa were (1) the use of microwave discharge to generate plasma and (2) the use of a carbon-carbon (CC) composite for the grids. Since there were no electrodes in the system, the life of the thruster was greatly extended to 18,000 hours.

**2.2.3. Autonomous descent and touchdown.** When the spacecraft made its initial approach to the surface of Itokawa, it jettisoned a target marker that served as an artificial landmark, illuminated by a flash lamp onboard the spacecraft once every second so that the optical navigation camera (ONC) could detect the marker by subtracting two images,

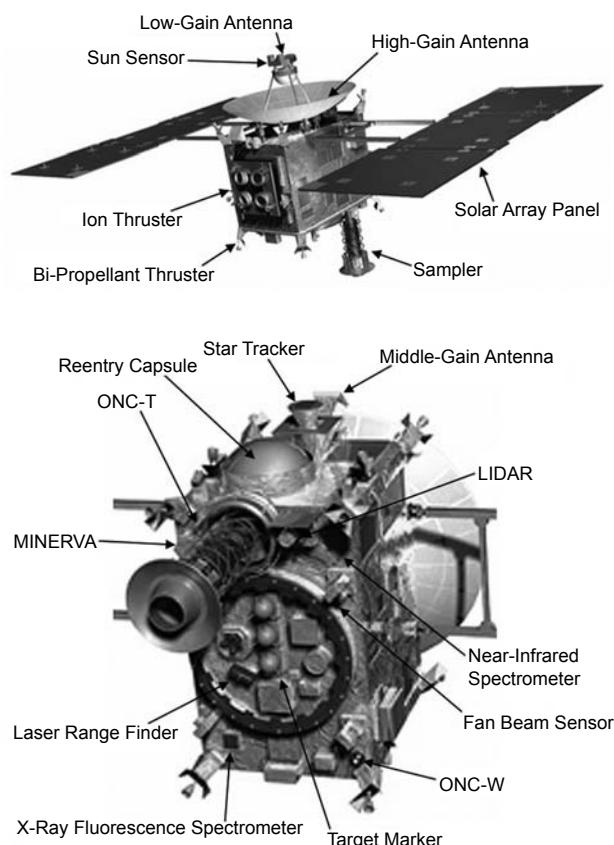

**Fig. 1.** Orbit of Hayabusa from launch to asteroid arrival. The EDVEGA phase was from launch to Earth swingby, and the transfer phase was from Earth swingby to asteroid arrival.

one that was illuminated by a lamp and the other that was not illuminated. The primary purpose of the target marker was to enable the spacecraft to autonomously identify lateral velocity. As is often the case with soft landing, the horizontal velocity detection and control is always key, while the vertical navigation and control is less difficult. The spacecraft then stopped RCS firings and touchdown was performed in a free-fall manner in order to avoid surface contamination.

**2.2.4. Sample collection device.** The sample collection was designed to be performed in a very unique manner, and depended upon the motion of fragments when a projectile impacts a surface in a vacuum in microgravity. The mission designers decided to avoid the problems of anchoring and drilling. Instead, the Hayabusa mission adopted ejecta collection via a projectile shot, which can cope with a variety of surface conditions, even sand, and collect sufficient samples for detailed analysis in a rapid manner.

In the adopted sampling technique, the ejected fragments are guided through a funnel-like device, the sampler horn. The device was deployed immediately after the spacecraft was in orbit. The length of the horn was  $\sim 1$  m, sufficient to prevent the tip of the SAP from hitting the asteroid's surface. The design called for the ejected sample to reach the canister, which would be pushed into the reentry capsule for recovery. The expected collected sample amount was approximately less than 1 g. The main advantage of sample return is that a very small sample is adequate.

**Fig. 2.** Diagram of the Hayabusa spacecraft and its instruments.

**2.2.5. Sample recovery capsule and its operation.** When the spacecraft returned to Earth, since the trajectory's incoming asymptote would point to the southern hemisphere so that the reentry flight path angle remained shallow, the reentry point needed to be in the southern hemisphere. Otherwise, the reentry would become steep and the heat flux experienced would become too high for successful recovery. As a result, the recovery location was situated in the Woomera Prohibited Area in Southern Australia.

The diameter of the capsule was 400 mm and weighed about 20 kg. The reentry capsule consisted of the thermal protection shield, structure, sample container, and sequencer, including the beacon transmitter. The heat shield shells consisted of forward and aft shells that were designed to be separated from the instrument section when the parachute deployed. The development of the heat shield was one of the most critical issues in the Hayabusa project. ISAS built an arc-heating test facility and also performed heating experiments at the NASA Ames Research Center in collaboration with NASA.

### 2.3. Summary of Incidents and Difficulties

The spacecraft was launched in May 2003. From the beginning, the flight was not easy and experienced many unfortunate events. The spacecraft experienced the largest solar flare that had ever happened, consequently resulting in degradation of a solar cell, eventual loss of two out of the three reaction wheels, a fuel gas eruption and consequent loss of attitude, loss of communication with the ground for seven weeks, loss of the lithium ion battery during loss of attitude, loss of the onboard chemical engines, the gradual loss of ion engines and loss of three out of the four neutralizers, and failure of the sample collector. The most significant critical events occurred when the spacecraft got lost after the completion of the second touchdown to the surface of asteroid Itokawa at the end of 2005, and when the spacecraft's ion engine shut down due to the end of life associated with the neutralizer six months prior to the return to Earth.

**2.3.1. Proximity operation and descent and touchdown sampling.** After the spacecraft arrived at the home position located 20 km above the asteroid's surface, the spacecraft conducted a mapping and imaging operation for more than a month. The spacecraft utilized asteroid gravity along with RCS firings to move up and down and side to side. Shape modeling of the asteroid was done during this period.

The spacecraft then performed practice descent maneuvers to practice and confirm the touchdown scenario. During this period the spacecraft released a surface robot, the Micro/Nano Experimental Robot Vehicle Asteroid (MINERVA), aiming it at the asteroid's surface. However, due to the very subtle but inaccurate ground-control operation, MINERVA was not accurately released, and it was traveling away from the asteroid. Thus the MINERVA operation largely failed, but the relay capability was successful and a photo of the solar paddle of Hayabusa taken by MINERVA was relayed back to the ground.

A sophisticated autonomous maneuver was successfully performed when Hayabusa performed its first touchdown attempt on November 20, 2005. At the first touchdown, after releasing a target marker, the spacecraft detected the marker and everything seemed ready for shooting a projectile. However, the spacecraft-carried obstruction detection sensor detected a reflection from some small particles, probably aloft above the surface, and the sample collection shot was not directed. The spacecraft bounced a few times and it settled down on the surface near the polar region waiting for commands from the ground for almost 30 minutes. The spacecraft lifted off when the emergency lift command was sent from the ground.

The second touchdown was attempted on November 25, 2005. During this attempt, a new target marker was not deployed because of the possibility that the spacecraft could detect two target markers at the same time, resulting in confusion. The guidance accuracy was well developed and the expected landing accuracy was sufficiently high. The spacecraft clearly photographed the target marker placed one week before when the spacecraft made its first touchdown (Fig. 3). The spacecraft touched down as planned and the projectile shot was directed from the inboard computer, and the sampling was thought at first to have been performed perfectly. However, it was revealed later that the shooting pyro control circuit was turned to safe mode and the projectile was not fired. Fortunately, the recovered capsule carried back many particles that must have been caught by static electricity when the spacecraft descended to the surface two times.

**2.3.2. Leak of reaction control system fuel.** When the spacecraft made a successful landing on the surface and lifted off from there on November 25, 2005, firing RCS thrusters on the top panel to decelerate the ascent speed, one of the thrusters began leaking fuel. This caused the

spacecraft to be placed in safe-hold mode. All the hydrazine leaked out, and the RCS became unusable for the remainder of the mission. Another large gas eruption made the spacecraft tumble, and beginning in December 2005, radio communication was lost for seven weeks.

### 2.3.3. Resumption of communication and restoration.

The tumbling precluded solar power and the spacecraft power was turned completely off. The onboard battery probably maintained the system for approximately 40 minutes, but it was probably dead after that. The project team developed a rescue operation plan to wake up the spacecraft. Fortunately, the spacecraft was designed to settle into a single spin motion around the maximum moment of inertia, the Z-axis. Once the gas eruption stopped, the attitude settled into a single spin whose rotation axis was fixed to a particular direction with respect to the background sky. There was a chance for the spacecraft to acquire solar power together with the omni-antenna aperture open toward Earth. The probability of this was calculated to be up to 60–70% during the following year. The project team devised the operation so that the command could be heard at any high spin rate, at any attitude, regardless of any antenna profile gaps. The ground team continued to monitor the spacecraft, hoping to receive any signal. The miracle occurred at the end of January 2006, when a carrier signal was finally received by JAXA's deep space antenna. The spacecraft was rotating in the opposite spin direction because of the gas eruption torque. The spin rate was high, and the radio signal was intermittent.

**2.3.4. Recovery operation.** The project team began recovery operations immediately. The biggest challenge was how to reorient the spacecraft attitude to Earth with the lowered spin motion. The operation started by initial Sun acquisition using the coarse Sun sensor. Ion engines were used to decelerate the spin motion by exhausting Xe gas with no electric acceleration. It took five months to properly correct the spacecraft attitude. There was the constant threat of loss of solar power, since the spacecraft spin direction was frozen in the inertial frame and the Sun direction shifts 90° over three months. The operation also had severe time constraints, and thus the project team gave up on the goal of the spacecraft returning in 2007. Instead, the project team amended the flight sequence, and decided to have it return in 2010.

**2.3.5. Auto-Sun tracking with no fuel.** While the spacecraft was restored and telemetry was again being received, the biggest anticipated obstacle was how to perform the attitude control to make sure the spacecraft was appropriately pointed toward the Sun while at the same time making sure that the apertures of its ion engines are properly pointed to the intended direction with no fuel. Hayabusa was equipped with ion engines independent of RCS and carried an additional propulsion system, even though the thrust was very weak and was never really intended for impulsive maneuvers. With the gimballed table on which ion engines were mounted, the angular momentum of the spacecraft was managed in the Y- and Z-axes. Since the ion engine thrust was along the X-axis, no propulsion torque was available

**Fig. 3.** Hayabusa's shadow on the surface during the second touchdown. The white dot in the circle is the target marker released during the first touchdown.

around that axis, and therefore the project team came up with another new strategy. It used solar radiation torque to maintain the spacecraft spin direction, keeping it automatically pointed toward the Sun like an arrow in the wind.

**2.3.6. Ion engine end of life and cross-connection of engines.** The spacecraft's ion engine drive performed successfully from 2007 to till 2009. However, the engines reached the end of their life in November 2009, when all four engines became inoperable due to the death of the neutralizers. Among the four engines, three neutralizers were broken and it was therefore not possible to extract electrons from them. However, there was a single intact neutralizer left, Neutralizer A. Engine A had remained undriven since launch, since a problem was discovered in its radio frequency cable, and the ion source A did not work well and had been left unused. Engine A was still not usable, but the decision was made to use its neutralizer combined with ion sources B, C, and D, even though the engines were not designed to function in such a cross-connection configuration. Thus the project team found that they could successfully drive engine B with neutralizer A, which allowed was a miraculous restoration of the propulsion system.

**2.3.7. Guidance via ion engines.** The consecutive ion engine cruise lasted until the end of March 2010. The reentry required accurate trajectory corrections. These were applied in five segments, from April to June 2010, with the goal of reentry on June 13, 2010. The trajectory correction maneuvers (TCMs) actually took 250 h 46 min 40 s just for  $13.54 \text{ m s}^{-1} \Delta V$ . There was a stringent attitude constraint in Hayabusa. The ion engine heads were aligned to the X-axis only, while the power source solar array panels were fixed to the Z-axis. Orbital control via ion engines only was a big challenge.

**2.3.8. Capsule reentry and recovery.** The project team had performed the successive TCMs via ion engine operation. The final maneuver, TCM 4, was performed to accurately target the touchdown point within the recovery area where the ground staff was deployed to locate the capsule landing point via radio signal. The anticipated accuracy was within several kilometers.

On June 13, 2010, Hayabusa returned to Earth, and a small reentry capsule containing the asteroid sample separated from the spacecraft three hours prior to its own reentry. Hayabusa plunged into the atmosphere over the Australian desert (Fig. 4). The deployment of the parachute was designed to be triggered by not only a given time, but also by the peak acceleration detected onboard, whichever occurred first.

The primary capsule detection system consisted of three sets of double UHF antenna arrays that precisely identified the signal direction. The combination of the signal confirmed the possible landing area within 5–10 km, and a helicopter was used to find the sample return container. The capsule was discovered within 30 minutes of reentry, about 500 m from the presumed location. The recovered capsule was placed inside a special container filled with nitrogen and shipped to Japan for sample removal (Kawaguchi, 2010a,b; Kawaguchi et al., 2011).

**Fig. 4.** Hayabusa's reentry into Earth's atmosphere.

**2.3.9. Remarks.** The Hayabusa mission presented a huge challenge that had never before been achieved. For seven years the Hayabusa mission was plagued with incidents and mishaps, but the mission team and engineers maintained their spirit and commitment to bringing the spacecraft safely home.

### 3. RESULTS OBTAINED BY IN SITU OBSERVATION

#### 3.1. Global Properties of (25143) Itokawa

Itokawa measures  $535 \times 294 \times 209$  m, and has a mean diameter of 320 m, a spin period of 12.1 h, a density of  $1.9 \text{ g cm}^{-3}$ , and revolves with retrograde rotation. More detailed information is given by Fujiwara et al. (2006). The mean diameter is in good agreement with the value obtained by groundbased mid-infrared (Sekiguchi et al., 2003) and radar observations (Ostro et al., 2004, 2005; see the chapter by Benner et al. in this volume). The pre-arrival results from groundbased observations of the rotation period and spin direction (retrograde rotation, perpendicularity of the spin axis to the ecliptic), along with its spectral type (Binzel et al., 2001; Dermawan et al., 2002; Kaasalainen et al., 2003; Ohba et al., 2003; Ostro et al., 2004, 2005; Lowry et al., 2005; see the chapter by Li et al. in this volume), were confirmed by the more detailed data obtained by Hayabusa. There is no apparent short-term precession of the spin pole, which shows that enough time has passed for the asteroid to be dynamically relaxed after the last large impact event.

No satellites were found by the Asteroid Multi-band Imaging Camera (AMICA) (also called ONC-T, one of the optical navigation cameras) images (Fuse et al., 2008), which is consistent with past optical and radar observations and not inconsistent with the suggestion of the existence of meteoroids related with Itokawa from groundbased observations (Otsuka et al., 2011), although none were directly observed by the spacecraft.

The mass of the asteroid was estimated from Hayabusa tracking and navigation. Using lidar (light radar) data (Abe et al., 2006b; Mukai et al., 2007), as well as navigation data, and considering the effects of attitude maneuvers, the mass was determined to be  $3.51 \times 10^{10} \text{ kg}$ . Coupled with the volume of Itokawa, estimated from the three-dimensional

shape models (*Demura et al.*, 2006), the bulk density of Itokawa is estimated to be  $1.9 \text{ g cm}^{-3}$ .

Itokawa has a bifurcated shape like a floating sea otter (Figs. 5, 6, and 7). The smaller part is called the “head” and the larger part is called the “body.” In the attitude of Fig. 6, south is up and north is down due to retrograde rotation. The overall shape of both parts is not angular like the asteroid (951) Gaspra (*Everka et al.*, 1994), but rather rounded and there is no global lineament as seen on (433) Eros (*Cheng et al.*, 2007). The size of the ellipsoid fitted to the body is  $490 \times 310 \times 260 \text{ m}$ , and that to the head is  $230 \times 200 \times 180 \text{ m}$ , respectively (*Demura et al.*, 2006). The appearance of the surface is different from any other asteroids so far observed by spacecraft, including (243) Ida, (253) Mathilde, and Eros, whose surfaces are globally covered with a thick regolith layer and many craters (*Chapman*, 2002), as seen even in images of Eros taken with scales comparable with Itokawa.

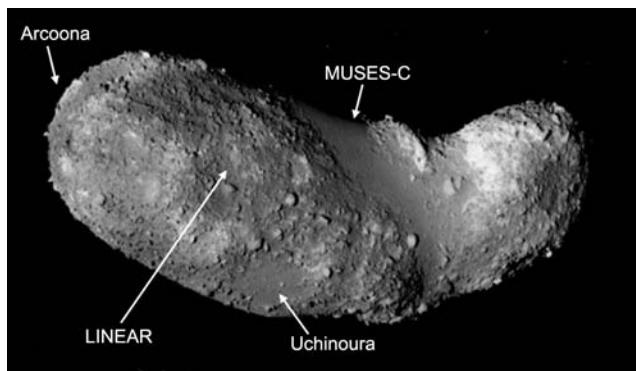

The surface of Itokawa is divided into two distinct types of terrain: *rough terrain*, consisting of numerous boulders, and *smooth terrain*, which shows the existence of a smoother regolith layer (see the chapter by Murdoch et al. in this volume). Rough terrain (see close-up view in Fig. 8) makes up ~80% of the surface (*Saito et al.*, 2006). The smooth terrain is distributed into two distinct regions: “MUSES-C,”

named for the wide region extending around the “breast” on the “body,” where the spacecraft landed for sampling, and “Sagamihara,” around the north-polar region near the “back” of the body. Close-up viewing of the MUSES-C Regio (Fig. 9) shows that the smooth terrain is composed of centimeter- to millimeter-scale fragmental debris and pebbles (*Yano et al.*, 2006). Most grains in the MUSES-C Regio are larger than those observed in the close-up view of Eros’ surface, and there is a strong depletion of fine grains on Itokawa compared with Eros. The boundaries between the rough and smooth terrains are relatively sharp, but a gradient of boulder number density and some evidence of movement of the surface material are evident (*Miyamoto et al.*, 2007).

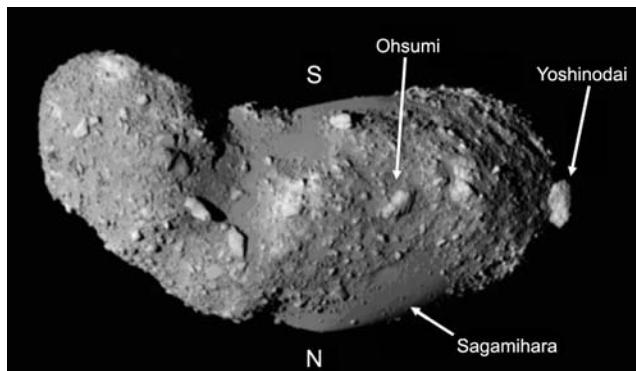

### 3.2. Boulders

Most boulders are found in the rough terrain, while in the smooth terrain boulders appear buried by regolith. The average number density of boulders larger than  $5 \text{ m}$  is  $10^3 \text{ km}^{-2}$  (*Michikami et al.*, 2008), which is slightly larger than that on the surface of Eros (*Thomas et al.*, 2001). A black boulder is found at the top of the head, where the gravitational potential is the highest (Fig. 7), and which was assigned as the prime meridian (longitude  $0^\circ$ ) (*Fujiwara et al.*, 2006). This boulder measures ~6 m and has unusually low brightness, resulting in a striking contrast with its surroundings. Three other smaller similar boulders were also found (*Hirata and Ishiguro*, 2011).

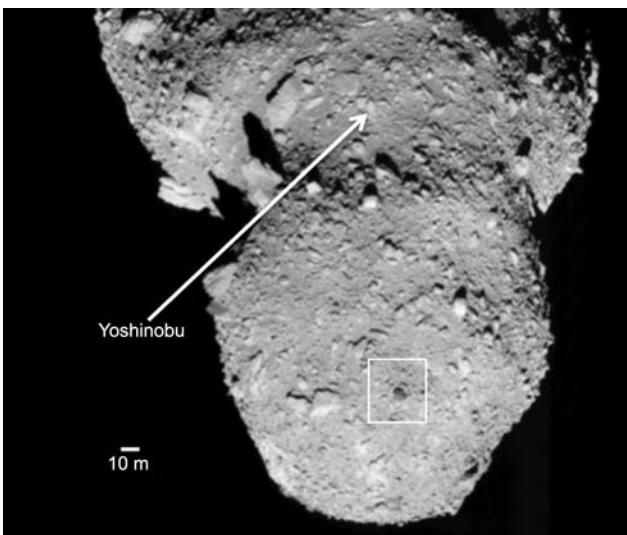

The largest boulder, named Yoshinodai, is about  $50 \times 30 \times 20 \text{ m}$  in size (*Saito et al.*, 2006) and is located near the “right foot” of the “body” (Fig. 6). There are several boulders with sizes larger than a few tens of meters on the western side (longitude  $0^\circ$ – $180^\circ\text{W}$ ) while large boulders are less abun-

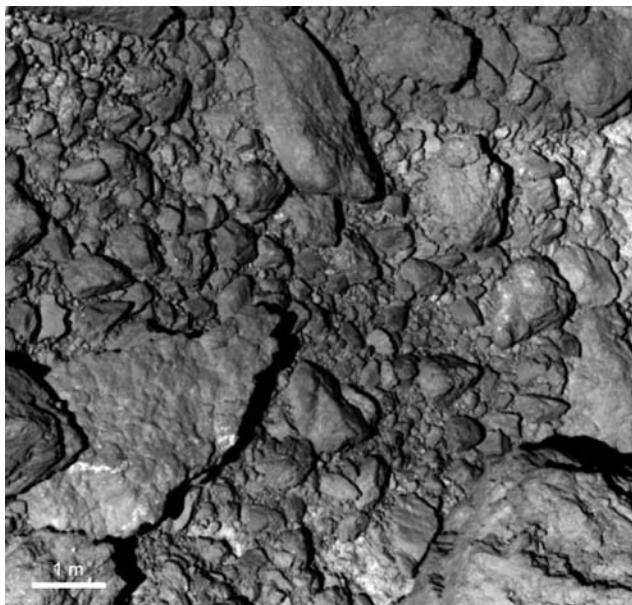

**Fig. 5.** Eastern side of Itokawa. The bottom is north. The spacecraft landed on the smooth terrain near MUSES-C.

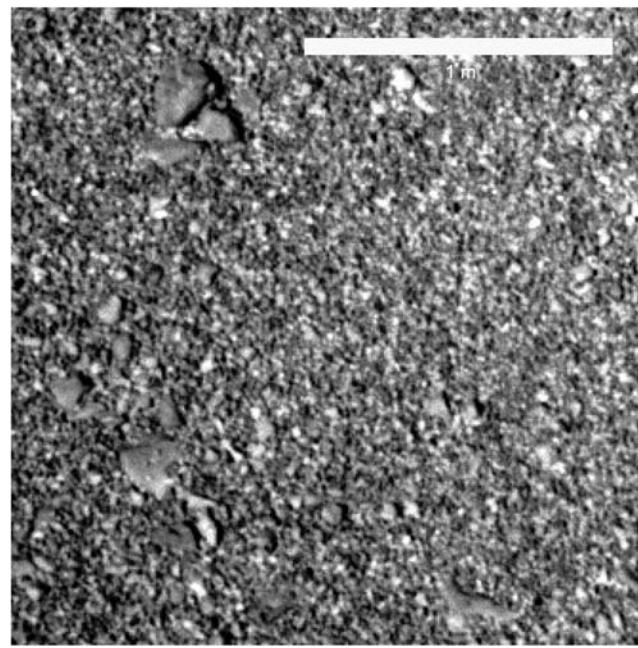

**Fig. 6.** Western side of Itokawa. On this side, large boulders are more abundant than on the eastern side. Yoshinodai is the largest boulder.

**Fig. 7.** “Back head” of Itokawa viewed from top. A large depression at the “neck” is Yoshinobu. On the top of the “head” a black boulder is evident (inside the square). Scale bar is 10 m.

**Fig. 8.** Close-up view of rough terrain on Itokawa. Irregular plate-like fragments are characteristic of impact spalls.

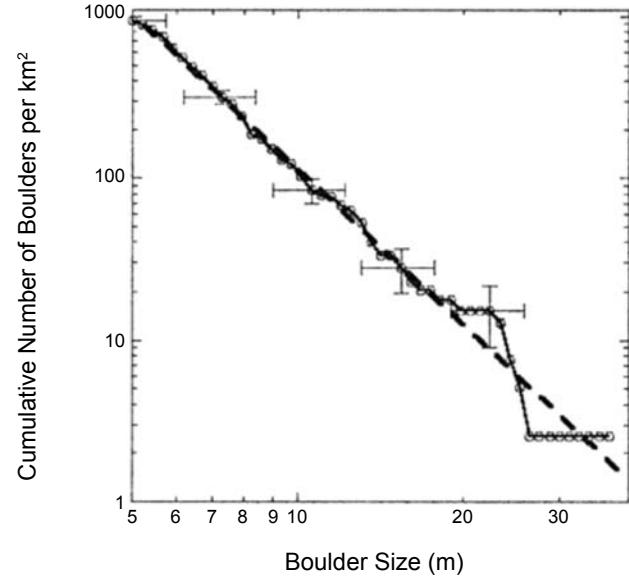

**Fig. 9.** Close-up view of MUSES-C Regio.

dant on the eastern side. There are several large pinnacles at the neck region on the western side (Fig. 6), believed to have resulted from landside from the higher gravitational potential of the “head” to the lower potential region of the “neck” to “breast” region.

An experimental relationship exists between the size of a crater and the maximum size of the excavated fragment (Gault *et al.*, 1963), which was confirmed observationally for the main-belt asteroid Ida and other asteroids (Lee *et al.*, 1996). These are also consistent with boulders around the Shoemaker crater on Eros (Thomas *et al.*, 2001). Following these empirical relationships, the size of the crater that would have produced the largest boulder, Yoshinodai, and some others actually exceeds the size of the largest crater candidates found on Itokawa. Hence these boulders are the likely relics formed in some cataclysmic event related to the formation of Itokawa’s current configuration.

The cumulative size distribution of boulders obtained by Michikami *et al.* (2008) is shown in Fig. 10. The slope index of the distribution is  $-3.1 \pm 0.1$ , which is comparable with the value of  $-3.2$  for the 15–80-m boulder size range on Eros (Thomas *et al.*, 2001). It should be noted that the index changes slightly depending on the measurement method, and in Michikami *et al.*’s (2008) work the size is defined as that measured horizontally. If the largest size is measured instead of horizontal size, the index is  $-2.8$  (Saito *et al.*, 2006). This is because larger boulders have longer or spall-like shapes, which suggests that those fragments are produced by impacts. Actually, this is consistent with the shape of many fragments observed on Itokawa’s surface (as shown in Fig. 8), which are very similar to those observed in some laboratory impact experiments (Nakamura *et al.*, 2008a; Michikami *et al.*, 2008). Morphological features

**Fig. 10.** Boulder size distribution on Itokawa (Michikami *et al.*, 2008). Size is defined as the mean horizontal dimension of a boulder. The broken line is a fitted regression line. The power-law index is  $-3.1 \pm 0.1$ .

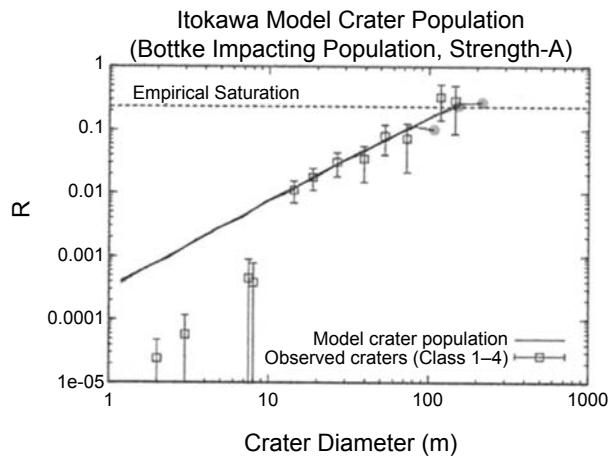

of Itokawa boulders are also discussed by Noguchi *et al.* (2010). Mazrouei *et al.* (2014) performed a more detailed study of the size distribution of boulders greater than 6 m and showed that the slope index is  $-3.5$ , which is significantly steeper than the slope obtained by Michikami *et al.* (2008). A latitudinal variation of the block population also exists on the body, which may suggest that the asteroid is a composite of two different bodies (i.e., a binary asteroid).

The boulder density does not show a correlation with the crater density. The boulders exist regardless of the position of the craters. The total estimated volume of boulders is  $8.2 \times 10^4 \text{ m}^{-3}$ , and the ratio of boulder volume to crater volume is  $\sim 25\%$  (Michikami *et al.*, 2008). This value is higher than that obtained so far for other small bodies. For example, on Eros the ratio is less than 1% (Thomas *et al.*, 2001), and on the Moon it is  $\sim 5\%$  (Cintala *et al.*, 1982). Considering that Itokawa is very small and has a very low escape velocity (on the order of  $10 \text{ cm s}^{-1}$ ), boulders currently observed on Itokawa could not have been produced from the recent craters.

### 3.3. Craters

Many crater-like depressions are found on Itokawa, but most of them have a shape that does not make them as easily identified as craters as those found on the surface of other asteroids. Hirata *et al.* (2009) listed 38 crater candidates on Itokawa's surface (see the chapter by Marchi *et al.* in this volume): five candidates — Yoshinobu (Fig. 7), Arcoona, LINEAR, Uchinoura (Fig. 5), and Ohsumi (Fig. 6) — have diameters larger than 100 m, and the others are smaller than 100 m. Generally, most of the crater-like depressions are shallower than craters observed on the surface of other planetary bodies and asteroids. Large craters have flat or convex floors affected by the pre-impact local surface curvature as shown in laboratory impact experiments (Fujiwara, *et al.*, 1993), and a typical example of this type is Arcoona, which has a circular structure about 150 m in diameter extending around the bottom of the “body” (longitude of  $\sim 180^\circ$ ). Many small craters are found on the smooth terrains on Itokawa, and those are also shallow. The depth/diameter ratio for the crater candidates is around 0.1 for diameters larger than 50 m, and has lower values for diameters less than 50 m (Hirata *et al.*, 2009). For comparison, the same ratio is 0.14 for fresh craters on Gaspra (Carr *et al.*, 1994), 0.15 for fresh craters on Ida (Sullivan *et al.*, 1996), and 0.13 for Eros (Barnouin-Jha *et al.*, 2001; Robinson *et al.*, 2002). The low value of the ratio for small craters on Itokawa could be due to some granular processes, such as seismic shaking and granular convection (Güttler *et al.*, 2014; Yamada and Katsuragi, 2014; Matsuura *et al.*, 2014).

The observed density of the crater candidates on Itokawa is close to the empirical saturation level at the largest diameter, and declines with decreasing diameter (Fig. 11). This decreasing trend is also seen for crater diameters less than 100 m for Eros (Chapman *et al.*, 2002). The lack of small craters on Itokawa may be attributed in part to elimination of craters due to seismic shaking and as well as the inefficiency of creating craters due to the effect of armoring by boulders (Miyamoto *et al.*, 2007; Barnouin-Jha *et al.*, 2008), as demonstrated by laboratory experiments (Güttler *et al.*, 2012). Michel *et al.* (2009) studied cratering and crater erasure processes and provided an age estimate for Itokawa. They find that the time necessary to accumulate Itokawa's craters was at least  $\sim 75$  m.y., and perhaps as long as 1 G.y.,

**Fig. 11.** R-plot diagram (differential crater size-frequency distribution divided by  $D^{-3}$ , where D is the crater's diameter) of Itokawa's crater population (Michel *et al.*, 2009). The observed data [including all crater candidates classified as class 1–4 by Hirata *et al.* (2009)] and one of the model fits (solid line) by Michel *et al.* (2009) are shown. The impacting population of Bottke *et al.* (2005) is assumed in the model to accumulate craters on Itokawa's surface over time and impact scaling laws (labeled Strength A) by Nolan *et al.* (1996) are used in this example to convert projectile size to crater size. The exposure times represented are 25, 75, and 150 m.y. (gray dots are placed to help discriminate between the different curves). The best fit occurs after about 75 m.y. However, given the small number statistics for the few largest craters, any exposure time in the range 25–150 m.y. is actually plausible. Note that the model predicts significantly more craters smaller than 10 m in diameter than are actually observed, which suggests that some processes may be efficient at erasing craters smaller than this size (see Michel *et al.*, 2009, for details).

and suggest that the pronounced deficiency of small craters ( $< 10$  m in diameter) may require another specific event (such as a low-velocity impact causing surface motion and crater erasure) in addition to the above-mentioned mechanisms.

The origin of the largest depression seen on the narrow “neck” region, Yoshinobu (Fig. 7), is enigmatic. If a crater of this size were formed by an impact on such a narrow “neck” made of competent material, the neck itself should have been altered. Instead, if the neck was composed of loosely coupled granular material, shock waves would quickly attenuate and the neck could be preserved. It is thus plausible that the neck region is made of granular material.

Careful observation of the “head” and “body” shows that these are multi-faceted surfaces (Saito *et al.*, 2006, Demura *et al.*, 2006). There is a possibility that some facets could be the exposed surfaces of large fragments embedded near the asteroid's surface.

### 3.4. Spectra and Space Weathering

Visible and near-infrared reflectance spectra of Itokawa collected by the Hayabusa spacecraft show typical S-type

characteristics with a broad absorption band near 1  $\mu\text{m}$  (*Abe et al.*, 2006a; *Saito et al.*, 2006) as observed by groundbased observations (*Binzel et al.*, 2001; *Lederer, et al.*, 2005). There is a slight difference between optical albedo and near-infrared spectra depending on the location (*Saito et al.*, 2006; *Abe et al.*, 2006a), which was also recognized from groundbased observations (*Abell et al.*, 2007). This difference was interpreted as being due to space weathering (*Hiroi et al.*, 2006). In lunar samples, space weathering makes the visible and near-infrared reflectance spectrum of a body darker and redder by increasing nanophase metallic iron particles in the space-exposed surface layer, as simulated experimentally (*Sasaki et al.*, 2001). Continuum-removed spectra of the dark regions were compared with meteorites mixed with a small amount of metallic iron nanoparticles and concluded that Itokawa's material is LL5–6 chondrite and the slight difference in spectra was interpreted as being due to differing degrees of space weathering (see the chapter by Brunetto et al. in this volume).

Albedo and color maps were made over Itokawa's surface in the visible and near-infrared (*Saito et al.*, 2006; *Ishiguro et al.*, 2007). Darker regions on Itokawa are interpreted as being more space-weathered, since brighter regions probably indicate areas newly exposed by impacts or shaking.

### 3.5. Shape/Potential Model and YORP Effect

Three-dimensional numerical shape models of Itokawa were developed using different methods, and based on these, potential and slope maps were constructed (*Fujiwara et al.*, 2006; *Demura et al.*, 2006; *Gaskell et al.*, 2006) [for a discussion that also includes the dynamical environment in Itokawa's near-space, see *Scheeres et al.* (2006)]. Toward the head and body the potential increases, while low potential regions exist near the neck and northern areas on the body. There are two areas where the surface consistently has slopes less than  $8^\circ$ : an isolated region around the north pole, and the MUSES-C Regio. In these regions, regolith is observed that maintains its smoothness down to at least centimeter to millimeter grain sizes (Fig. 9). A surface region with zero slopes is considered to be an energetically relaxed shape to the surface normal. This would be consistent with the existence of a loose regolith layer in these regions of minimum energy. Hence the accumulation of small grains could be explained by transport of these grains across the surface through seismic shaking induced by impacts (*Cheng et al.*, 2002; *Miyamoto et al.*, 2007), or by tidal disturbance from close planetary encounters or electrostatic levitation (*Lee*, 1996).

The YORP effect (radiative spin-up/spin-down effect) was proposed for Itokawa based on groundbased observation (*Vokrouhlický et al.*, 2004; *Scheeres et al.*, 2007; see also the chapter by Vokrouhlický et al. in this volume). *Scheeres et al.* (2007) reported that Itokawa was spinning with a period of 6.5 h 100,000 to 180,000 years ago and has slowed to the current spin state in the absence of a disturbing event. This rotation rate is fast enough for the head and body to have gone into mutual orbit.

However, the theoretical YORP value (spin-up or spin-down rate) is sensitive to the resolution of the shape model (*Scheeres and Gaskell*, 2008; *Ďurech et al.*, 2008; *Breiter et al.*, 2009) and lies in the range from  $-2$  to  $-3 \times 10^{-7}$  rad d $^{-2}$  (*Ďurech et al.*, 2008). The observed change of rotation rate  $-9.0 \times 10^{-8}$  rad d $^{-2}$  (*Kitazato et al.*, 2007) and upper limit  $\sim 1.5 \times 10^{-7}$  rad d $^{-2}$  (*Ďurech et al.*, 2008) are slightly lower than the expected value. To solve this inconsistency, the possibility of density inhomogeneity for Itokawa was suggested (*Scheeres and Gaskell*, 2008). Recently, *Lowry et al.* (2014) measured an acceleration of rotation  $3.54 \times 10^{-8}$  rad d $^{-2}$  (equivalent to a decrease of the rotation period of  $\sim 45$  ms yr $^{-1}$ ). From thermophysical analysis they found that the center of mass must be shifted by  $\sim 21$  m along the long axis of the asteroid to reconcile the observed YORP strength with theory. From these results they proposed that Itokawa is composed of two bodies of very different bulk densities,  $1750 \pm 110$  kg m $^{-3}$  and  $2850 \pm 500$  kg m $^{-3}$ , and was formed by their merging via either reaccumulation following a catastrophic disruption of a larger, partially differentiated body, or the collapse of a binary system.

### 3.6. Regolith

Past impacts by interplanetary projectiles would have repeatedly fragmented and released Itokawa's surface material since most of the excavated finer particles would have velocities much higher than Itokawa's escape velocity. In impact experiments, fragments having velocities less than this escape velocity are limited to a very small number of the largest fragments (*Nakamura and Fujiwara*, 1991; *Onose and Fujiwara*, 2004; *Michikami et al.*, 2007). Hence one could suppose that fine-grained regolith is gradually lost and the surface becomes covered with large boulders.

In spite of this expectation, a significant amount of regolith with millimeter- to centimeter-sized grains is present on Itokawa, although the constituent particle size may be larger than that on larger asteroids. This is a remarkable result given that Itokawa is very small. One probable scenario is that the regolith existed from the time of the initial formation of the head and body and has been gradually depleted through cratering. If the strength of Itokawa is weak, the excavated materials have lower speeds as suggested by experiments (*Onose and Fujiwara*, 2004) and will be able to accumulate on the surface. *Barnouin-Jha et al.* (2008) estimated the strength from this point of view and it should be less than 100 Pa. This value is small compared with loosely consolidated breccia ( $\sim 1$  kPa) and is higher than typical values for lunar regolith (approximately a few Pascals). Another probable scenario for creating small particles is that larger blocks cracked as the result of fatigue by thermal cycling (*Dombard et al.*, 2010; *Delbo et al.*, 2014).

Moreover, it is probable that regolith grains may be continuously produced if Itokawa is composed of boulder aggregates of various sizes and has considerable macroporosity — at least near the surface. Such a structure would not only reduce the shock effect during impacts, but could also

help produce fine fragments in the shallow interior near the aggregated body's surface, if the characteristic sizes of the aggregate boulders are roughly comparable with the projectile sizes. This is also the armoring process that appears to create the shallow crater-like deposits. Thus a considerable amount of grains will be retained within the interior of the asteroid, and the fine particles can easily migrate through spacing between larger boulders toward low potential regions like MUSES-C, triggered by seismic shaking.

No small amount of fine particles such as found inside the returned sampler capsule seems to exist on Itokawa's surface. These may be continuously produced by thermal cycling and migrate on the surface through levitation by their electrical charge (Lee, 1996; Kimura *et al.*, 2014).

### 3.7. Rubble-Pile Structure

Itokawa's bulk density was found to be  $1.9 \text{ g cm}^{-3}$ , which is considerably lower than the  $\sim 2.6 \text{ g cm}^{-3}$  determined for other S-type asteroids with well-determined bulk densities (Thomas *et al.*, 2001). Assuming Itokawa's composition is like LL chondrites, and that Itokawa's grain density is similar to the bulk density of LL chondrites,  $3.2 \text{ g cm}^{-3}$  (Britt *et al.*, 2002), the macroporosity of Itokawa is estimated to be 41% (Fujiwara *et al.*, 2006; Abe *et al.*, 2006b). Although it is not clear what the relative micro- and macroporosity values are, it is clear that Itokawa contains considerable void spaces in its interior, and it is likely that Itokawa has a rubble-pile structure (Fujiwara *et al.*, 2006). It is also noted that near-surface bulk density was estimated to be within 20% of  $2.5 \text{ g cm}^{-3}$  based on radar observations from the ground (Ostro *et al.*, 2004).

The ellipsoidal shapes of the head and body are also suggestive of a rubble-pile structure, because an ellipsoid is the configuration that an aggregated body takes under self-gravitation and centrifugal force. However, the fact that the current shape of Itokawa is not gravitationally relaxed to a single ellipsoid means that the head and body acquired some strength before the contact of these bodies. Shrama's (2010) theoretical study on the shape of rubble-pile binaries shows that Itokawa material has a high global friction angle, suggestive of internal cohesion. There are no conspicuous long linear structures on Itokawa (Fujiwara *et al.*, 2006; Hirata *et al.*, 2009), which is consistent with Itokawa being an aggregate of rubbles  $<50 \text{ m}$  in size. In fact, numerical simulations of catastrophic disruptions of asteroids and fragment reaccumulations were able to produce aggregate objects whose shape resemble that of Itokawa (Michel and Richardson, 2013; see the chapter by Michel *et al.* in this volume), suggesting that Itokawa is the product of the reaccumulation of small fragments generated by the disruption of a larger parent body.

Large-scale, landslide-like deposits are observed at the base of the head (Fujiwara *et al.*, 2006; Demura *et al.*, 2006), and this region has slopes in excess of  $35^\circ$  while most angular grain materials have an angle of repose on the order of  $32^\circ\text{--}35^\circ$ . The observation of the candidate landslides, along

with the fact that the steep slopes on the head measure up to  $50^\circ$ , suggests the possibility that this region at the base of the head resulted from an angular rubble pile that collapsed.

The existence of a thermally insulating layer consisting of gravel on the smooth terrain (Yano *et al.*, 2006) and many boulders in the rough terrain is also suggestive of rubble-pile structure, and this is consistent with groundbased thermal inertia measurements (Mueller *et al.*, 2005) — Itokawa's thermal inertia of  $350 \text{ J m}^{-2} \text{ s}^{-0.5} \text{ K}^{-1}$  is at least an order of magnitude higher than large main-belt asteroids ( $5\text{--}25 \text{ J m}^{-2} \text{ s}^{-0.5} \text{ K}^{-1}$ ) and the Moon ( $50 \text{ J m}^{-2} \text{ s}^{-0.5} \text{ K}^{-1}$ ).

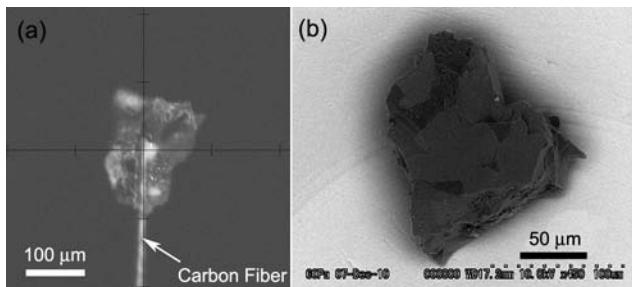

Thus Itokawa is the first observationally verified rubble-pile body, although the existence of rubble piles was predicted long ago (Davis *et al.*, 1979; Hartmann, 1979; Fujiwara and Tsukamoto, 1980) and more recently through numerical simulations of asteroid disruptions (Michel *et al.*, 2001; see the chapter by Michel *et al.* in this volume). According to recent groundbased studies of rotation rates and amplitudes, most small asteroids may well be rubble piles or have shattered interior structures (Pravec *et al.*, 2002). The rubble-pile structure of Itokawa supports speculation that most asteroids larger than about 150 m may be rubble piles (Benz and Asphaug, 1999; Whitely *et al.*, 2002).

## 4. THE SCIENTIFIC RESULTS OF SAMPLE ANALYSIS

### 4.1. Sample Collection and Curation

The Hayabusa spacecraft made two touchdowns on Itokawa's regolith area, named MUSES-C Regio (Fig. 5). In the original sampling plan, a bullet was to have been shot from the spacecraft at the touchdown, and up to  $\sim 1 \text{ g}$  of small particles should have been collected (Yano *et al.*, 2006). Unfortunately, no bullets were shot during the two touchdowns, but thousands of very small particles were recovered in the two sample catcher rooms in the sample container, A (samples from the second touchdown) and B (samples from the first touchdown) (Nakamura *et al.*, 2011).

The sample container was opened in the clean chamber at the Planetary Material Sample Curation Facility (PMSCF) of JAXA (Yada *et al.*, 2014a). All the processes for sample transfer and storage were performed in a high-purity nitrogen atmosphere. Four methods were used to remove particles from the sample containers (Nakamura *et al.*, 2011; Yada *et al.*, 2014a). The first attempt was made using an electrostatic needle to try to remove apparent grains clinging to the walls of Catcher A, but this was unsuccessful. The second method involved sweeping the inner wall of catcher Catcher A with a Teflon spatula. However, most of the particles collected on the spatula were too small (smaller than  $10 \mu\text{m}$ ) to be safely handled without losing them. The third method was to collect particles that fell from Catchers A and B onto a quartz (silica glass) disk after physically tapping the container with a very clean screwdriver. Relatively larger particles (with a maximum size about  $300 \mu\text{m}$ ) were safely collected from the quartz plates (Fig. 12). Most recently, particles sticking on the

**Fig. 12.** (a) Optical microscope image and (b) SEM image of particle RA-QD02-0010 collected by the Hayabusa spacecraft. This particle is mainly composed of olivine.

cover lid of sample Catcher B were also removed (Yada et al., 2014b). Gas in the sample container, which might have been released from Itokawa particles during the return to Earth or entry into Earth's atmosphere due to temperature increase, was also sampled during the opening procedure. The noble gas elemental ratios of the gas, however, are essentially identical to those of the terrestrial atmosphere, probably due to atmospheric contamination across the O-ring seal (Okazaki et al., 2011).

Initial descriptions of harvested particles were performed using a scanning electron microscope equipped with an energy dispersive X-ray spectrometer (SEM/EDX) at the PMSCF (Yada et al., 2014a). Analyses were made using a low-vacuum, low-beam current mode without a conductive coating. The particles were grouped into four categories: Category 1 particles are composed mainly of olivine, pyroxene, and feldspar; Category 2 particles consist of additional minerals, i.e., troilite, pentlandite, Fe-Ni metal, phosphates, and chromite; Category 3 particles are composed mainly of carbon-bearing phases; and Category 4 particles are contaminants such as aluminum, quartz glass, and stainless steel. The particles are given unique names such as RA-QD02-XXXX, RB-QD04-XXXX or RB-CV-XXXX (XXXX: four-digit sequential numbers), where RA and RB mean Catcher A or B respectively, QD means quartz disk, and CV means cover lid. The harvested samples are stored in a clean chamber at PMSCF with a clean nitrogen atmosphere. By agreement, one-tenth of the harvested samples were transferred to NASA's curation facility at the Johnson Space Center in Houston (<http://curator.jsc.nasa.gov/hayabusa/index.cfm>).

#### 4.2. The Purpose of Sample Analysis

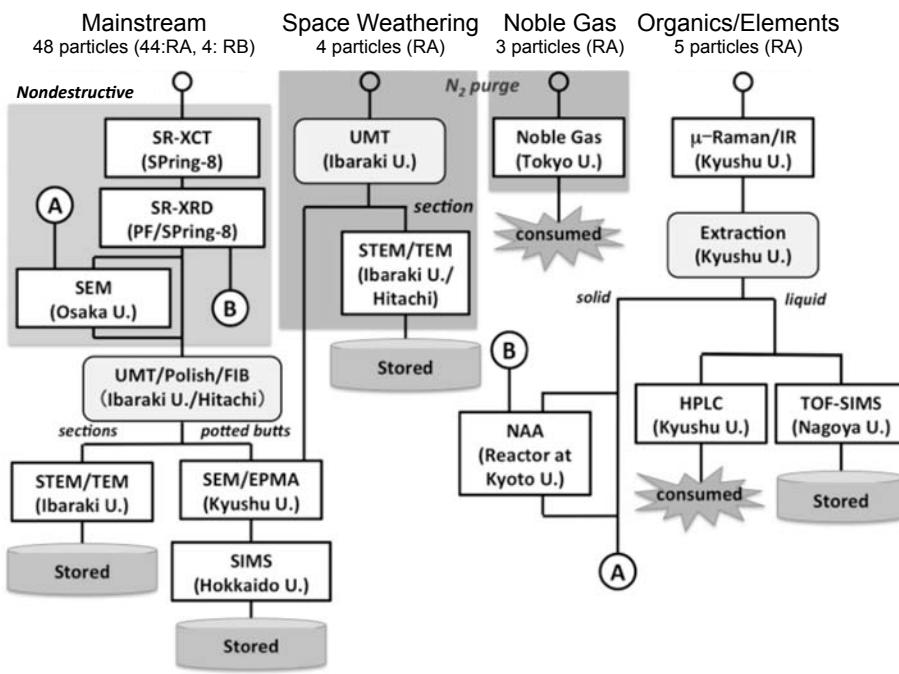

The particles from Itokawa were the first samples recovered by spacecraft from a known asteroid with an observed geological context and returned to Earth. It has long been accepted that most meteorites originate from asteroids, as demonstrated by orbital determinations from observed meteorite falls (e.g., Cloutis et al., 2014). Groundbased observations indicate that the materials on S-type asteroid Itokawa are similar to thermally metamorphosed LL chondrites belonging to petrologic type 5–6 (i.e., LL5–6), which suffered limited space weathering (see the chapter by

Brunetto et al. in this volume) (Binzel et al., 2001; Abe et al., 2006a). Itokawa samples thus provide a direct validation of the relation between S-class asteroids and ordinary chondrites. They can also be compared with the other extraterrestrial regoliths, particularly lunar regolith materials sampled by the Apollo and Luna mission (Heiken et al., 1991), and studied to understand surface processes on an asteroid, such as regolith formation and space weathering. Exotic materials, including organic-rich matter brought by impacts on the asteroid's surface, might also be included in the samples. The returned samples from Itokawa are ideal for such examination because they come from a known source, they have experienced minimal contamination from Earth's atmosphere and organic materials, and the surface of the samples was not chemically or physically processed during Earth entry, i.e., the surface structure of the samples has been preserved.

#### 4.3. Sample Analysis

Sixty-five particles 30–180 μm in size removed from the quartz disks (61 and 4 particles from Catcher A and B respectively) were examined by the Hayabusa preliminary analysis team (HASPET) in the year following recovery on Earth (Nakamura et al., 2011, 2012; Tsuchiyama, 2014). The total volume of 48 particles examined by X-ray microtomography was approximately  $4 \times 10^6 \mu\text{m}^3$ , corresponding to a sphere of about 100 μm in radius or 15 μg in mass (Tsuchiyama et al., 2014). This may suggest that the total mass of samples collected by the spacecraft is roughly 100 μg, although the exact amount is not known. It was critical to make the initial analysis according to a systematic sample-analysis program, where different analyses were made grain by grain, to obtain as much information as possible from the limited number of tiny particles. Sixty particles were divided among the two HASPET groups: one for sequential analysis from nondestructive to progressively more destructive methods (mainstream group), and the other for the characterization of space weathering, noble gases, and carbonaceous and organic materials, while minimizing contamination (Fig. 13).

Forty-eight particles were examined as the mainstream group (Nakamura et al., 2011). First, X-ray microtomography (XCT) and X-ray diffraction (XRD) using synchrotron radiation were applied to obtain three-dimensional structures (Tsuchiyama et al., 2011, 2013a, 2014) and mineral phases together with their specific crystallographic structures (Nakamura et al., 2011, 2014; Tanaka et al., 2014), respectively. The use of these nondestructive analyses, which were previously applied to comet coma dust samples returned from Comet 81P/Wild 2 by the Stardust mission (Nakamura et al., 2007, 2008b; Tsuchiyama et al., 2009), is one of the key features of the Hayabusa initial analysis strategy involving sequential studies. The three-dimensional distribution of minerals using analytical dual-energy microtomography (Tsuchiyama et al., 2011, 2013a) provided critical information concerning where a particle should be cut to ensure that the subsequent destructive analyses examined the optimal

**Fig. 13.** Flowchart of the Hayabusa preliminary sample analysis. RA and RB mean Catcher A and B, respectively. SR-XCT: synchrotron radiation (SR)-based X-ray computed tomography, SR-XRD: SR-based X-ray diffraction, SEM: scanning electron microscopy, UMT: ultramicrotome, FIB: focused ion beam micro-sampling, Hitachi: Hitachi High-Technologies Co., (S)TEM: (scanning) transmission electron microscopy, EPMA: electron-probe microanalysis, SIMS: secondary ion mass spectroscopy,  $\mu$ -Raman/IR: micro-Raman and infrared spectroscopy, Extraction: extraction by dichloromethane/methanol solution, NAA: neutron activation analysis, HPLC: high-precision liquid chromatography, TOF-SIMS: time-of-flight secondary ion mass spectroscopy. "A" and "B" show connections of the analytical flows, respectively.

areas of the minerals exposed in the cross sections. Then, the particles were polished or sectioned using an ultramicrotome (UMT) or focused ion beam (FIB) and analyzed by transmission electron microscopy (TEM) to examine the nanostructures (Nakamura *et al.*, 2011; Noguchi *et al.*, 2011, 2014a). Some sections were examined using an optical microscope and a field-emission scanning electron microscope (FE-SEM) coupled with electron backscattered diffraction (EBSD) (Zolensky *et al.*, 2012), and the chemical compositions of minerals were measured by an electron probe microanalyzer (EPMA) (Nakamura *et al.*, 2011, 2014). Subsequently, oxygen and magnesium isotope compositions of minerals together with some minor-element compositions were determined using secondary ion mass spectroscopy (SIMS) (Yurimoto *et al.*, 2011a,b). The surface nanomorphologies of eight particles were also observed by FE-SEM before sectioning (Matsumoto *et al.*, 2012, 2014, 2015; Tsuchiyama *et al.*, 2012, 2013b).

For the analysis of space weathering, TEM observation was made of ultrathin sections from 12 particles (Noguchi *et al.*, 2011, 2014a). Some of these were prepared by a UMT in a purged nitrogen atmosphere to avoid oxidation of Fe nanoparticles. The isotopic compositions of noble gases in

three different particles were measured by laser ablation mass spectrometry (Nagao *et al.*, 2011). The surfaces of five different particles were examined nondestructively by micro-Raman and micro-infrared spectroscopy to seek carbonaceous materials (Kitajima *et al.*, 2011). These particles were then rinsed with a small amount of dichloromethane/methanol solution, and the extracts were examined using high-precision liquid chromatography (HPLC) to seek amino acids or using time-of-flight secondary ion mass spectrometry (TOF-SIMS) to analyze other organic compounds, including a search for polycyclic aromatic hydrocarbons (Naraoka *et al.*, 2012). Neutron activation analysis (NAA) was made of one particle after rinsing (Ebihara *et al.*, 2011). Two additional samples have recently been examined by NAA (Ebihara *et al.*, 2015). Unconsumed samples were returned to the PMSCF after initial analysis.

Five different particles were independently studied by Nakamura *et al.* (2012). The surface micronano morphologies of these particles were first observed by FE-SEM, and then FIB sections of them were observed using an optical microscope and FE-SEM; the elemental and oxygen isotope compositions of minerals were measured by EPMA and SIMS, respectively.

#### 4.4. Results from Sample Analysis

**4.4.1. Materials on Itokawa's surface.** The Hayabusa samples mainly consist of olivine, Ca-poor and Ca-rich pyroxenes, plagioclase, and troilite with small amounts of kamacite, taenite, chromite, K-feldspar (sanidine), apatite, and merrillite. The chemical compositions, oxygen isotope compositions, and modal abundances of these minerals are shown in Table 1. The chemical compositions of minerals fall within the compositional range of LL chondrites (Fig. 14) (Nakamura et al., 2011, 2012, 2014; Mikouchi et al., 2014; Noguchi et al., 2014b; Ebihara et al., 2015; see the chapter by Vernazza et al. in this volume). The oxygen isotope compositions of the minerals are consistent with equilibrated LL chondrites (Fig. 15) (Yurimoto et al., 2011a; Nakashima et al., 2013). The modal abundances are also consistent with LL chondrites (Table 1) (Tsuchiyama et al., 2011, 2014). The  $\text{Fe}^{3+}/(\text{Fe}^{2+} + \text{Fe}^{3+})$  ratio of plagioclase, determined by synchrotron radiation-based X-ray absorption near-edge structure (SR-XANES), is approximately 0.5, indicating formation under a relatively oxidizing environment, which also is consistent with LL chondrites (Mikouchi et al., 2014). Based on the abundances and the chemical compositions of minerals, the bulk chemical composition (Table 2) (Nakamura et al., 2011, 2014) and the bulk density of the samples ( $3.4 \text{ g cm}^{-3}$ ) (Tsuchiyama et al., 2011, 2014) were calculated and these values also correspond to LL chondrites. The Fe/Sc and Ni/Co ratios by NAA are consistent with those of ordinary chondrites. Depletion of Ir, which may be the result of condensation in the early solar nebula before chondrite formation, was also reported (Ebihara et al., 2011).

The textures of the samples were examined by X-ray tomography (Tsuchiyama et al., 2011, 2014) and FE-SEM (Nakamura et al., 2011, 2012, 2014). About 90% of the Itokawa particles examined exhibit triple junctions at the boundaries between coarse silicates (Fig. 16a) or almost monomineralic features (Figs. 16c, d). Minerals have almost homogeneous chemical compositions, indicating that they have been thermally annealed, and thus they are similar to LL5 and/or LL6 chondrites (Nakamura et al., 2011, 2014). Their microtextures, including porosity (1.5% average), grain size, voids, and cracks, are also similar to LL5/LL6 chondrites (Tsuchiyama et al., 2011, 2014). Most of the remaining Itokawa particles (~10%), which are made of fine silicate grains and/or have more heterogeneous chemical compositions (Fig. 16b), are similar to LL4 chondrites (Nakamura et al., 2011, 2014; Tsuchiyama et al., 2011). No differences were found between particles from Catchers A and B (Nakamura et al., 2014; Noguchi et al., 2014b; Tsuchiyama et al., 2014). The above results clearly show that the materials making up Itokawa's surface correspond to equilibrated LL chondrites. This provides the first direct link between one class of asteroids and one group of meteorites.

**4.4.2. Itokawa's parent body.** The maximum temperature estimated from the chemical compositions of an equilibrated mineral pair of Ca-poor and Ca-rich pyroxenes is about  $800^\circ\text{C}$  (Nakamura et al., 2011). Crystallization temperatures

of plagioclase based on crystal structure range from  $\sim 800^\circ\text{C}$  (Nakamura et al., 2011; Mikouchi et al., 2014) to  $655^\circ\text{--}660^\circ\text{C}$  (Tanaka et al., 2014). The latter indicates the temperature during prograde metamorphism. If a small body like Itokawa were heated to  $800^\circ\text{C}$ , even its interior would have cooled very fast. Based on a heating model calculation using the extinct nuclide  $^{26}\text{Al}$  as a heat source, the original Itokawa parent body radius should have been larger than 20 km (Nakamura et al., 2011), and accreted between 1.9 and 2.2 m.y. after CAI formation (Fig. 17) (Wakita et al., 2014), which is consistent with the  $^{26}\text{Al}$ - $^{26}\text{Mg}$  isotope evidence (Yurimoto et al., 2011b). The LL4 Itokawa particles probably formed near the original parent-body surface.

Some of the Itokawa particles have minerals with impact shock features. Optical microscope observations suggest moderate impact at the meteorite shock stage of S3–4 (Zolensky et al., 2012, 2014; Mikouchi et al., 2014), which corresponds to a shock pressure of 30–35 GPa. These features might be due to moderate impacts on Itokawa's parent body, although we cannot exclude the possibility that the impact was responsible for destroying the Itokawa's precursor asteroid if the investigated particles were located at some distance from the impact point.

Some features on Itokawa particles might be related to annealing after shock events, such as the presence of healed cracks [negative crystals aligned on a plane; see Fig. 4 in Tsuchiyama et al. (2014)] and euhedral mineral grains with condensation steps on the surfaces of porous particles, probably due to annealing of fine regolith breccia (Figs. 18c,d) (Tsuchiyama et al., 2014). Shock-induced disturbance of the Na-K distribution in plagioclase was also reported (Nakamura et al., 2014).

We can draw up the following scenario for the Itokawa parent body: (1) Formation of the Itokawa parent body  $>20$  km in radius as a planetesimal composed of LL-chondrite material. According to one heating model, this occurred at  $\sim 2$  m.y. after CAI formation ( $\sim 4.565$  G.y. ago). (2) Thermal metamorphism with a peak temperature of  $\sim 800^\circ\text{C}$  (probably  $\sim 4$  m.y. later) followed by slow cooling. (3) Post-metamorphic impact heating. (4) A catastrophic impact should occur to form Itokawa as a rubble-pile asteroid (Fujiwara et al., 2006; Michel and Richardson, 2013), although direct evidence of this has not been obtained by the sample analyses. It should be noted that neither the absolute ages of metamorphism nor the age of the catastrophic impact have been yet measured.

**4.4.3. Surface processes on Itokawa.** Regolith particles can be regarded as the interface with the space environment, where the impacts of small objects and irradiation by the solar wind and galactic cosmic rays can be recorded.

Examination of regolith particle size and shape provides important information on surface processes that cannot be obtained from existing meteorites. The particle size distribution determined both by SEM and microtomography has a slope index of about  $-2$ , which is more gradual than that of the Itokawa boulders (Fig. 10) [about  $-3$  (Saito et al., 2006; Michikami et al., 2008)], indicating a lower abundance of  $10\text{--}100\text{-}\mu\text{m}$  particles than of millimeter- to centimeter-sized

b.d.: below the detection limit. n.a.: not analyzed. Data for the chemical compositions of olivine, pyroxenes, and plagioclase are from Nakamura *et al.* (2014) and those of other minerals are from Nakamura *et al.* (2011). Data for oxygen isotope ratios are from Nakashima *et al.* (2013). Data for the modal abundances are from Tsuchiyama *et al.* (2014).

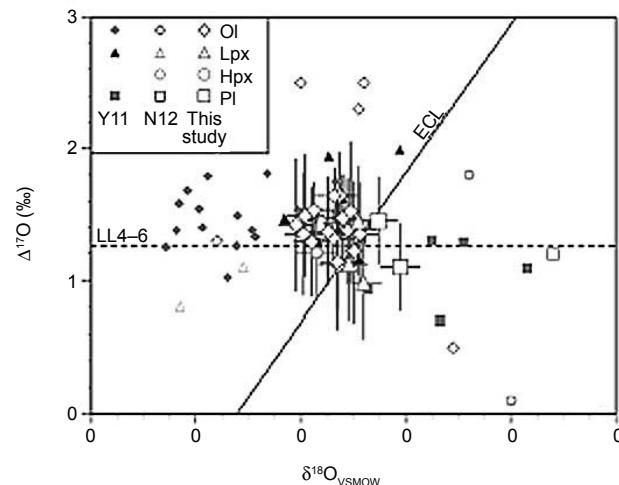

**Fig. 14.** Mean Fa contents in olivine and Fs contents in Ca-poor pyroxene of Itokawa particles in comparison with those of H, L, and LL chondrites (from Nakamura et al., 2011).

regolith (Tsuchiyama et al., 2011, 2014). This is consistent with the close-up images of regolith taken by the Hayabusa spacecraft (Fig. 9) (Yano et al., 2006). This size distribution may be explained by smaller particles having higher ejection velocities and thus higher loss rates. In contrast, abundant submillimeter-sized fragments in regolith are observed on much larger bodies such as the Moon (Heiken et al., 1991).

The shape distribution of Itokawa particles with respect to their three axial ratios is not statistically different from that of fragments formed by high-speed impact in laboratory experiments (Fig. 19), indicating that Itokawa's particles resulted from mechanical disaggregation, primarily as a response to impacts (Tsuchiyama et al., 2011, 2014). The shape distribution of lunar regolith particles (Tsuchiyama et al., 2013c; Katagiri et al., 2014) indicates that the lunar particles are more spherical than the Itokawa particles, indicating that the shape of the lunar particles may have evolved, probably by gardening in the regolith. Thermal fatigue is another possibility for regolith formation on asteroids (Delbo et al., 2014). Fragments produced by thermal fatigue experiments should be compared with Itokawa particles.

Submicrometer-sized impact craters were observed on the surfaces of only a limited number of Itokawa particles (Fig. 18e) (Nakamura et al., 2012); they may have been created by the impact of high-speed secondary nanoparticles produced by impact into Itokawa's regolith. Tiny, flattened glass objects, which seem to be melt splashes (Fig. 18f) (Nakamura et al., 2012; Matsumoto et al., 2012), also formed as a result of small-scale impacts. Similar melt droplets were also observed on Itokawa particle surfaces by TEM (Keller and Berger, 2014; Thompson et al., 2014). Large-scale melting features, such as agglutinates found in lunar regolith, have not been observed among the Itokawa samples (Tsuchiyama et al., 2011). This can be explained by the differences between the mass and impact velocities for asteroids and the Moon (representative velocity of about  $5 \text{ km s}^{-1}$  and over  $10 \text{ km s}^{-1}$ ,

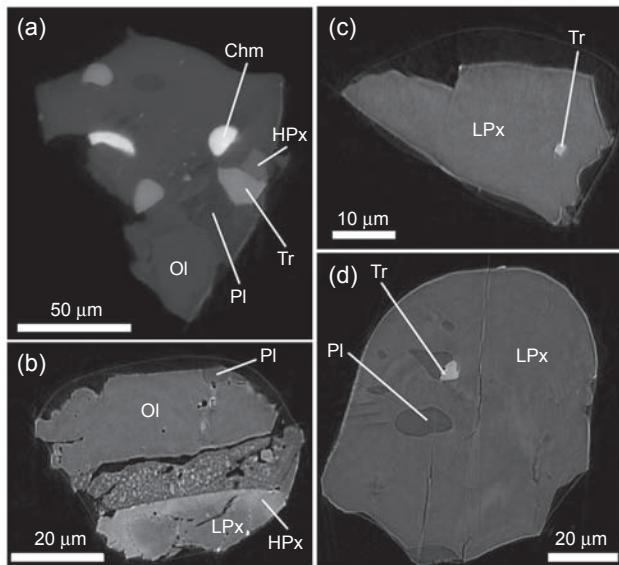

**Fig. 15.** Oxygen three-isotope ratios of Itokawa particles (from Nakashima et al., 2013). ECL represents the equilibrated chondrite line. The dashed line labeled LL4–6 is defined by average  $\Delta^{17}\text{O}$  values of equilibrated LL-chondrite data. The line at  $\Delta^{17}\text{O} = 0\text{‰}$  corresponds to the terrestrial fractionation line.

respectively). Shock defects in olivine and tetrataenite were observed by TEM only below local particle surfaces, indicating small-scale impact and collisional fragmentation during regolith formation (Langenhorst et al., 2014).

Two kinds of surface modifications, formation of space-weathering rims and surface abrasion, have been recognized on Itokawa's particles. Space-weathering rims were observed by TEM and scanning transmission electron microscopy (STEM) (Noguchi et al., 2011, 2014a,b; Matsumoto et al., 2015; Keller and Berger, 2014; Thompson et al., 2014). They are classified into three types (Noguchi et al., 2014a): (1) redeposition rim composed of only a very thin (2–3 nm) amorphous zone with

different compositions from the substrate mineral (Zone I), indicating vapor deposition from micrometeorite impacts or radiation-induced sputter deposition (Figs. 20a,b); (2) composite rim composed of Zone I and a partially amorphized zone (30–60 nm) containing nanophase Fe ± S (Zone II) (Figs. 20c,d); and (3) composite vesicular rim composed of Zone I and a thicker Zone II (60–80 nm) with vesicles about 100 nm across (Figs. 20e,f). The rim structures of the latter two types can be explained by amorphization, *in situ* reduction of iron, and blistering due to the implantation of solar wind particles, particularly He, as deduced from the mean penetration depth (about 40 nm for 4 keV  ${}^4\text{He}^+$ ).

Blisters were also recognized on the particle surfaces by FE-SEM (Fig. 18d) (Matsumoto *et al.*, 2015). The presence of blisters on both sides of one particle shows that the particle rotated on the surface of Itokawa. Solar flare tracks were observed on particles with well-developed space-weathered rims, and their densities give an exposure age on the order of  $10^3$ – $10^4$  yr (Noguchi *et al.*, 2014a,b; Keller *et al.*, 2014). Noguchi *et al.* (2014b) reported that space-weathered rims are less developed and solar flare tracks are rarely observed on particles from the first touchdown site (Catcher B) as compared to the second (Catcher A).

The presence of nanophase Fe below particle surfaces (Fig. 20) is the cause of the reddening and darkening of the reflectance spectra. The cause of the space-weathered rim formation is significantly different from that on the Moon, where the process primarily involves vapor deposition of

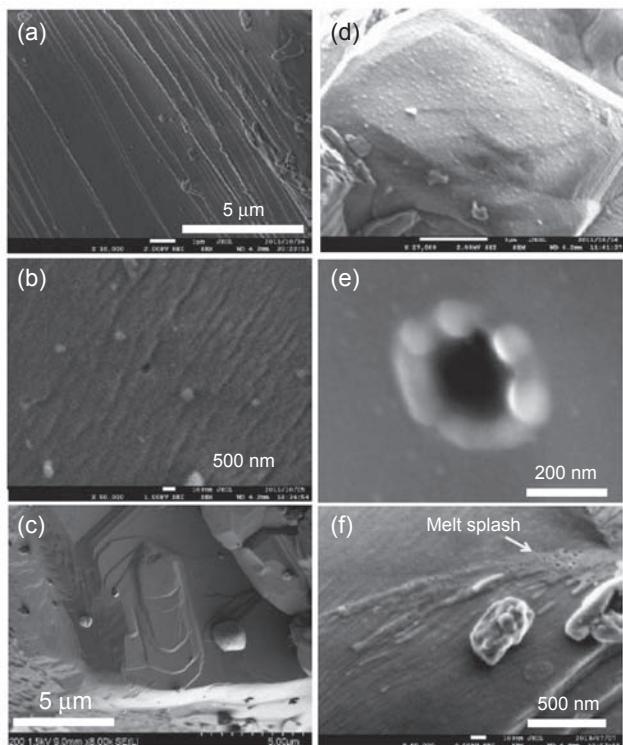

**Fig. 17.** Temperature at the center of parent bodies 30 km in radius plotted against the time after CAI formation as a function of accretion period (1.8, 2.2, and 3.0 m.y. after CAI formation). From Wakita *et al.* (2014).

amorphous materials containing nanophase Fe caused by bombardment of micrometeoroids (e.g., Pieters *et al.*, 2000). This difference might be due to the much larger residence timescales for regolith on the Moon (typically over 400 m.y.) than on Itokawa (roughly 1 m.y. as described below).

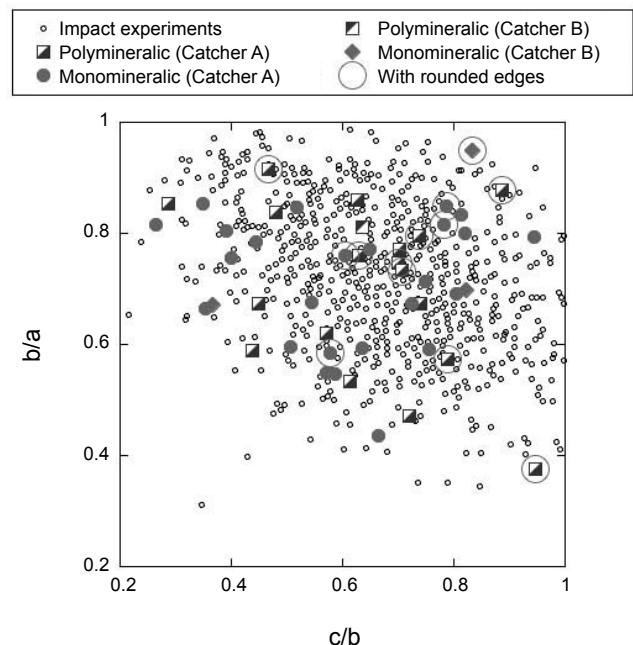

The other observed surface modification that has taken place on Itokawa's particles is grain abrasion (Tsuchiyama *et al.*, 2011, 2013b, 2014). The particle surfaces observed by microtomography are usually angular (Figs. 16a,c), but some are rounded (Figs. 16b,d). Both types of surfaces can be present on a single particle. Similar features were also observed at higher resolution by FE-SEM: sharp steps formed by fracturing on angular surfaces (Fig. 18a), faint or no steps on rounded surfaces (Fig. 18b) (Tsuchiyama *et al.*, 2013b; Matsumoto *et al.*, 2014). These results indicate that mechanically crushed fragments were abraded later. The degree of space-weathered rim development is apparently not related to the abrasion (Tsuchiyama *et al.*, 2013b). Thus, the abrasion process can be regarded as a different type of space weathering with a longer timescale, and has been called “space microerosion.” Tsuchiyama *et al.* (2011) proposed that the abrasion is probably the result of grain migration, which is caused by impact-driven seismic waves repeatedly reflecting off the surface of Itokawa (e.g., Miyamoto *et al.*, 2007). Alternatively, Connolly *et al.* (2014) proposed tidal disruption and YORP effects as possible causes of the physical weathering.

Solar-wind-implanted noble gases (He, Ne, and Ar) have been detected in Itokawa particles (Nagao *et al.*, 2011, 2013). This clearly shows that the particles were for some period of time located on the uppermost regolith layer. The residence

**Fig. 18.** Surface micronanomorphologies of Itokawa particles observed using a field-emission scanning microscope (FE-SEM). (a) Sharp steps on a fractured surface (sample RB-QD04-0049), (b) faint steps on a rounded surface (RB-QD04-0023), (c) growth steps on an olivine surface with facets (RB-QD04-0102), (d) blister structure on a surface with an euhedral grain (RA-QD02-0033), (e) pit with ornaments resembling a crater (sample RA-QD02-0093), (f) flattened glass like melt splash with bubble (sample RB-QD04-0043). Substrates of all the images are olivine (Ol). (a),(b),(f) are from Tsuchiyama (2014); (e) from Nakamura et al. (2012). Ca-zoning in pyroxene and mesostasis are seen in (b), which corresponds to a less-equilibrated sample (LL4-like).

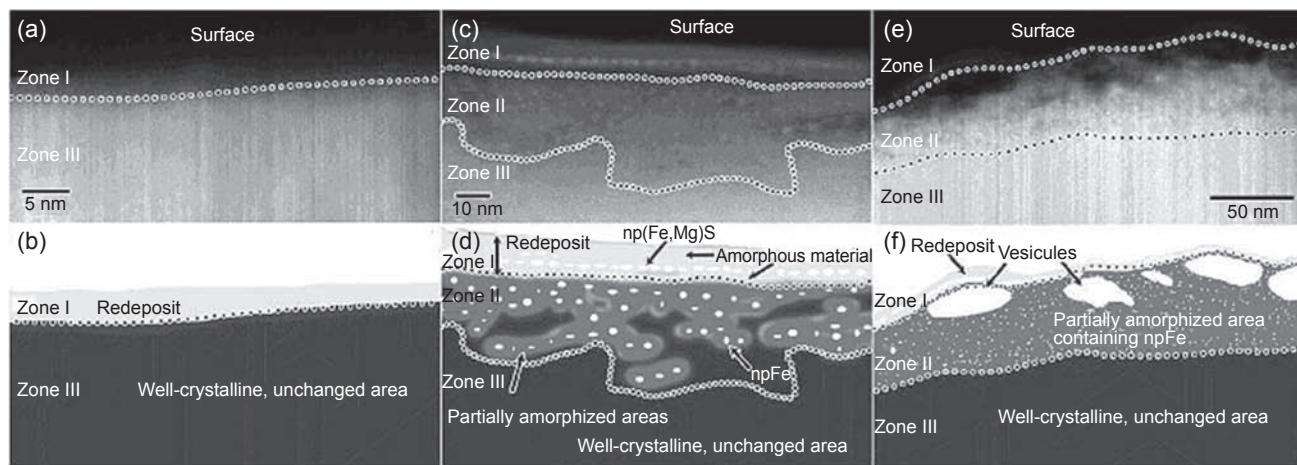

time spans were estimated to be 150–550 yr from the Ne concentrations (Nagao et al., 2011). Release profiles of the solar noble gases are consistent with grain motion in the regolith layer, and observed He losses suggest preferential abrasion of the space-weathered rims from the particle surfaces (Nagao et al., 2011). Galactic cosmic rays (GCR) can reach much deeper levels (several tens of centimeters to 1 m below the surface) in an asteroid. Nagao et al. (2011, 2013) detected no measurable GCR-produced Ne, which permits estimation of the upper limit of the residence timescale of grains in the regolith layer, namely, about 8 m.y. Meier et al. (2014) detected GCR-produced Ne, giving a residence timescale of ~1.5 m.y., which is much smaller than the crater age of Itokawa [60–75 m.y. (Michel et al., 2009)] but comparable with the period that Itokawa spent in near-Earth object (NEO) orbit [on the order of millions of years (Michel and Yoshikawa, 2005)]. This is much shorter than the nominal exposure ages of >400 m.y. for mature lunar regolith (Wieler, 2002).

**Fig. 19.** Three-dimensional shape distributions of Itokawa particles in comparison with fragments of impact experiments (from Tsuchiyama et al., 2014). a, b, and c are the longest, intermediate, and shortest axis lengths, respectively.

We can construct the following scenario for Itokawa's surface: (1) Formation of regolith by impacts of small objects, with selective escape of the finest-scale particles. Thermal fatigue might also play an important role in regolith formation. (2) Implantation of solar wind into the uppermost particle surfaces and formation of space-weathered rims with a timescale of ~10<sup>3</sup>–10<sup>4</sup> yr. (3) Grain abrasion, probably due to seismic-induced particle motion, with time periods significantly longer than 10<sup>4</sup> yr. Processes (2) and (3) and impact fragmentation occurred repeatedly. (4) Final escape of some particles from the asteroid by impact(s) within the final 1 m.y. Vernazza et al. (2009) proposed two-stage space-weathering models for asteroids based on the reflectance spectrum of S-type asteroid families and their ages: rapid spectral change mainly by solar wind implantation within 1 m.y. followed by slow change due to micrometeorite impact effects (~1 m.y. to ~30 b.y.). The timescale for the space-weathered rim formation (10<sup>3</sup>–10<sup>4</sup> yr) is much shorter than that for the observed reflectance spectral change (1 m.y.). The spectral change should proceed more slowly than simple space-weathered rim formation because of grain migration, removal of space-weathered rims by grain abrasion, and the refreshment of particle surfaces by impact fragmentation.

**4.4.4. Exotic materials that fell on Itokawa.** It is expected that exotic materials that originated from other celestial bodies fell on Itokawa and should be included among the Hayabusa samples. Carbonaceous materials, especially organic materials, are being actively sought but have not been detected for Category 1 and 2 particles thus far (Naraoka et al., 2012; Kitajima et al., 2011). Category 3

**Fig. 20.** Three typical surface features observed by HAADF-STEM on surficial olivine and pyroxene in Itokawa particles and corresponding schematic diagrams with interpretation of their textures (from Noguchi *et al.*, 2014a). np(Fe,Mg)S: nanophase (Fe,Mg)S; npFe: nanophase Fe.

carbonaceous particles were also examined. Differences in their microstructures and elemental distributions suggest multiple origins (Uesugi *et al.*, 2014), but measured H, C, and N isotopic compositions suggest (but do not prove) that they are of terrestrial origin (Ito *et al.*, 2014).

Micrometer- to submicrometer-sized alkali halides (NaCl and KCl) were identified on the surfaces of two Itokawa particles (Noguchi *et al.*, 2014c). These phases were clearly present on the particles' surfaces before allocation from JAXA, but there is not at this time direct evidence for their extraterrestrial origin. Handling of these very tiny grains (less than 10  $\mu\text{m}$  across) is difficult at present, but their examination is proceeding. Halides are occasionally found in ordinary chondrite regolith breccias (Zolensky *et al.*, 1999), and are of considerable interest.

## 5. SUMMARY

Although the origin and evolution of Itokawa are still speculative, from the results of the Hayabusa mission we can construct the following scenario: Originally, a parent body  $\sim$ 20 km in diameter was catastrophically disrupted by a smaller projectile. Among the dispersing fragments, some aggregated bodies were formed through gravitational interaction, as numerically demonstrated by Michel and Richardson (2013). The rubble-piled “head” and “body” were two of these aggregates, and they formed a co-rotating binary that eventually came into contact by collision at relatively low velocity, forming Itokawa as a result. The different orientations of the principal axes of the head and body (Saito *et al.*, 2006) also imply that these bodies were originally separate bodies. As suggested by Scheeres *et al.* (2007), the mutual configuration of the “head” and “body” might have changed from the initial contact of both bodies, due to various disturbances such as planetary encounters, impacts, and the YORP effect. This is the scenario that we derived from the Hayabusa data.

Itokawa was brought into a typical NEO orbit through  $v_6$  secular resonance in the main belt, as suggested by the numerical backtrack study of Itokawa's current orbit (Michel and Yoshikawa, 2006). Major craters had been formed on the surface of the asteroid before injection into NEO orbit, and the exposure time of the surface for cratering is estimated to be at least 60–75 m.y. (Michel *et al.*, 2009). The length of time that Itokawa spent in NEO orbit may have been on the order of millions of years, which is equivalent to its expected lifetime against an impact with Earth (Michel and Yoshikawa, 2005).

Hayabusa was a technological demonstration. We have learned a lot about the technology of sample return missions, and experienced the reality that sample return is very difficult, to say the least. However, this first experience demonstrated that the results are worth the challenge. We revealed the nature of a very small asteroid for the first time, and this will lead to an improved understanding of the origin of the solar system.

Thanks to the splendid results from Hayabusa, the next asteroid sample return mission, Hayabusa2 (Fig. 21), was planned (Tsuda *et al.*, 2013; Yoshikawa *et al.*, 2014) and then successfully launched on December 3, 2014. Hayabusa2 is similar to Hayabusa, but the target asteroid is a C-type asteroid, (162173) Ryugu (1999 JU<sub>3</sub>), which is expected to be more primitive and to contain organic material. Hayabusa2 will arrive at 1999 JU<sub>3</sub> in 2018, and return to Earth in 2020. The result of Hayabusa2 will be yet another breakthrough in the study of asteroids and of the solar system as a whole.

**Acknowledgments.** The Hayabusa mission was accomplished through the tremendous effort of many people. We appreciate all the engineers, scientists, researchers, administrative staff, and others who supported the Hayabusa mission so well. We are grateful to M. Zolensky, P. Michel, and an anonymous reviewer for their useful comments that helped to improve the manuscript greatly.

---

The objective of the Dawn mission is to travel back in time by interviewing two intact survivors of the earliest days of the solar system in the heart of the asteroid belt. The means of transport is a solar-powered spacecraft using electrostatically accelerated xenon ions to propel the flight system outward in the solar gravitational well to the points where it can orbit Vesta and later Ceres. While in orbit, it completely maps the surface topography, composition, and gravitational fields of the target bodies. At this writing, the Vesta phase of the mission is complete, and the spacecraft is nearing Ceres. Vesta's structure and composition are consistent with it being the parent body of the howardite, eucrite, and diogenite meteorites (HEDs). Although heavily bombarded and sheathed in a thick regolith, Vesta is largely intact and shows signs of possible endogenic processes, suggesting that Vesta is neither completely dry nor dormant. Resurfacing due to impacts and associated gravitational forces and seismic activity dominate the complex geologic history. While early understanding of Vesta's differentiation was modeled using very simple magma ocean models, Dawn's observations coupled with geochemical analyses of HEDs suggest a more complex evolutionary path. Since Ceres has provided no recognizable meteorites to our terrestrial collections, our pre-encounter understanding of Ceres is much less informed than it was at Vesta. Remote sensing has prepared us for a darker, water-rich environment.

## 1. INTRODUCTION

Geochemical investigations of meteorites pinpoint the beginning of the solar system to be 4.567 Ga, when the calcium-aluminum-rich inclusions (CAIs) were formed. At that time, the solar system was seeded with short-lived radioactive elements such as  $^{26}\text{Al}$  and bodies that accreted then trapped these radionuclides and their heat. If sufficiently large, the earliest-formed bodies melted and differentiated. The differentiation led to metallic cores, ultramafic mantles, and mafic crusts. Bodies that accreted later did not incorporate as much radiogenic heat of short-lived nuclides, and hence did not differentiate, so they did not devolatilize as completely as those formed earlier. The period of accretion in the region of the asteroid belt is thought to have continued until the formation of Jupiter, whose gravitational stirring perturbed the more regular orbits present in the earlier days of the solar system. Eventually the outer solar system became

fully developed, and interactions between the giant planets led to their migration, possibly into the asteroid belt, causing havoc and much scattering among the original members of the belt (Tsiganis *et al.*, 2005; Walsh, 2012).

While early civilizations realized that Venus, Mars, Jupiter, and Saturn existed, the only hint of the asteroid belt's existence was a gap where a planet should have existed, if the solar system followed a regular sequence. In the eighteenth century, this led astronomers to postulate such a body; and in the beginning of the nineteenth century, astronomers were rewarded by the discovery of (1) Ceres in 1801 and (4) Vesta in 1807. Remote sensing data eventually linked Vesta to the howardite-eucrite-diogenite (HED) meteorites (McCord *et al.*, 1970), but no link to Ceres has been found in the meteorite collection. Geochemical analysis of these meteorites provided a glimpse of the composition and structure of its parent body, but these studies took us only so far. We needed to obtain a closer look than remote sensing and

geochemistry could provide. Even the resolved imagery of the Hubble Space Telescope did little but increase the desire to visit the major asteroids.

In the early days of space exploration, flagship missions were sent to the major planets while the minor planets were ignored. It took the advent of NASA's Discovery program in 1992, which allows a principal investigator to lead a focused investigation to a particular target, for attention to turn to the minor planets. The Near Earth Asteroid Rendezvous (NEAR) mission (Russell, 1997) was one of the first two Discovery class missions and was sent to the near-Earth asteroid (433) Eros. In order to study larger asteroids, farther away, a much greater change in spacecraft velocity was required. Fortunately, xenon ion thrusters had become available that could accomplish the significant change in velocity required by such missions. By the time of the celestial alignment of Vesta and Ceres that enabled a visit to both on a single mission, these thrusters had been tested by the Deep Space 1 (DS-1) spacecraft and were ready for use on Discovery missions. The Dawn team's proposal to NASA was selected for implementation in 2001, launched in 2007, reaching Vesta in July 2011, leaving in September 2012, and currently destined to arrive at Ceres in March 2015.

## 2. THE DAWN MISSION

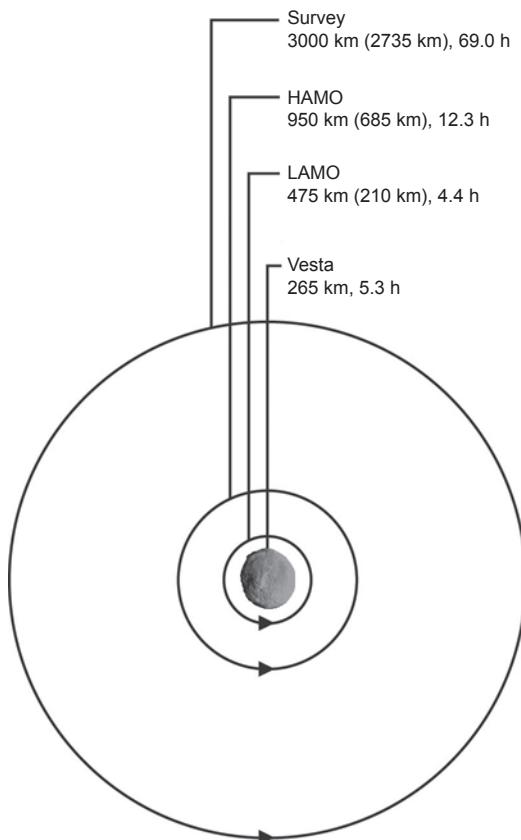

The Dawn spacecraft (Fig. 1) is powered by a large solar array that can rotate to allow the panels to remain orthogonal to the solar direction while the spacecraft points its instruments either at the body around which it orbits or to its telemetry antenna at Earth. It has two means of orienting itself in space: reaction wheels and thrusters. The reaction wheels were available for Vesta mapping, but most of the Ceres mission will be performed using the thrusters. The spacecraft carries a framing camera (FC) (Sierks *et al.*, 2011) that returns either clear filter images or images in one of seven color bands in the visible and near-infrared (IR). A visible and IR mapping spectrometer (VIR) (De Sanctis *et al.*, 2011) also covers the visible range and extends further into the near-IR. Here the silicate pyroxene has several absorption bands that allow the separation of diogenite and eucrite as well as the

identification of olivine. The VIR instrument has greater sensitivities for mineral identifications, but the FC provides greater spatial resolution and hence these two instruments are complementary. A gamma-ray and neutron detector (GRaND) (Prettyman *et al.*, 2011) provides elemental abundances of the major rock-forming elements (including H, Fe, Si, K, and O and other elements) included in a determination of mean atomic mass. The mineralogical and chemical data from Dawn's instruments have solidified the link between Vesta and the HEDs (McSween *et al.*, 2013a), allowing the meteorites to be used in instrument calibration and data interpretation. The camera is used to obtain topographic information by acquiring images from different vantage points (Raymond *et al.*, 2011), and radiometric tracking allows the gravity field to be determined (Konopliv *et al.*, 2011).

The science data are acquired in three separate orbits called the survey orbit, high-altitude mapping orbit (HAMO), and low-altitude mapping orbit (LAMO), as shown in Fig. 2. The HAMO observations were repeated as Dawn was leaving Vesta to obtain more complete stereo coverage and to see closer to the pole. The initial gravity field is determined in the survey orbit as is the VIR's global, but low-resolution, mineralogy map. In HAMO, the FC is the prime instrument obtaining full coverage and multiple views for topography. In LAMO, both the gravity survey and the GRaND measurements are prime, but there are ride-along measurements

**Fig. 1.** See Plate 6 for color version. The Dawn spacecraft depicted as it left Earth on September 27, 2007.

**Fig. 2.** Dawn's orbits at Vesta giving the orbital radii, altitudes, and periods. Vesta's rotational period is 5.3 h.

that provide high-resolution near-global imaging by the FC and targeted coverage with VIR. The observation plans for Ceres are similar to those used at Vesta, adjusted for Ceres' larger size. A summary of the mission can be found in the overview and accompanying articles of a special issue of the journal *Space Science Reviews* (Russell and Raymond, 2011).

One of the objectives of the Dawn mission is to produce geologic maps of the surfaces at Vesta and Ceres. To accomplish this, Vesta was divided into 15 quadrangles (Roatsch, 2012, 2013). A band of five quadrangles is identified around the equator going from  $0^{\circ}$  to  $360^{\circ}$  in  $72^{\circ}$  steps with a north-south extent of  $\pm 22.5^{\circ}$ . Above and below this are two bands of four quadrangles, each  $90^{\circ}$  in extent, also beginning at  $0^{\circ}$  and  $45^{\circ}$  wide in latitude. The north and south polar cap quadrangles had radii of  $22.5^{\circ}$ . Since Dawn found a significantly different rotation axis than had been derived from groundbased data, and since the earlier longitude reference was a broad feature whose source was not obvious in Dawn's images, a new coordinate system was drawn that was anchored in the small crater Claudia whose position could be well measured; this system used a prime meridian that was different than that derived previously. The Dawn project felt there were advantages to defining a new system to clearly distinguish it from the older system based on the incorrect pole. Subsequently, the International Astronomical Union (IAU) approved a system using the new rotational elements but with a prime meridian defined to align with that of the pre-Dawn system. To date, all papers in the literature use the Claudia-anchored Dawn coordinate system. Data in this coordinate system are available from the Dawn project (<http://dawndata.igpp.ucla.edu>). For Ceres, close collaboration with the IAU has been established to define the Ceres coordinate system.

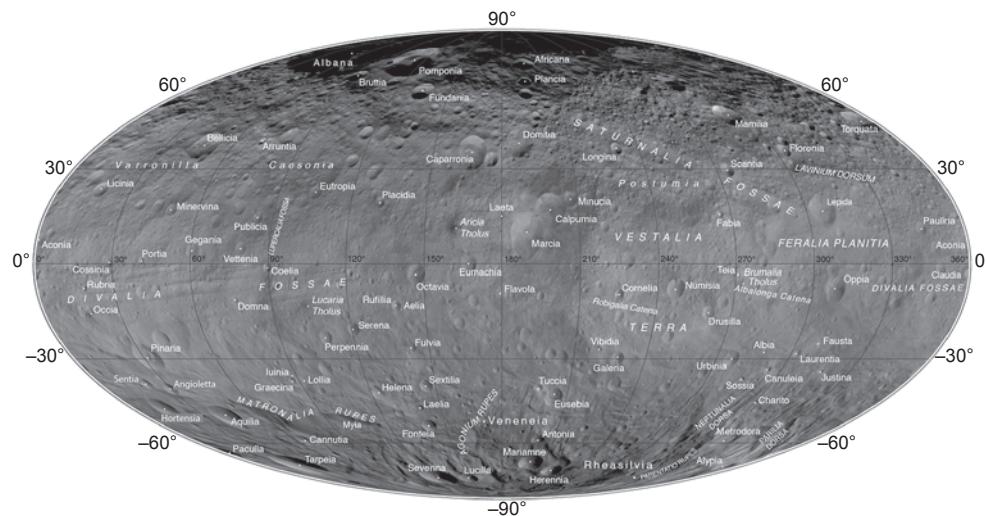

The names selected for Vesta's craters were drawn from an IAU-approved database based on the written history of the Vestals, who devoted themselves to the service of

the goddess Vesta. This was supplemented with a list of historical Roman women. Other feature names were associated with festivals related to Vesta and Roman towns. Naming has gone smoothly and an analogous process with a different theme is in progress for Ceres. Figure 3 shows a mosaic of the surface of Vesta in Dawn Claudia coordinates with the names approved to date. Figure 4 shows the same projection of the FC color data, using Clementine color ratio composites, as derived for the Clementine mission data analysis (*Pieters et al.*, 2011). These ratios demonstrate the broad chemical diversity of the vestan surface, indicating that our simplistic models of Vesta's formation and evolution needed revision.

As had been proposed originally for both Vesta and Ceres, participating scientists were added to the science team in the year before arrival at Vesta. Many of these new participants had experience developing geologic maps of planetary surfaces. When the images were returned to Earth, these geologic mappers selected quadrangles and mapped their geology. These maps were then combined into a planet-wide geologic map as shown in Fig. 5. In addition to the geologic characterization of the surface, Dawn determined Vesta's physical properties. Vesta has a mass of  $2.591 \times 10^{20}$  kg, with a volume of  $74.97 \times 10^6$  km $^3$ , resulting in an average density of 3456 kg m $^{-3}$  (*Russell et al.*, 2012). Its shape is described by a triaxial ellipsoid of radii 286.3/278.6/223.2 km.

### 3. EVOLUTION OF CRUST

The Dawn spacecraft extensively imaged Vesta's surface, revealing a collision-dominated history. Vesta's cratering record has a strong north-south dichotomy (Figs. 3, 4, and 5). The northern heavily cratered terrains retain much of their earliest history, while the southern hemisphere was reset by two major collisions in more recent times (Fig. 6). The younger, larger Rheasilvia basin, centered at 300°E and 78°S,

**Fig. 3.** Mosaic of Vesta's surface using Mollweide projection. Names of surface features are those approved by the International Astronomical Union (IAU) at the time of this writing. From Roatsch *et al.* (2014).

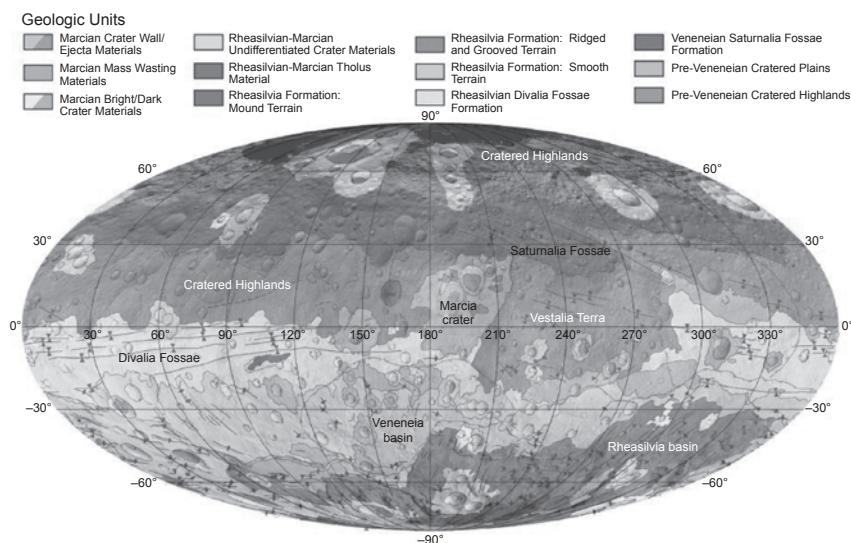

**Fig. 4.** See Plate 7 for color version. Mollweide projection of FC color mosaic using Clementine ratios (A. Nathues, personal communication, 2014).

has a diameter of  $500 \pm 25$  km and a central mound 180 km wide and about 20 km high, and the older, more degraded Veneneia basin, centered at  $173^{\circ}\text{E}$ ,  $51^{\circ}\text{S}$ ,  $400 \pm 25$  km wide, is partly overlapped by the Rheasilvia structure (Russell *et al.*, 2012; Jaumann *et al.*, 2012; Schenk *et al.*, 2012). The Rheasilvia event occurred at about 1 Ga (Schenk *et al.*, 2012; Marchi *et al.*, 2012) according to an asteroid flux-derived chronology (e.g., O'Brien *et al.*, 2014) or 3.5 Ga, according to a lunar-derived chronology (e.g., Schmedemann *et al.*, 2014). The material excavated by this collision formed asymmetric mega-ejecta deposits close to Vesta's equator as can be seen in the global topography shown in Fig. 7. Because Vesta was subject to intense cratering, impact-related processes played a major role in (re)shaping the surface. With respect to their erosional appearance, impact craters on Vesta range from fresh craters, showing sharp, uneroded crater rims and ejecta deposits, to craters with heavily degraded, even ruined, crater rims (Jaumann *et al.*, 2012).

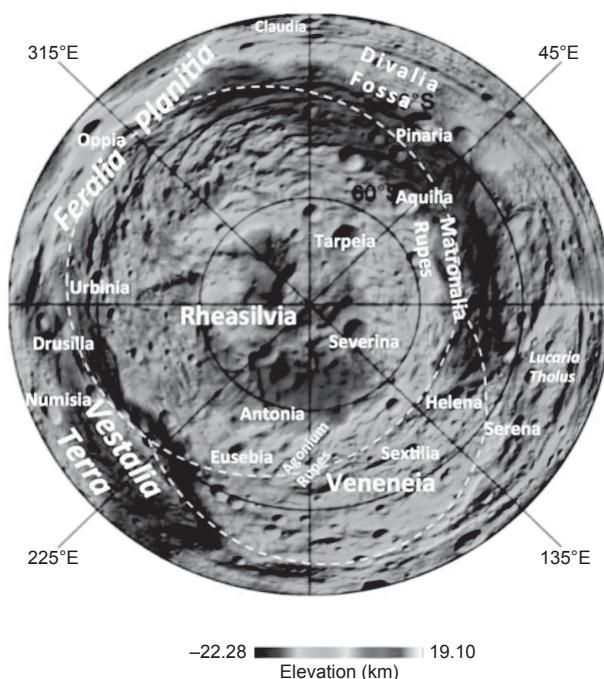

Large-scale structural features, including sets of graben, occur in the equatorial and northern regions of Vesta, as

shown well in Fig. 7. The equatorial troughs (Divalia formation) are wide, flat-floored, and bounded by steep scarps circling about two-thirds of the asteroid, as illustrated in the FC image shown in Fig. 8. Their lengths vary from 19 to 380 km and can be as wide as 15 km (Jaumann *et al.*, 2012). Muted troughs, grooves, and pit crater chains are evident in the remaining part of the asteroid (Jaumann *et al.*, 2012; Buczkowski *et al.*, 2012). The other set of large-scale linear trough structures extend to the northwest at an angle of about  $30^{\circ}$  from the equatorial troughs (Saturnalia formation). The primary structure in this group is 390 km long and 38 km wide. Although larger than the equatorial troughs, their walls display gentler slopes and rounded edges. They show considerable infilling and heavy cratering, suggesting an older age (Jaumann *et al.*, 2012; Buczkowski *et al.*, 2012). Most of the large-scale graben are co-planar (Buczkowski *et al.*, 2012). The poles of the global equatorial and northern troughs agree within the errors with the coordinates of the basin centers of Rheasilvia ( $318^{\circ}\text{E}$ ,  $70^{\circ}\text{S}$ ) and Veneneia ( $173^{\circ}\text{E}$ ,  $51^{\circ}\text{S}$ ) at the south pole (Jaumann *et al.*, 2012; Buczkowski *et al.*, 2012), respectively. This strongly suggests that the formation of the troughs is related to the formation of the basins as extensional graben. The older sets of graben are exposed only in the northern hemisphere; they were obliterated in the southern hemisphere by the Rheasilvia impact. This is consistent with the younger age of Rheasilvia, and also indicates that all structures in the southern hemisphere were destroyed or at least affected by the Rheasilvia impact and its ejecta (Jaumann *et al.*, 2012).

Vesta can be divided geologically into three terrain types: heavily cratered terrain; ridge-and-trough terrain (equatorial and northern); and terrain associated with the Rheasilvia basin (Fig. 5) (Jaumann *et al.*, 2012; Yingst *et al.*, 2014; Williams *et al.*, 2014c). Localized features include bright and dark material and ejecta (some defined specifically by color), lobate deposits, and mass-wasting materials (Otto *et*

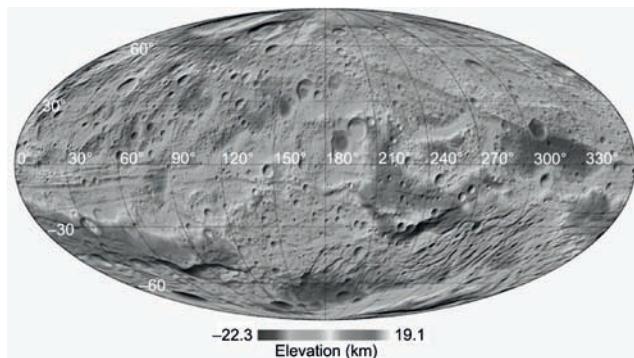

**Fig. 5.** See Plate 8 for color version. Geologic map of Vesta using Mollweide projection. Major terrains are identified here. From Jaumann *et al.* (2012) and Williams *et al.* (2014a).

**Fig. 6.** See Plate 9 for color version. The Veneneia and Rheasilvia south polar basins and their geological environment. From Jaumann et al. (2012).

al., 2013; Krohn et al., 2014a). The ages of these deposits range from 3.4 Ga for ancient cratered highlands and the Saturnalia Fossa formation, to 100 Ma or less for more recent deposits associated with Marcia crater (Fig. 5). The units associated with the Rheasilvia impact structure range from 1.5 to 1.8 Ga (Marchi et al., 2012; Schmedemann et al., 2014; Williams et al., 2014c). Stratigraphy of Vesta's geologic units suggests a history in which magmatic differentiation and crystallization of a primary crust were followed by the formation of impact basins and craters, including Veneneia and the associated Saturnalia formation. Formation of Rheasilvia followed, along with associated structural deformation that formed the Divalia ridge-and-trough formation at the equator (Figs. 7 and 8). Subsequent impacts and mass wasting events subdued impact craters, basin rims, and portions of ridge-and-trough sets, and formed slumps and landslides, especially within crater floors and along basin rims and scarps (Jaumann et al., 2012). Subsequent to the Rheasilvia formation, discontinuous low-albedo deposits were emplaced stratigraphically above the equatorial ridges that likely were triggered by the Rheasilvia event. The latest features to be formed were craters with bright rays and other surface mantling deposits.

The geologic maps also enabled the development of a time stratigraphic sequence for Vesta (Fig. 9). We identified four geologic time periods: pre-Veneneian, Veneneian, Rheasilvian, and Marcian (Williams et al., 2014a). The Pre-Veneneian period covers the time from the formation of Vesta (1–2 m.y. after the formation of the first solids in the protosolar disk) up to the Veneneia impact event. The

**Fig. 7.** See Plate 10 for color version. Mollweide projection of Dawn topography data.

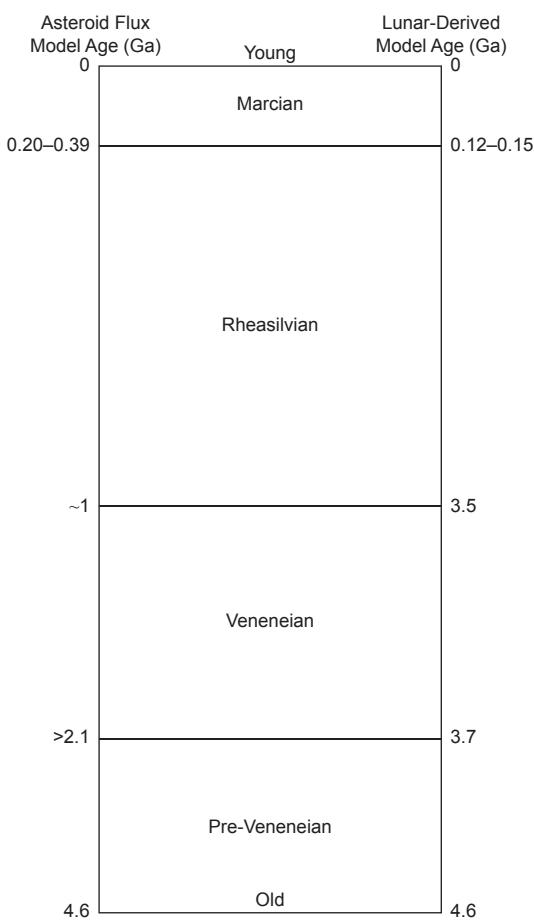

**Fig. 8.** Divalia Fossae, large-scale grabens on Vesta circling around the equator. The tectonic graben structures are related to the Rheasilvia and Veneneia impacts.

Veneneian period encompasses the time between the Veneneia and Rheasilvia impact events. The Rheasilvian period is defined as the time between the formation of Rheasilvia and Marcia craters, and the Marcian period covers the time between the formation of Marcia crater until the present. Absolute ages for the boundaries of these periods have been derived by applying two crater chronologies: One is based on the current understanding on asteroidal impact rate at Vesta and its evolution over time (Marchi et al., 2014), and the other is based on an extrapolated version of the lunar crater chronology (Schmedemann et al., 2014). While the ages and durations of the various periods change considerably depending on which chronology is applied, the relative age of the Veneneia and Rheasilvia impact is unambiguously determined by superposition relationships, while the formation of Marcia crater clearly represents the youngest major geologic event on Vesta. This system is consistent with those developed for the Moon, Earth, Mars, and Mercury.

### 3.1. Particular Geologic Features (Asymmetric Craters, Spirals, Pits, Gullies, etc.)

Topography plays a significant role in crater formation and modification processes on Vesta. Compared to its radius,

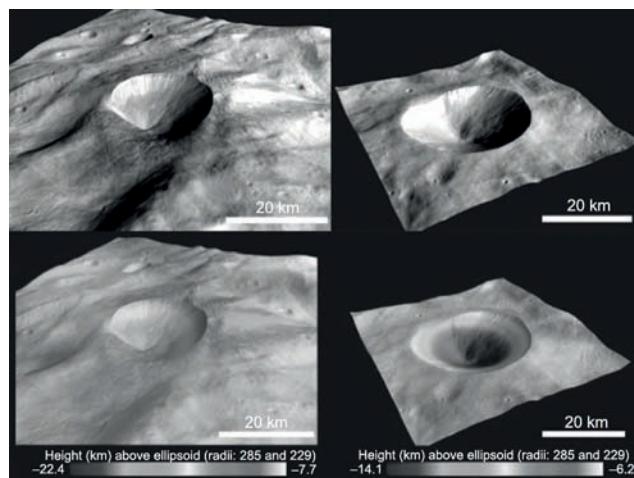

**Fig. 9.** Chronostratigraphy of Vesta. From Williams *et al.* (2014a).

Vesta has a very intense relief resulting in relatively steep slopes (reaching up to 55°) (Jaumann *et al.*, 2012). Impacts onto such steep surfaces, followed by slope failure, makes resurfacing due to impacts and their associated gravitational and seismic activity an important geologic process on Vesta that significantly alters the morphology of geologic features and adds to the complexity of Vesta's surface evolution. There are numerous cases of craters formed on slopes where pronounced collapse and slumping occurred on upslope sides of the craters, resulting in an extreme asymmetric morphology with a wider upslope crater wall and a narrower downslope wall. In extreme cases, the upslope material has fallen back into the crater, overrun the downslope rims, and flowed out of the craters (Jaumann *et al.*, 2012). Slopes >20° prevent the deposition of ejected material in the uphill direction, and slumping material superimposes the ejecta deposit on the downhill side. Crater-sized frequency measurements for ejecta deposits, crater interiors, and surrounding surfaces reveal similar ages, within measurement and cratering chronology model uncertainties, indicating that the deposits most likely formed during impact and no major post-impact processes modified the crater (Krohn *et al.*, 2014b). These asymmetries are the result of the local slope, which prevents deposition of ejected material in the

uphill direction and results in a larger accumulation of ejecta within the crater and on the downhill crater rim (Fig. 10).

Smooth, flat regions occur in the interiors of some craters and in small depressions as pond-like accumulations with well-defined geological contacts, which indicate that they are younger than their surroundings (Jaumann *et al.*, 2012). Several scenarios of the origin of these deposits seem plausible, including impact deposition, impact melt, dust levitation and transport, seismic shaking, or slumping of fine material. Another observation is pitted terrain on the floor of some impact craters like Marcia (Fig. 11) and Cornelia (Fig. 12). Pitted terrain is characterized by irregular rimless depressions, a distinct morphology not observed on other airless bodies (Denevi *et al.*, 2012). Similar terrain is associated with numerous martian craters, where pits are thought to form through degassing of volatile-bearing material heated by the impact. Pitted terrain on Vesta may have formed by a similar process, indicating the surface contains a relatively large volatile component (Denevi *et al.*, 2012).

Some of Vesta's craters, notably Marcia and Cornelia, exhibit gullies eroding the crater walls as linear systems or curvilinear systems (Fig. 11) (Scully *et al.*, 2014). Linear systems consist of straight and non-intersecting gullies that are parallel to one another, similar to lunar gullies, suggesting an origin by dry granular flow. Complete curvilinear systems, however, consist of interconnected, partly dendritic to subparallel nonlinear gullies. They originate from the upper and middle sections of crater walls out of alcove-like features and terminate in lobate deposits near the base of the walls. In places, lobate deposits partially lie on top of one another, indicating multiple phases of accumulation. The shapes of the

**Fig. 10.** See Plate 11 for color version. Typical impact crater on Vesta: Antonia (200.8°E, 58.7°S; diameter 16.75 km) is an impact on a slope of asymmetric shape with the ejecta mainly concentrated downhill also covering the downslope crater rim; Sextilia (145.9°E, 39°S; diameter 19.48 km) is of approximately the same size, located on a more gentle slope, and circular in shape but exposing significant mass wasting inside the crater on the uphill rim (Jaumann *et al.*, 2012; Krohn *et al.*, 2014b).

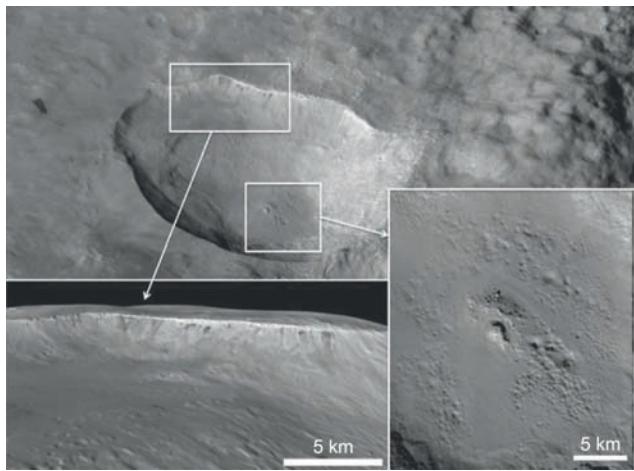

lobate deposits resemble terrestrial alluvial fans formed by debris flows. The morphological preservation of curvilinear systems is age-dependent: Well-preserved systems occur in the walls of young (less than hundreds of million years old) craters such as Marcia, whereas less well-preserved systems, characterized by strong modification of original morphology by later geologic processes, occur in the older Calpurnia crater. Curvilinear gullies differ markedly from linear gullies (Scully et al., 2014). Recent studies suggest the presence of hydrated minerals (De Sanctis et al., 2012b; McCord et al., 2012; Prettyman et al., 2012; Reddy et al., 2012; Jaumann et al., 2014) and past subsurface water on Vesta (Sarafian et al., 2013; Warren et al., 2013), and the gullies are direct geologic evidence of water activity on Vesta's surface. The morphology of the curvilinear systems suggests that they formed by flow of transient water that was released from buried ice-bearing deposits by impact-induced heating and melting. This interpretation is also in accordance with the occurrence of pitted terrain on Vesta, resulting from degassing of volatiles. The buried ice-bearing deposits are likely localized in extent and may still be present in Vesta's subsurface (Scully et al., 2014).

### 3.2. Regolith (Formation, Structure, Thickness, Mixing Models, Dark Material, and Space Weathering)

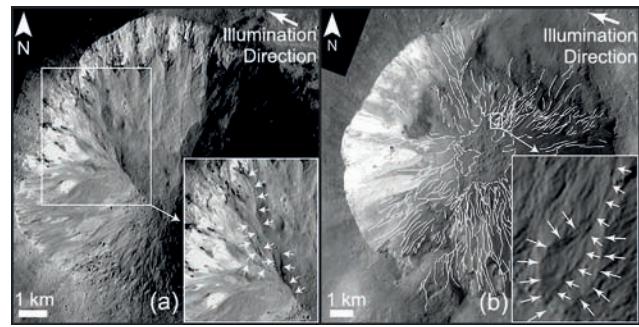

Vesta is quite different from other airless bodies. Although freshly exposed material on the surface of Vesta is mixed into surrounding background regolith with time (a form of mechanical space weathering), Vesta's surface does not involve significant accumulation of nanophase opaque particles on rims of regolith grains (Pieters et al., 2012). Instead, physical regolith processes on Vesta appear to be sufficiently robust to produce a locally well-mixed regolith derived from host lithologies containing variable amounts of bright and darker components (McCord et al., 2012). The

dominant processes involved with regolith mixing at Vesta must include large- and small-scale impact events that not only produce particulate material and distribute absorbing components at a fine scale, but also continually garden the local regolith vertically and laterally. The low average impact velocity ( $\sim 5 \text{ km s}^{-1}$ ) (Bottke et al., 1994) expected for Vesta's location in the main asteroid belt suggests that mechanical brecciation dominates over melting and vaporization (Pieters et al., 2012). Vesta's basaltic composition, coupled with relatively steep topography (Jaumann et al., 2012) and weak gravity (Konopliv et al., 2013) compared to planets and large moons, certainly contributes to the mobility of its regolith. The regolith of Vesta indicates space weathering focuses on solar wind and micrometeorite interactions accompanied by regolith mobility and fine-scale mixing as part of the complex assortment of processes acting on the planetary surface with time (Pieters et al., 2012). The cratering record of Vesta comprises crater sizes of up to tens of kilometers in diameter that are partly covered by ejecta. Scaling to the depth/diameter ratio to these sizes suggest regolith thicknesses of up to a few thousand meters (Jaumann et al., 2012). However, the ejecta of the youngest basin Rheasilvia presumably exceed this number significantly and dominate the surface of the southern hemisphere.

Deposits of dark material appear on Vesta's surface as features of relatively low-albedo in the visible wavelength range of Dawn's camera and spectrometer (Jaumann et al., 2012, 2014; McCord et al., 2012; Reddy et al., 2012). Mixed with the regolith and partially excavated by younger impacts, the material is exposed as individual layered outcrops in crater walls (Fig. 11) or ejecta patches, having been uncovered and broken up by the impact. Dark fans on crater walls and dark deposits on crater floors are the result of gravity-driven mass wasting triggered by steep slopes and impact seismicity. The fact that dark material is mixed with impact ejecta indicates that it has been deposited together with the ejected material. Some small craters display continuous dark ejecta, indicating that the impact excavated the material from beneath (Jaumann et al., 2014). The asymmetric distribution of dark

**Fig. 11.** This true-color composite of Marcia crater ( $189.5^\circ\text{E}$ ,  $9^\circ\text{N}$ ; diameter  $67.6 \text{ km}$ ) shows pitted terrain on its crater floor (lower right), gullies on its crater walls, and dark material cropping out from the crater wall (lower left). From Denevi et al. (2012) and Jaumann et al. (2014).

**Fig. 12.** (a) Rubria crater ( $18.3^\circ\text{E}$ ,  $7.3^\circ\text{S}$ ; diameter  $10.27 \text{ km}$ ) with gullies originating from alcoves, cutting the crater wall in subdendritic and subparallel pattern ending in an apron; (b) Cornelia crater ( $225.6^\circ\text{E}$ ,  $9.4^\circ\text{S}$ ; diameter  $14.9 \text{ km}$ ) showing a dense dendritic pattern of gullies and pitted terrain in the center of the crater floor. From Scully et al. (2014).

material in impact craters and ejecta suggests noncontinuous distribution in the local subsurface (Jaumann *et al.*, 2014). Some positive-relief dark edifices appear to be impact-sculpted hills with dark material distributed over the hill slopes (Jaumann *et al.*, 2012; Williams *et al.*, 2014b). Dark features inside and outside of craters are in some places arranged as linear outcrops along scarps or as dark streaks perpendicular to the local topography. The spectral characteristics of the dark material resemble that of Vesta's regolith (De Sanctis *et al.*, 2012b; Stephan *et al.*, 2013). Dark material is distributed unevenly across Vesta's surface with clusters of all types of dark material exposures. On a local scale, some craters expose or are associated with dark material, while others in the immediate vicinity do not show evidence of dark material. The variety of surface exposures of dark material and their variable geological correlations with surface features, as well as their uneven distribution, indicate a globally inhomogeneous distribution in the subsurface. However, the dark material seems to be concentrated near the rim and ejecta of the older Veneneia south polar basin structure (Jaumann *et al.*, 2014). The origin of the dark material is still being debated; however, the geological analysis suggests that it is exogenic, from carbon-rich low-velocity impactors, rather than endogenic, from freshly exposed mafic material or melt, exposed or created by impacts (McCord *et al.*, 2012; Reddy *et al.*, 2012; Jaumann *et al.*, 2014). Among the three types of dark components found in HED meteorites (Russell *et al.*, 2012), which include clasts of carbonaceous chondritic material, impact melt, and impact-shock-blackened material (McSween *et al.*, 2011, 2013a), the carbonaceous component provides the best match with the spectral properties (McCord *et al.*, 2012) and in almost all cases with the geological setting and the subsurface structure of the dark material.

#### 4. VESTA'S SURFACE AND INTERIOR COMPOSITIONS

##### 4.1. Accretion and Bulk Composition

Vesta formed early and differentiated rapidly. Thermal evolution models based on heating by decay of short-lived radionuclides require Vesta to have accreted within  $\sim 1.4$  m.y. of solar system formation (Formisano *et al.*, 2013; Neumann *et al.*, 2014). The measured  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  and  $^{26}\text{Al}$ - $^{26}\text{Mg}$  isochrons for HEDs indicate crust-mantle differentiation at 1–3 m.y. after the formation of the earliest solar system solids (CAIs) (Trinquier *et al.*, 2008; Schiller *et al.*, 2011), consistent with the  $\sim 3$ -Ma age of core formation determined from the  $^{182}\text{Hf}$ - $^{182}\text{W}$  chronometer (Kleine *et al.*, 2009).

The geochemistry of HED meteorites together with the gravity field constrains Vesta's bulk composition. The most successful model (Toplis *et al.*, 2013) combines 75% Na-depleted H chondrite and 25% CM chondrite. This composition has an ultramafic mantle rich enough in orthopyroxene to produce abundant diogenite cumulates that can also yield basaltic (eucrite) melts, a Fe/Mn ratio, oxygen-isotopic composition, and oxidation state consistent with HEDs,

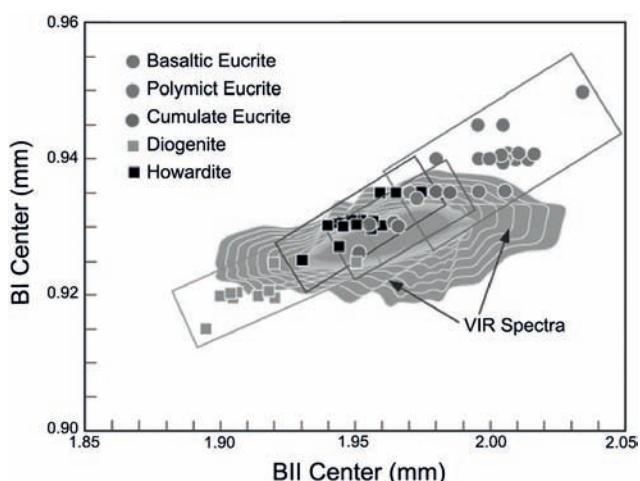

and a bulk silicate density and inferred core mass like those estimated from Dawn gravity data.

#### 4.2. Surface Distribution of Howardite-Eucrite-Diogenite Compositions

Dawn compositional data have significantly reinforced the pre-Dawn (Gaffey, 1997) identification of Vesta as the HED parent body (McSween *et al.*, 2013b). Using HED calibrations, Dawn instruments have mapped the distributions of the various lithologies on Vesta's surface. These match basalts or gabbros (eucrites), ultramafic rocks composed of orthopyroxene and olivine (diogenites), and brecciated mixtures of eucrites and diogenites (howardites). The identification of eucrites, diogenites, and howardites is based on the positions of 1- $\mu\text{m}$  and 2- $\mu\text{m}$  band centers (called BI and BII) from VIR reflectance spectra (De Sanctis *et al.*, 2013). This relationship (Fig. 13) was used to construct a global lithologic map (Fig. 14) (De Sanctis *et al.*, 2012b), which documents that howardites and/or eucrites (many pixels plot in the overlapping fields) comprise most of Vesta's surface. The VIR map is fully consistent with a higher-spatial-resolution FC map of color parameters (Thangjam *et al.*, 2013), as shown in Fig. 4.

The distribution of HED lithologies has also been mapped using GRaND's neutron-absorption properties (Prettyman *et al.*, 2013). A GRaND map, cast in terms of percentage of eucrites in the regolith, shows very similar abundances and distributions as the VIR map (Fig. 14). Other GRaND map products, including global maps of iron abundance (Yamashita *et al.*, 2013) and high-energy gamma rays (Peplowski *et al.*, 2013), give similar distribution patterns.

All these maps show a regolith surface composed mostly of howardites, except for an equatorial region dominated by basaltic eucrites and a concentration of diogenites within the Rheasilvia basin and its ejecta blanket. The regional diversity in proportions of eucrites and diogenites in Vesta's regolith, as seen Fig. 14, is similar to the diverse mixing ratios in

**Fig. 13.** See Plate 12 for color version. BI vs. BII for VIR data and HEDs (De Sanctis *et al.*, 2012a, 2013).

howardites (Warren et al., 2009). A swath of diogenite-rich material extends northward from Rheasilvia. The iron map also shows a distinctive low-Fe region in the western hemisphere that is not evident in other maps and may indicate cumulate eucrites (Yamashita et al., 2013), which are otherwise difficult to distinguish spectrally from basaltic eucrites. The mapped distributions are plausible based on geologic reasoning—slowly cooled diogenite cumulates should have been excavated from the largest impact basin, and basaltic eucrites are expected to dominate regions having the oldest surfaces, as determined from crater densities. Basin ejecta are howardites rich in the diogenite component, and howardites elsewhere have a higher proportion of crustal eucrites. However, none of these regions should necessarily be considered launch sites for HEDs; nearly all these meteorites were probably carved out of, and ejected from, the Rheasilvia cavity, forming the vestoids (Binzel and Xu, 1993).

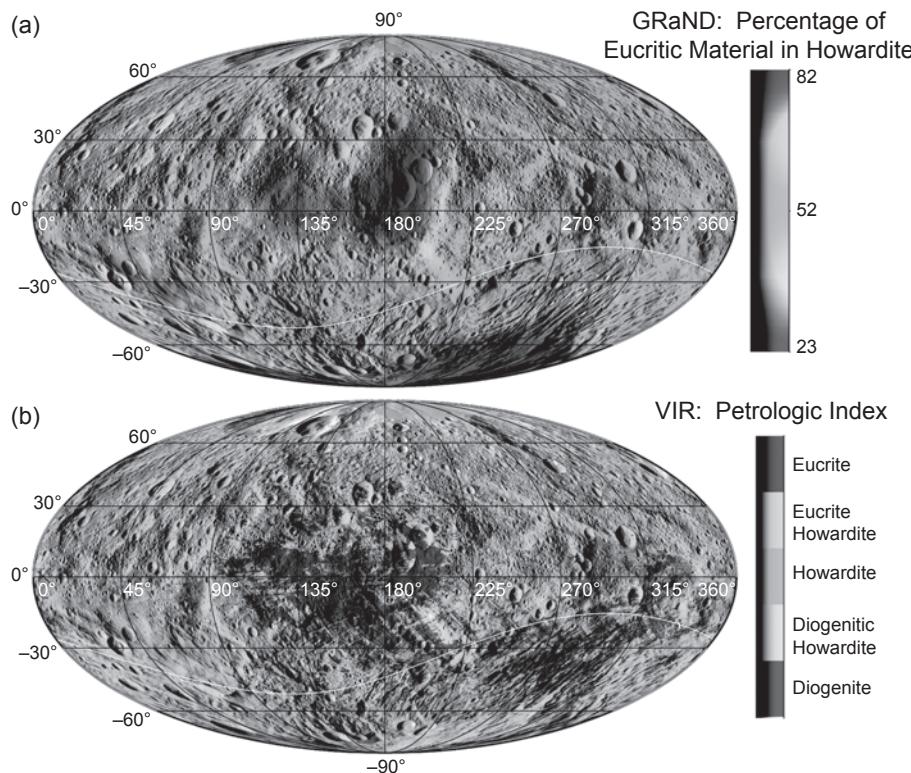

GRaND analyses showed regions of dark material (described in section 3.2) to have higher H abundances ( $>400 \mu\text{g g}^{-1}$ ) (Prettyman et al., 2012), and VIR spectra identified an OH absorption feature in the same areas (De Sanctis et al., 2012b). This compositional anomaly is attributed to exogenic carbonaceous chondrites incorporated into the regolith. Some howardites contain clasts of carbonaceous chondrites, and comparison of the VIR spectra with those

of eucrite-CM chondrite mixtures suggests 1–6% chondrites (Reddy et al., 2012). This amount is consistent with the H abundance measured by GRaND (Prettyman et al., 2012).

### 4.3. Vesta's Excavated Interior

Models for formation of the overlapping Rheasilvia and Veneneia basins estimate excavation depths of as much as 60–100 km (Jutzi et al., 2013). Given Vesta's nominal basaltic crustal thickness of ~15–20 km (McSween et al., 2013b; Toplis et al., 2013), these impacts should have exposed mantle rocks, thought to contain significant amounts of olivine.

Some diogenite breccias contain harzburgite (olivine + orthopyroxene) or dunite (>90% olivine) clasts (Beck and McSween, 2010), so exposure of mantle olivine in the Rheasilvia and Veneneia basins was expected. However, spectrally identifying <25% olivine in the presence of orthopyroxene is challenging (Beck et al., 2013), and no olivine has been detected in Rheasilvia by VIR (McSween et al., 2013b). However, a few higher concentrations of olivine (>50%) in other areas have been identified in VIR spectra. Ammannito et al. (2013) found olivine in the Bellicia and Arruntia craters in the northern hemisphere, and other isolated occurrences have been noted in the diogenite “lane” in Vesta's eastern hemisphere (Fig. 14a) (Ruesch et al., 2014). These exposures

**Fig. 14.** See Plate 13 for color version. Lithologic maps of Vesta remapped in Mollweide projection. (a) Map of HED distribution mapped by VIR (Ammannito et al., 2013). (b) Map of the percentage of eucritic material from GRaND data (Prettyman et al., 2013). Eucritic regions appear as blue in the color version, whereas regions that are more diogenitic appear as red.

occur in association with howardite rather than diogenite in regions of thin crust, as determined from gravity models. Highly magnesian olivines discovered in a few howardites have been interpreted as mantle grains (Lunning *et al.*, 2014), but they comprise only a tiny fraction of the meteorites.

Noting the lack of detection of olivine in Rheasilvia, Clenet *et al.* (2014) suggested that the crust of Vesta must be >80 km thick. Their notion of “mantle” is olivine-rich rock, and they apparently define other ultramafic rocks, such as orthopyroxene-rich diogenites, as “crust.” In arguing that Rheasilvia sampled the mantle, McSween *et al.* (2013b) defined the crust as mafic rocks (eucrites) and upper mantle rocks (diogenites). This distinction is not trivial; a bulk-chondritic Vesta, if fully differentiated, could only produce a ~20-km thickness of basalt. Earth’s crust-mantle boundary (“moho”) separates mafic and ultramafic rocks, and Vesta’s moho should be defined similarly. The missing olivine in the diogenitic upper mantle is likely to be sequestered in the lower mantle, as a solid residue from incomplete but widespread partial melting (Neumann *et al.*, 2014).

#### 4.4. Differentiation from a Magma Ocean or Serial Magmatism?

Pervasive melting to form an early magma ocean is consistent with Vesta’s rapid differentiation and the HED’s homogenized oxygen isotopes (Greenwood *et al.*, 2005), and numerous magma ocean models have been proffered (e.g., Righter and Drake, 1997). Fractional crystallization in a Vestan magma ocean would be difficult because crystal setting is impeded by high effective viscosity resulting from a large fraction of crystals at all depths. The magma ocean model of Mandler and Elkins-Tanton (2013) thus involves equilibrium crystallization of olivine and orthopyroxene, at least until 60–70% solidification.

The model of Wilson and Keil (2012) predicts very efficient removal of melts from the mantles of asteroid-sized bodies, so that only a small amount of melt is present at any one time, precluding a magma ocean. Mandler and Elkins-Tanton (2013) recognize the need for crystal fractionation to make orthopyroxene cumulates (diogenites), so their model incorporates continuous extraction of residual melts from the mostly crystallized magma ocean into shallow magma chambers. Crystal accumulation in these chambers, accompanied by magma recharge, can explain the perplexing geochemical variations in eucrites and diogenites (McSween *et al.*, 2011). These magma bodies might stagnate at the crust-mantle boundary or intrude higher in the crust, in either case forming plutons that would make the crust appear thicker and shield the lower mantle from excavation by impacts consistent with Dawn observations.

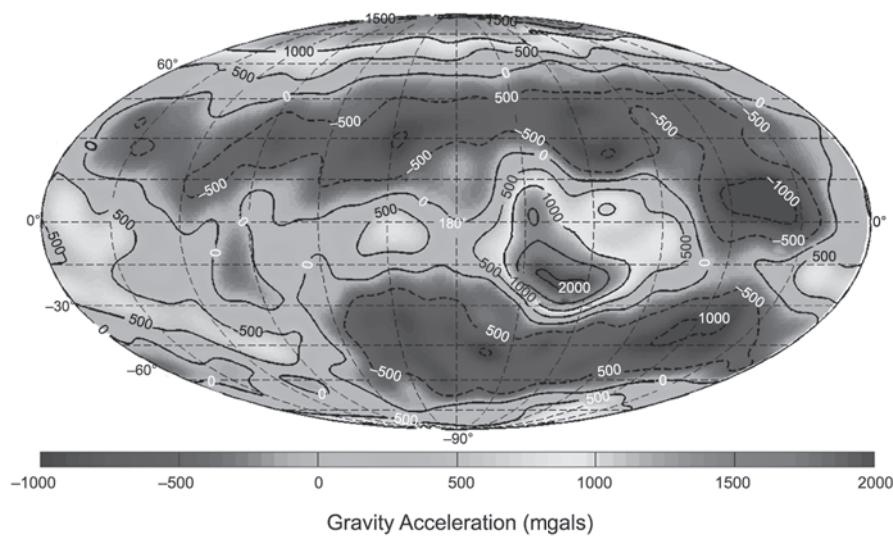

#### 4.5. Gravity Constraints on Interior Structure

High-accuracy radiometric tracking data, in combination with optical landmark tracking, was used to produce a spherical harmonic gravity field of Vesta accurate to degree

and order 18 (Konopliv *et al.*, 2013). The radial gravity field, shown in Fig. 15, is dominated by the shape of Vesta. The gravity data are consistent with a ~110-km-radius iron-nickel core (Russell *et al.*, 2012); a range for the core radius of 126–105 km is obtained for a geochemically plausible core density range of 6000–8000 kg m<sup>-3</sup> (Toplis *et al.*, 2013). Average crustal and mantle densities, found by minimizing the residuals between the observed gravity and the field calculated for a three-layer model that uses the derived average core size and density (7400 kg m<sup>-3</sup> and 110-km radius) and a crustal layer whose outer surface follows the shape of Vesta and whose thickness is defined by a mantle ellipsoid that touches the surface at the deepest point on Vesta, are 2970 kg m<sup>-3</sup> and 3160 kg m<sup>-3</sup>, respectively (Park *et al.*, 2013). The derived crustal density is lower than the 3260 kg m<sup>-3</sup> grain density of the expected 2:1 eucrite-diogenite mixture (Consolmagno *et al.*, 2008), and the mantle density is lower than expected for a harzburgitic composition, indicating significant macro-porosity in the silicate fraction and a more complex interior structure than predicted by fractional crystallization.

Crustal density variations obtained for the three-layer model reveal the underlying structure as well as porosity variations in the megaregolith. As shown in Fig. 15 from Konopliv *et al.* (2013), density variations of 2310–3440 kg m<sup>-3</sup> in the crustal layer are required to account for the gravity variations. This crustal layer has an average thickness of 22.4 km, consistent with estimates from geochemical differentiation models (e.g., Righter and Drake, 1997; Toplis *et al.*, 2013). However, these derived density variations indicate significant heterogeneity in the layer, and likely reflect significant variations in magmatic architecture, indicating that Vesta’s crust is not sharply defined, in agreement with recent modeling (Mandler and Elkins-Tanton, 2013). The density and thickness of the megaregolith also contribute to the bulk crustal density variations, but to a lesser degree than the compositional variations.

The crustal density distribution in Fig. 16 shows a preponderance of isolated, high-density anomalies and broader low-density regions. Higher density is found in a broad region of the eastern hemisphere, northward of the rim of the Rheasilvia basin. The highest density of 3440 kg m<sup>-3</sup> occurs in the region of the eastern equatorial troughs (Divalia Fossae formation), while the deepest density deficit is associated with the older troughs of the Saturnalia Fossae formation in the northern hemisphere. Low density within the Rheasilvia and Veneneia basins is consistent with thick ejecta fill, and a high occurs over the central mound, as expected for uplifted mantle; however, isolated, high-density anomalies are also present whose origin is difficult to explain within the construct of excavation of a layered body. One such high-density anomaly occurs over the southern portion of Vestalia Terra, at the western intersection of the two giant basins. Vestalia Terra is an ancient highland that appears to be resistant to shattering, as evidenced by the lack of well-defined troughs crossing this structure (Buczkowski *et al.*, 2012). The age, strength, and high density (3200 kg m<sup>-3</sup>) of southern Vestalia Terra argue for a primordial plutonic origin

**Fig. 15.** See Plate 14 for color version. The Vesta radial gravity solution mapped to a  $290 \times 265$ -km ellipsoid surface through degree 20. The  $J_2$  coefficient has been removed. The maximum and minimum range is given by 2100 mgal at the large equatorial high near  $126^\circ\text{W}$  longitude and  $-1270$  mgal, also near the equator at  $44^\circ\text{W}$ . From Konopliv et al. (2013).

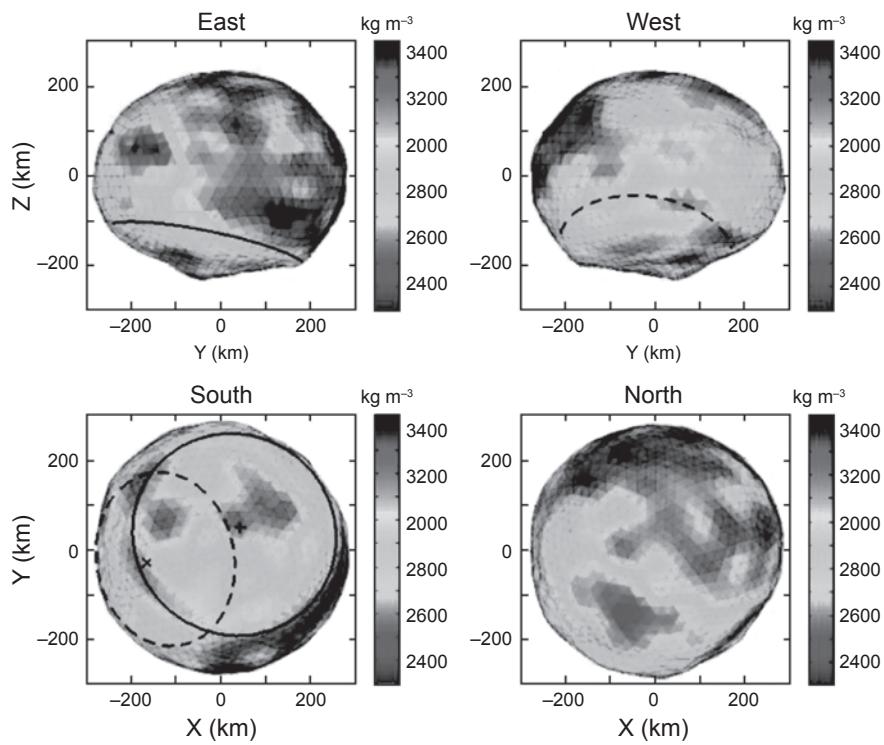

(Raymond et al., 2014). The isolated high-density anomalies within Rheasilvia may have a similar origin. Of note is the high density associated with the Rheasilvia rim near the center of the older Veneneia basin, which likely represents the uplifted central mound of Veneneia that was disrupted by the Rheasilvia impact.

The broad swath of high density in the eastern hemisphere is bounded on the west by the cratered highlands of eucritic composition, and on the east by the northern troughs and Ferialia Planitia. This large region shows generally higher density but also includes isolated highs and lows of similar size to those in the southern hemisphere. The region is associated with the “lane” of diogenite and diogenite-rich howardite that extends from Rheasilvia to the north polar region. The association of the high density with the presence of diogenitic terrains argues for a variation in crustal properties in this region, rather than Rheasilvia ejecta deposited on the surface, as the cause of the compositional variation. The high density is consistent with the presence of diogenite and olivine-bearing rocks in the near surface, which provide a source for the diogenite present in the regolith and are consistent with magma chambers at the base of the eucritic crust predicted by serial magmatism models discussed previously. Furthermore, olivine has been detected by VIR at the edge of one of two isolated lows at the center of this broad region of high density, indicating that olivine-dominated rocks have been exhumed from depth in this region. The presence of olivine near the density low is consistent with excavation of the high density material to the surface by impact, where it was later exposed by subsequent impact. As discussed in Raymond et al. (2014), the preponderance of the high-density anomalies in the eastern hemisphere, and their association with olivine and

diogenitic-rich ejecta, points toward a plutonic or plume-dominated crustal architecture in this region.

## 5. SUMMARY AND CONCLUSIONS

The Dawn spacecraft arrived at Vesta in July 2011, mapping the body in three separate orbits: survey orbit, high-altitude mapping orbit, and low-altitude mapping orbit. It remained in orbit until September 2012, at which time solar illumination reached the north pole. Dawn found Vesta’s surface to be characterized by impact craters of all sizes, a variety of ejecta blankets, large troughs extending around the equatorial region, enigmatic dark material, and considerable evidence for mass wasting (e.g., Jaumann et al., 2012). Dawn confirms the large impact basin covering Vesta’s south pole (Rheasilvia), inferred from the Hubble Space Telescope images (Thomas et al., 1997), and reveals evidence for an earlier, underlying large basin. Vesta’s global tectonic patterns (two distinct sets of large troughs) strongly correlate with the locations of the two south polar impact basins, and were likely created by the formation of the basins. Impact craters on Vesta range from fresh to highly degraded, comparable to the Moon, indicating an intensive cratering history over the age of the solar system. The primary crust is covered by a thick (100 m to a few kilometers), multi-layered sheet of debris (regolith) formed by the accumulation of ejecta from the numerous impacts that have resurfaced Vesta over time. The surface of Vesta exhibits very steep topographic slopes that are near to the angle of repose. Impacts onto these steep surfaces, followed by slope failure, makes resurfacing due to impacts and their associated gravitational forces and seismic activity an important geologic process on Vesta that significantly alters the

**Fig. 16.** See Plate 15 for color version. The lateral crustal density estimation of the three-layer Vesta (257 × 207-km mantle and 117 × 105-km core). Solid black and dashed black circles represent Rheasilia and Veneneia impact basins, respectively. The lateral crustal density variation ranges from 2310 to 3440  $\text{kg m}^{-3}$ , which is required to remove the gravity anomaly. From R. S. Park (personal communication, 2014).

morphology of geologic features and adds to the complexity of its geologic history. Linear gullies are interpreted to form by flow of dry granular material and curvilinear gullies are possibly formed by transient flow of water. Deposits of dark material intermixed into the regolith and partially excavated by younger impacts are exposed as blocks or layers outcropping in crater walls and rims. The mixing of dark material with impact ejecta indicates that this material is processed together with the ejected material. Small craters possess continuous dark ejecta similar to lunar dark-halo impact craters, indicating that the impact excavated the material from beneath the surface. Asymmetric distribution of dark material in impact craters and ejecta suggests noncontinuous distribution in the local subsurface. The composition of the dark material resembles that of the Vesta regolith. Dark material is distributed unevenly across Vesta's surface. On a global scale the dark material seems to be correlated with the rim and ejecta of the older Veneneia south polar basin structure. The origin of the dark material is still debated and it is tentatively suggested that dark material is exogenic, from carbon-rich low velocity impactors. This is supported by the broad correlation between dark material and the OH hydration band, suggesting carbonaceous chondrites as a darkening agent. Besides Vestalia Terra, direct surface evidence for volcanic or plutonic activity is lacking so far. This may be due to a dearth of large-scale volcanic features

on Vesta and/or to volcanism ending early in Vesta's evolution so that the evidence has been destroyed and covered up by extensive subsequent cratering, regolith formation, and resurfacing. However, the pattern of the high-density anomalies and their association with olivine and diogenite-rich ejecta points toward a plutonic or plume-dominated crustal architecture that is consistent with the geochemical considerations that magma bodies might stagnate at the crust-mantle boundary or intrude higher in the crust, in either case forming plutons.

The time stratigraphic sequence for Vesta comprises four major periods: pre-Veneneian, Veneneian, Rheasilvian, and Marcian. The pre-Veneneian period covers the time from the formation of Vesta (1–2 m.y. after the formation of the first solids in the protosolar disk) up to the Veneneia impact event. The Veneneian period encompasses the time between the Veneneia and Rheasilvia impact events. The Rheasilvian period is defined as the time between the formation of Rheasilvia and Marcia craters, and the Marcian period covers the time between the formation of Marcia crater until the present.

The composition of Vesta's regolith is consistent with mixtures of HEDs in various proportions, as mapped by VIR spectra, GRaND neutron absorption and high-energy gamma rays, and FC band ratios. Euclidean-rich regions occur near the equator, corresponding to older terrains. Diogenite-rich areas

are associated with the Rheasilvia basin and its ejecta, or with relatively thin crust. Olivine is uncommon, but when mixed with orthopyroxene, amounts <25% are difficult to detect spectrally. Diogenite is interpreted as mantle material, likely occurring in plutons underplating the basaltic crust. The missing olivine may be sequestered in the lower mantle, as a residue from incomplete melting. The lithologic distributions represent reflect differentiation by pervasive, early magmatism, although not necessarily whole-body melting. Redistribution of these lithologies by large impacts is illustrated by dark, hydrogen-rich regions with OH absorption features, interpreted as admixed carbonaceous chondrite, possibly introduced during the Veneneia impact.

The instrumentation carried by Dawn has enabled the geology, structure, and chemistry of the vestan surface to be extensively characterized, and has proven it to be consistent with the HED meteorites, which have been even more extensively studied on Earth. These analyses have allowed Vesta to join the Moon and Mars as the best characterized solar system bodies.

**Acknowledgments.** We thank the many people who made this mission possible: the teams at Orbital Sciences Corporation and the Jet Propulsion Laboratory/California Institute of Technology who built the spacecraft; the teams at the Max Planck Institute for Solar System Research, Galileo-SeleX, and Los Alamos National Laboratory who built the instruments; the women and men at the Jet Propulsion Laboratory who operate and navigate the spacecraft; and the Max Planck Society, the German Space Agency, the Italian Space Agency, the National Institute for Astrophysics (INAF), and NASA for their support, as well as the many team members who analyzed the data.

---

Three flybys of asteroids have occurred in the period between 2008 and 2012. (2867) Šteins and (21) Lutetia have been observed by the European Space Agency's Rosetta spacecraft, and (4179) Toutatis was observed by the Chinese National Space Agency's Chang'e-2. The properties of these three bodies are very different from other asteroids visited to date. Šteins seems to have been subject to a combination of various processes, including collisions and significant reshaping as a result of rotational forces (the YORP effect). Lutetia has a high density, which has led to speculation that it is a partially differentiated body. Images display a surface with complex morphology exhibiting different structures: pits, craters, crater chains, scarps, and vast younger terrains have been observed. The shape of Toutatis shows two major lobes, suggesting a contact binary object. A comparison with data obtained by previous asteroid flybys is presented. Limitations of flyby results, in particular interpretation of the composition, are also discussed.

## 1. INTRODUCTION

In the last few years three successful asteroid flybys have been completed by two spacecraft. Two main-belt asteroids, (2867) Šteins and (21) Lutetia, were visited in September 2008 and July 2010 respectively by the European Space Agency's (ESA) Rosetta spacecraft on its journey toward Comet 67P/Churyumov-Gerasimenko (Schulz et al., 2009). The near-Earth asteroid (4179) Toutatis was flown by on December 2012 by the China National Space Administration (CNSA) lunar exploration probe, Chang'e-2.

### 1.1. Rosetta Mission

Rosetta is an ESA cornerstone mission and is expected to make a major contribution to the study of the small bodies of the solar system. The mission, named after the Rosetta Stone, housed in the British Museum in London, has the objective of deciphering the mysteries of the building blocks of our solar system. The mission, launched on March 2, 2004, is composed of two elements: the orbiter and the lander, Philae.

The combined scientific payload consists of 25 remote sensing and *in situ* experiments with an unprecedented capability to characterize the nature of comets and asteroids (Schulz et al., 2009). To reach the target comet, the Rosetta spacecraft needed to acquire the necessary orbit characteristics. The journey was to take more than 10 years and included two swingbys of Earth and one of Mars before the first asteroid flyby with Šteins. Another Earth gravity assist followed before the flyby of Lutetia. On June 8, 2011, the spacecraft was placed in deep-space hibernation mode for 31 months. The spacecraft was successfully woken up on January 20, 2014. It reached Comet 67P/Churyumov-Gerasimenko when it was still far away from the Sun (heliocentric distance of about 4 AU) in order to start the characterization of the comet nucleus prior to the delivery of the Philae lander (at a time when the nucleus was still at a low state of activity) and to start the comet escort phase until its perihelion passage in August 2015, with the end of the nominal mission on December 31, 2015. Rosetta performed a complex series of maneuvers to reduce the separation between the spacecraft and comet up to a distance of 10 km in order to map the

comet and choose a landing site for Philae. On November 12, 2014, when the comet was at a heliocentric distance of 3 AU, Philae landed successfully on the comet nucleus.

For the Rosetta mission, the final choice of the asteroid flyby targets was made only after the launch and the first orbital correction maneuver. In this way, an accurate value for the available  $\Delta V$  could be used to identify potential targets for the asteroid flybys. Barucci *et al.* (2005) analyzed all the possible candidates proposed before the launch and recommended the selection of (21) Lutetia and (2867) Šteins to the Rosetta Project because of their high potential scientific return. Lutetia was selected mostly because of its large size (it would be the largest asteroid to be visited by a spacecraft at the time of selection), which was expected to lead to accurate mass and density determinations. Šteins was known to have an unusual surface composition, similar to the rare E-type class, which had never been observed by space missions before.

The flyby with Šteins took place on September 5, 2008, at a relative velocity of  $8.6 \text{ km s}^{-1}$  and a closest approach distance of 803 km. Fourteen instruments were switched on, providing spatially resolved multi-wavelength observations and *in situ* measurements of its dust, plasma, magnetic, and radiation environment. Four instruments performed imaging and spectrometric observations from the ultraviolet (70 nm) through the visible and infrared to the millimeter range (1.3 mm). The flyby of Lutetia was performed on June 10, 2010, at a closest distance of 3168.2 km and a velocity of  $15.0 \text{ km s}^{-1}$ . The same suite of instruments was switched on. The main scientific results for both asteroids have been obtained by the Optical, Spectroscopic, and Infrared Remote Imaging System (OSIRIS) imaging system, the Visible and Infrared Thermal Imaging Spectrometer (VIRTIS), the Alice ultraviolet spectrometer, the Microwave Instrument for Rosetta Orbiter (MIRO), and the radio science investigation (RSI) [see Shulz *et al.* (2009) for details of all the Rosetta instruments]. Both asteroids were also observed by the Spitzer Space Telescope to support preparation and optimization of the operations of the spacecraft in order to maximize the scientific return from the flybys (Barucci *et al.*, 2008). Lutetia was also observed by the Herschel infrared space telescope prior to and around the time of the Rosetta flyby (O'Rourke *et al.*, 2012).

## 1.2. Chang'e-2 Mission

Chang'e-2 was the second Chinese mission dedicated to the investigation of the Moon. The spacecraft was launched on October 1, 2010, and was in orbit around the Moon for six months, obtaining high-resolution maps of the lunar surface. After completing its prime mission, Chang'e-2 still had significant amounts of propellant onboard. The spacecraft was capable of escaping lunar orbit and traveling into interplanetary space.

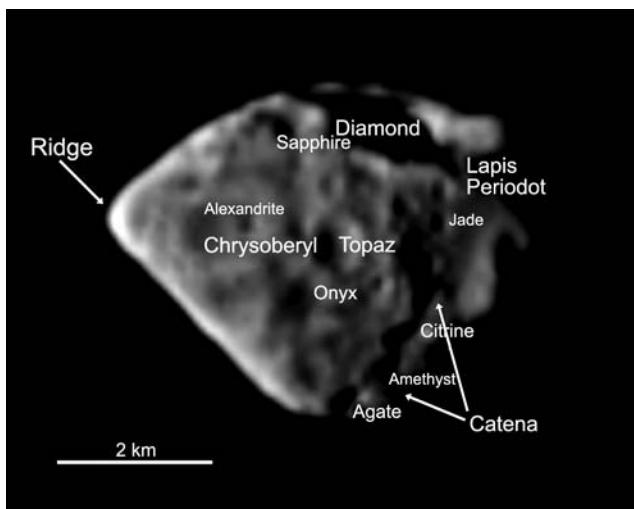

On June 9, 2011, Chang'e-2 departed its lunar orbit and was commanded to perform a slow transfer to the Sun-Earth Lagrangian point (L2). L2 has technical interest as a

potential parking position for spacecraft, allowing assembly, refueling, and efficient dispatch toward solar system objects. Chang'e-2 arrived at L2 on August 25, 2011, and started to explore the space environment. The selection of a potential flyby asteroid was proposed prior to the launch of Chang'e-2. After Chang'e-2 reached L2, asteroid (4179) Toutatis was finally selected for the flyby, taking into account its closest approach to Earth (to occur on December 12, 2012), the residual fuel of the spacecraft, and the capability of the tracking and control network. Chang'e-2 had been intentionally controlled to move near L2 for more than 230 days to favor the Toutatis-flyby injection maneuvers until April 15, 2012, when Chang'e-2 left L2.

A groundbased observation campaign for Toutatis was organized by the Chinese Academy of Sciences from May to November 2012, to improve the orbit of Toutatis, which was refined with uncertainties on the order of a few kilometers. Chang'e-2 completed its flyby of Toutatis on December 13, 2012, passing at a closest distance of  $770 \pm 120 \text{ m}$  (Huang *et al.*, 2013) from the asteroid's surface at a relative velocity of  $10.73 \text{ km s}^{-1}$ . At the time of writing, Chang'e-2 remains alive and is more than 100 million kilometers away from Earth in a heliocentric orbit.

## 2. (2867) ŠTEINS

Images of Šteins were acquired by the OSIRIS imaging system, a two-camera system comprising a narrow-angle camera (NAC) and a wide-angle camera (WAC) (Keller *et al.*, 2007). Resolved images were obtained starting 4 h before closest approach at a distance of  $\sim 60,000 \text{ km}$  when the phase angle was  $38^\circ$ . The spacecraft was targeted to pass close to opposition geometry and actually reached a minimum phase angle of  $0.27^\circ$  before reaching  $51^\circ$  at the closest distance of 803 km and finally  $141^\circ$  at the end of observations at a distance of 60,000 km post-encounter. The high-resolution camera (NAC) unfortunately stopped 10 min before the closest approach (putting itself in safe mode) when the spacecraft was 5200 km from the asteroid. Consequently, the highest-resolution images were acquired by the WAC. The numerous images taken up to a best resolution of about 80 m/pixel (Keller *et al.*, 2010) covered 60% of the surface and showed a diamond-shaped object (Fig. 1) with a surface dominated by depressions of possible impact origin (Marchi *et al.*, 2010; Besse *et al.*, 2012). The complete shape with dimensions of  $6.8 \times 5.7 \times 4.4 (\pm 0.1) \text{ km}^3$  was derived using these images and the inversion of lightcurves taken from ground and by OSIRIS during approach (Jorda *et al.*, 2012). The pole was found to be almost perpendicular to the ecliptic plane with ecliptical coordinates of  $99^\circ \pm 5^\circ$ ,  $59^\circ \pm 5^\circ$  and retrograde rotation. The siderial rotational period of  $6.04681 \pm 0.00002 \text{ h}$  had already been computed by Lamy *et al.* (2008) and confirmed by OSIRIS data. The phase function obtained with more than 100 images covering  $0^\circ$  to  $132^\circ$  in phase allowed a determination of the geometric albedo of  $0.410 \pm 0.016$  with an absolute magnitude of  $H = 12.90$  and a slope parameter  $G = 0.45$ .

**Fig. 1.** Image of asteroid (2867) Šteins acquired with the Rosetta/OSIRIS wide-angle camera on September 5, 2008, at 18:38:06 from a distance of 803 km. The principal regions and craters have the name reported. The south pole is up. (For feature names, see <http://planetarynames.wr.usgs.gov/Page/Steins/target>.) Credit: ESA/Rosetta/MPS for OSIRIS Team MPS/UPD/LAM/IAA/SSO/INTA/UPM/DASP/IDA.

## 2.1. Surface Structures and Age

Most notably, Šteins shows an equatorial ridge (Keller et al., 2010; Jorda et al., 2012), which has been suggested to have formed by centrifugal acceleration as the asteroid was spun up by the Yarkovsky-O’Keefe-Radzievskii-Paddack (YORP) effect (see the chapter by Vokrouhlický et al. in this volume). The YORP effect can cause the migration of the regolith from the polar regions toward the equator, thereby forming the ridge (see the chapter by Walsh and Jacobson in this volume).

At higher resolution, the surface of Šteins is covered by shallow craters, pits, ejecta and regolith. The asteroid exhibits a large crater (2.1 km in diameter, dubbed Diamond) near the south pole, and a series of circular features (catena) 250–600 m in diameter extends from this crater to the north side. This catena may be linked to the impact that caused the larger crater, and another groove, surrounded by small craters, is visible on the opposite side of the asteroid as a possible continuation of the catena. This is somewhat remarkable given that such chains are normally associated with breakup of a body, such as a comet, in a gravitational field immediately prior to impact [see similar structures on Callisto, e.g., Schenk et al. (2004)]. Alternative mechanisms, possibly of endogenic origin such as the formation of drainage pits, should also be considered as a potential formation mechanism (see, e.g., Basilevsky et al., 2014).

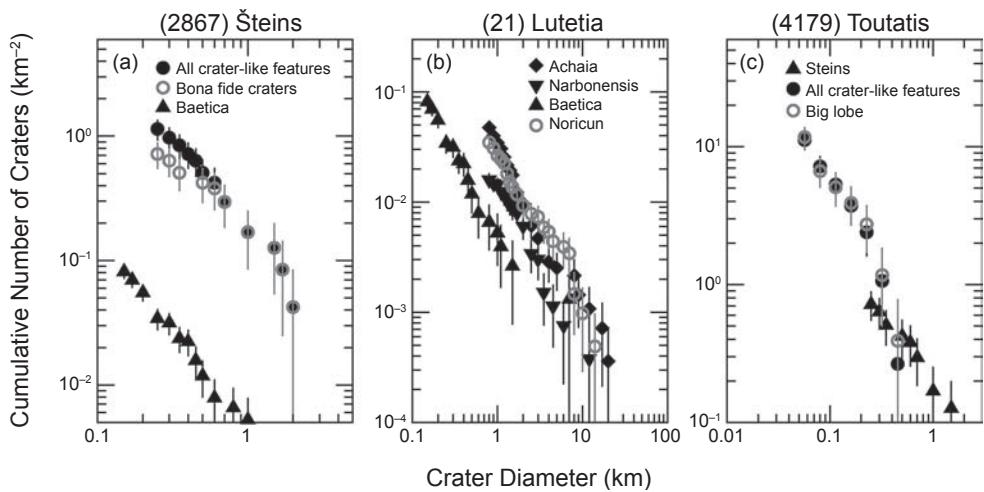

Based on analysis of the images, Šteins can be considered a rubble-pile body. Around 42 craters-like depressions were identified on the surface and the crater population seems to exhibit a dichotomy between the two sides of Šteins (Besse

et al., 2012). For the analysis of Šteins’ age, we limited our study to the portion of the surface better imaged and retained a total of 18 craters in the assessment (Marchi et al., 2010). Their cumulative crater size-frequency distribution (SFD) is remarkably shallow (Fig. 2a), if compared to that of larger siblings (see the chapter by Marchi et al. in this volume). The slope of the cumulative crater SFD is, however, comparable to that of (25143) Itokawa and (433) Eros for crater sizes smaller than 0.1 km. A possible interpretation for the shallow slope is that it is the result of erasure of small craters. Given the small size of Šteins, there are a number of processes that may be responsible for this erasure; in particular, seismic shaking may be relevant (Richardson et al., 2004). On the basis of this, Marchi et al. (2010) concluded that small craters could have been erased by cumulative seismic shaking of small impacts or by an impulse of erasure caused by the formation of the Diamond impact crater (see Fig. 1 and the chapter by Marchi et al. in this volume).

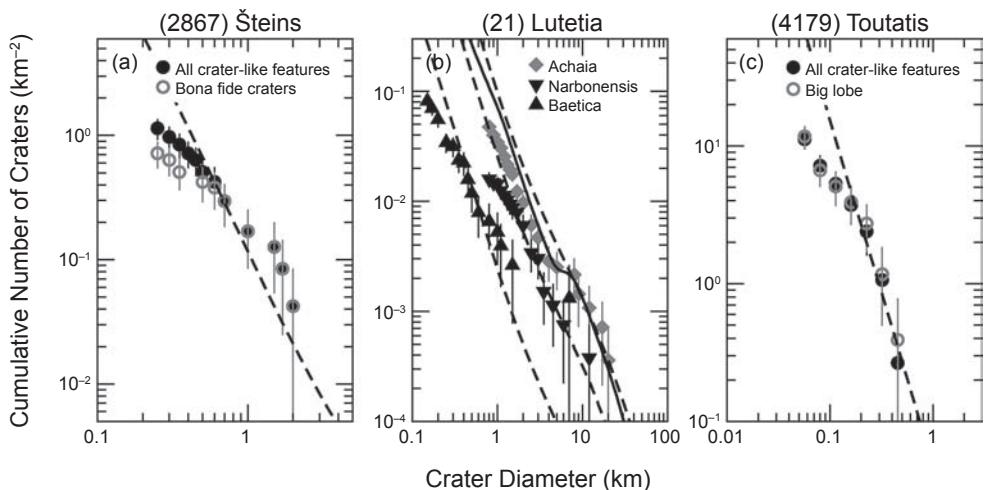

An alternative view is that many of the observed crater-like features are not impact craters at all, but rather drainage pits caused by regolith sinking into subsurface fractures and voids. Support for this hypothesis comes for numerical simulations. Jutzi et al. (2010) simulated the impact resulting in Diamond crater and concluded that the impact would have damaged a monolithic parent body and transformed Šteins into a rubble pile structure, allowing it to be reshaped in its current form by the YORP spinup thermal effect.

Following the interpretation of Šteins’ shape as being the result of YORP evolution, mass wasting of loose regolith may also have contributed to the degraded and shallow depression of almost all the craters (except Diamond).

The determination of the absolute cratering retention age of Šteins is challenging in light of the above-mentioned processes that may have resulted in significant changes to the observed crater SFD. On the other hand, if most of the crater-like features are indeed drainage pits, then their number provides no constraint on the surface age. In the assumption that all bona fide craters are impact craters, we have estimated the surface cratering retention age following the methodology presented in Marchi et al. (this volume). Given the likely highly fractured nature of Šteins, an improved rubbly material crater-scaling law has been implemented (see Marchi et al. this volume) and an estimate of the current impact rate for Šteins (Marchi et al., 2010) has been used. The propagation back in time of the impact flux follows the recent model of O’Brien et al. (2014). The main conclusion of this analysis is that our model represents a poor fit of Šteins’ crater SFD (Fig. 3a), thus making the age estimate highly uncertain. If we attempt to fit the largest craters ( $>0.6$  km), the resulting surface age is  $\sim 1.3$  Ga (for an assumed material strength of  $2 \times 10^5$  Pa; for comparison, lunar regolith has a strength of  $\sim 10^3$  Pa, while terrestrial near-surface alluvium has  $\sim 6 \times 10^4$  Pa). If the formation of the largest crater occurred during this time, it may have triggered an impulse of erasure, responsible for the mismatch at small crater sizes (0.1–0.5 km). In this case, for our estimate to be reliable, Šteins should have been already

**Fig. 2.** A comparative view of cratering on recent flyby asteroids. (a) (2867) Šteins crater size-frequency distributions. (b) (21) Lutetia crater size-frequency distributions. The most representative units are shown here (Achaia, Noricum, Narbonensis, Baetica). (c) (4179) Toutatis crater size-frequency distributions. Data from Marchi *et al.* (2010, 2012), Besse *et al.* (2012), and Huang *et al.* (2013).

**Fig. 3.** Best fits (solid and dashed thick black curves) of some of the crater SFDs presented in Fig. 2.

highly fractured. However, we caution that it is likely that most of the observed crater-like depressions are not impact craters, therefore the age of  $\sim 1.3$  Ga should be considered as an upper, highly uncertain limit.

## 2.2. Composition

The spectra obtained by Visible and Infrared Thermal Imaging Spectrometer (VIRTIS)-M, observing from 200 to 5000 nm, and by the NAC and WAC cameras observing with 11 filters from 220 to 960 nm are very similar to those from the ground, showing a reddening at wavelengths  $< 1000$  nm with strong signature at 490 nm, a steep drop below 400 nm, and almost flat and featureless for wavelengths  $> 1000$  nm.

They confirm the surface taxonomy of an E-type asteroid. This rare taxonomic class is dominated by iron-free or iron-poor silicates (Gaffey *et al.*, 1993). The characteristic absorption feature at 490 nm is tentatively attributed to sulfides. In particular, Šteins' spectra are similar to the "Angelina-like" asteroid E(II) subtype (Gaffey and Kelley, 2004), for which the main mineralogical components are enstatite and oldhamite with small amounts of low-iron silicate mineral. Generally, the E-type class is associated with aubrites, but this meteorite does not fit the prominent 490-nm absorption band. Aubrites are achondrite meteorites mainly composed of Fe-poor, Mg-rich orthopyroxene, or enstatite containing a variable amount of olivine, nickel-iron metal, sulfides such as oldhamite and troilite, and rare minerals. To reproduce

the spectra, an additional significant percentage of oldhamite seems necessary to be present on the surface of Šteins (*Fornasier et al.*, 2008). None of the known meteorites alone fit the spectral properties of this rare asteroid. The igneous composition argues for an origin as part of the interior of a larger differentiated parent body. *Leyrat et al.* (2010) searched for surface inhomogeneity over almost 30% of the surface using OSIRIS images with multiple filters and using the G-mode multivariate statistical method (*Barucci et al.*, 1987). The analyzed data, adopting a polyhedron shape model of 58,000 facets with photometric corrections using Hapke's model, suggested no surface inhomogeneity greater than 4% at the 95% confidence level. *Schroder et al.* (2010) found a small variation (5–10%) around Diamond crater, which is spectrally slightly bluer than the rest of the object, although an influence of illumination cannot be ruled out.

### 2.3. Thermal Inertia

The surface temperature of Šteins was measured by inversion of the infrared spectra acquired by the VIRTIS-M imaging spectrometer (*Leyrat et al.*, 2011). Minimum and maximum temperatures of 185 K and 225 K were measured, leading to a thermal inertia of  $110 \text{ J m}^{-2} \text{ K}^{-1} \text{ s}^{-1/2}$  assuming a smooth surface. This value is in good agreement with the previous results obtained using the Spitzer Space Telescope (*Barucci et al.*, 2008; *Groussin et al.*, 2011) and implies a thick layer of regolith. The conclusion by *Leyrat et al.* (2011) was that the thermal inertia is not uniform over the surface, with some surfaces having a higher thermal inertia, implying that roughness may be different in some areas. The MIRO instrument also observed Šteins during closest approach observing at millimeter wavelengths at 190 GHz (1.6 mm) and submillimeter at 562 GHz (0.53 mm). Unfortunately, due to pointing uncertainties, the MIRO main beams were never filled by the nightside of Šteins, limiting the ability to measure the day-night temperature contrast and consequently the measurements were difficult to interpret (*Gulkis et al.*, 2010). A higher value for the thermal inertia was nonetheless deduced.

## 3. (21) LUTETIA

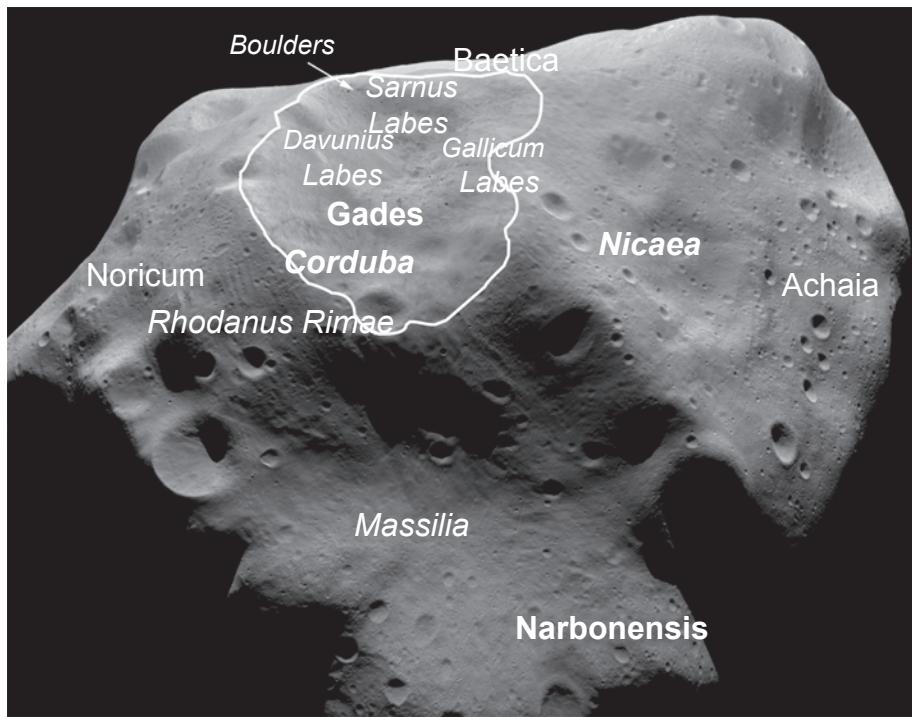

The Rosetta spacecraft flew by asteroid (21) Lutetia, obtaining resolved images for about 10 h around closest approach and revealing an object with a highly complex history. The camera systems observed the asteroid in 21 broad and narrow-band filters covering more than 50% of the surface with spatial scales of  $\geq 60 \text{ m/pixel}$  (*Sierks et al.*, 2011). The global shape with principal axis dimensions of  $121 \pm 1 \times 101 \pm 1 \times 75 \pm 13 \text{ km}^3$  was modeled using OSIRIS data. In combination with the inversion of photometric lightcurves and contours of adaptative optics images, a north pole directed toward ecliptical coordinates  $51.8^\circ \pm 0.4^\circ$  and  $+10.8^\circ \pm 0.4^\circ$  was found (*Sierks et al.*, 2011). The rotational period of  $8.168271 \pm 0.000002 \text{ h}$  had already been computed from OSIRIS data acquired in 2007 when

the spacecraft was 1.64 AU from the asteroid (*Lamy et al.*, 2010). From the shape model, a volume of  $(5.0 \pm 0.4) \times 10^5 \text{ km}^3$  has been derived. The northern hemisphere was well imaged with a good three-dimensional reconstruction (*Preusker et al.*, 2012). However, a large fraction of the asteroid's southern hemisphere was not visible during the flyby and consequently the shortest semimajor dimension is not well constrained (*Carry et al.*, 2012), giving uncertainty in the volume estimation. Combining the estimated volume and the mass obtained by the RSI ( $1.7 \times 10^{18} \text{ kg} \pm 1\%$ ), a bulk density of  $3.4 \pm 0.3 \text{ g cm}^{-3}$  has been computed (*Pätzold et al.*, 2011). The north pole is located near a depression that has been produced by multiple impacts: the north polar crater cluster (NPCC). The north rotational pole was roughly pointed toward the Sun at the time of the Rosetta encounter and hence high-resolution imaging was restricted by the illumination to one hemisphere despite the relatively rapid rotation rate (*Carry et al.*, 2010). Some parts of the northern hemisphere were not well imaged because of the low phase angle of the approach ( $\sim 7.7^\circ$ ) and hence interpretation must account for possible observational biases. The measured visible albedo is  $0.19 \pm 0.02$ . Variations on the surface up to 30% in reflectivity correlated with geographic morphologies have been detected (*Sierks et al.*, 2011).

### 3.1. Surface Structures

Impact craters dominate the overall structure. The largest depression is the Massilia structure (see Fig. 4), which is a highly degraded 57-km-diameter crater-like structure. Its rim appears to have been modified by subsequent impacts to such an extent that its origin as an impact structure has been questioned (*Thomas et al.*, 2012), although alternative formation mechanisms have not been identified. The other dominant feature in the images is the NPCC itself, which forms the most striking construct within the Baetica region. This appears to be one of the youngest surfaces on the object and is made up of four principal impacts of varying size that have overlapped each other. Other smaller impacts have also influenced the structure. The largest crater (Corduba) is  $\sim 34 \text{ km}$  in diameter and slightly elliptical. Subsequently the Gades crater, roughly into the center of Corduba, has produced a remarkable structure with boulders and landslides evident within it. The relatively low density of smaller impact craters within the NPCC contrasts sharply with the high crater density seen in the Noricum region. Other surfaces (notably Narbonensis) have intermediate crater densities.

**3.1.1. Ejecta deposition.** The impacts producing the NPCC appear to have erased craters in a non-uniform manner about the impact site. The transition between low and high crater density regions across the Noricum boundary is remarkably abrupt ( $< 150 \text{ m}$  in width) with no evidence of ejecta falling onto the Noricum region (*Thomas et al.*, 2012). Significant amounts of ejecta were observed on the opposite side of the impact crater, which has draped and partially covered the Achaia region. This has been taken as evidence that the largest impact of the NPCC was a relatively oblique one

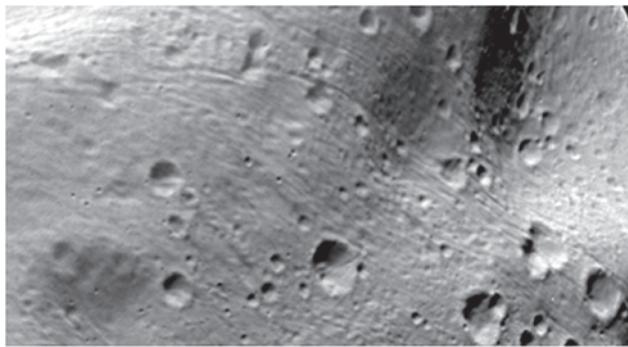

**Fig. 4.** (21) Lutetia as seen using the OSIRIS imaging system on Rosetta. Some regions mentioned in the text are noted in large font. Craters mentioned are identified in bold italic. Other surface features are in regular italic. The NPCC area is reported by white line. See <http://planetarynames.wr.usgs.gov/Page/LUTETIA/target> for more information. Credit: ESA/Rosetta/MPS for OSIRIS Team MPS/UPD/LAM/IAA/SSO/INTA/UPM/DASP/IDA.

with respect to the local surface (*Jutzi et al.*, 2013). *Krohn et al.* (2014) studied oblique impacts into slopes on the more rounded asteroid (4) Vesta, and concluded that slopes  $>20^\circ$  prevent deposition of ejected material in the uphill direction. Given the limited knowledge of the surface topography of (21) Lutetia prior to the largest NPCC impact and the lower gravity, this conclusion is somewhat difficult to apply in this case. The modeling work of *Jutzi et al.* (2013), using the smooth particle hydrodynamics (SPH) technique, has shown that collection of ejecta in potential wells (e.g., in craters) is surprisingly effective, providing an explanation for younger surface ages in some depressions within older units. In particular, ejecta from the NPCC impact(s) can be deposited in the interior of Massilia, potentially explaining its younger age (see section 3.2), while a relatively limited amount of material ends up on the older units of Noricum. Furthermore, the apparent youth of surfaces in depressions in Achaia such as Nicaea can be explained by the same mechanism. The irregular gravitational field is clearly something that must be taken into account in ejecta calculations on intermediate-sized asteroids and, in ideal cases, may provide constraints on internal mass distributions. The maximum extent of the ejecta toward the subsolar point at the time of the Rosetta flyby is unclear. The low phase angle of the approach led to low contrast in the data acquired (comprising the Etruria and Raetia regions), but qualitatively lower densities of

intermediate-sized craters were reported in the Etruria region (*Thomas et al.*, 2012).

**3.1.2. Lineaments.** Lutetia possesses a remarkable set of lineaments. The prevalence and diversity of lineaments on the surface is striking. Some of the observed lineament sets are  $>80$  km long, although their depths are mostly below the resolution limit of the best digital terrain model ( $\sim 100$  m). An example of the prevalence of lineaments is shown in Fig. 5.

*Thomas et al.* (2012) attempted to categorize the various types of linear structures (Table 1). The table illustrates that there are different types of linear and quasi-linear troughs and linear reflectance discontinuities all over the surface except in the Baetica region. The lineaments show alignment (preferred orientation) in several regions. The preferred orientation is not uniformly circumferential about any one crater. Three possibilities to reconcile this observation are being studied independently: (1) *Jutzi et al.* (2013) used the SPH code discussed above with respect to ejecta to compute the surface velocity field caused by the 34-km impact into the Baetica region. They showed that the velocity vector orientations were strongly affected by the irregular shape of the body and some qualitative agreement with observed orientations of lineaments was noted. (2) *Besse et al.* (2014) have suggested that impacts produce circumferential lineaments and have then further suggested that the lineaments

**Fig. 5.** Lineament set in the Etruria-Achaia region. Note the craters that have been cut and distorted by lineaments. Credit: ESA/Rosetta/MPS for OSIRIS Team MPS/UPD/LAM/IAA/SSO/INTA/UPM/ DASP/ IDA.

on Lutetia require production via three separate impacts, one of which is on the hemisphere unseen by OSIRIS. (3) *Giacomini et al.* (2014) suggested that the lineaments reflect previously defined fault planes within a parent body from which Lutetia was formed and that the lineaments pre-date all the major cratering events.

These three competing models have advantages and disadvantages. The *Jutzi et al.* (2013) model does not clearly identify, as the authors note themselves, why the lineaments should be generated parallel to the local surface velocity field. However, the model is physical and explains the observed ejecta deposition. There is also no doubt that reflections from

interfaces should play a role in modifying the disturbance as it passes through the body, and this is most accurately computed using the SPH approach. The *Besse et al.* (2014) model follows approaches used at other asteroids (e.g., *Buzkowski et al.*, 2008). However, the approach is empirical and requires that lineaments produced by previous impacts are not erased by the newer ones on Lutetia [which would place significant constraints on the transmission of seismic waves; e.g., see *Asphaug et al.* (1996)]. It should be noted that depth-diameter plots of impact craters show depth dropping more steeply with decreasing diameter (*Vincent et al.*, 2012) — an effect noted on, e.g., (951) Gaspra (*Carr et al.*, 1994) and an indication of degradation by either impact erosion, filling by ejecta from younger craters, or seismic-induced downslope motion (*Carr et al.*, 1994), all of which must influence lineaments as well. The *Giacomini et al.* (2014) model requires that the internal and external structure has retained its properties since its formation as a fragment of a bigger body and that, again, disturbance of the lineaments via mechanisms such as seismic jolt are ineffective. *Jaumann et al.* (2012) note that troughs on Vesta, when mapped onto the shape model, can be modeled as planes that cut through the asteroid. However, *Buczkowski et al.* (2012) suggest an impact origin for the troughs, which would be dissimilar to the *Giacomini et al.* (2014) concept. On the other hand, as *Buczkowski et al.* (2012) note, the Vesta troughs are morphologically and structurally different from the lineaments seen on Lutetia.

Three other observations may be significant in assessing these models. First, crossing of lineaments is evident in several places (notably in the Achaia and Etruria regions;

TABLE 1. Lineament categories on (21) Lutetia (after *Thomas et al.*, 2012).

Lineament Type	Description	Where Best Seen
Irregular troughs	Older, 1-km-wide depression, often curved, possibly result of extension due to tensile stress; often cut by craters; some examples on ridge apexes	Everywhere outside NPCC
Larger faults	Linear, narrow faults; possibly tectonic in origin; unknown depth; observed to cut craters	Narbonensis/Noricum
Organized linear reflectance variations (OLRV)	Quasi-regular reflectance variations produced by subtle topographic changes	Noricum/Achaia
Pit-chains	Lineaments with alternating bright/dark pattern along their length	Narbonensis, possibly Achaia
Intracrater trenches	Irregular depressions or faults within craters	All except NPCC
Intracrater layers	Horizontal lineaments in crater wall	NPCC
Ejecta layers	Curved discontinuities in layers of ejecta	Baetica-Etruria border
Ridges	Major structural element as a topographic high	Possibly all areas
Scars	Isolated steep scarps often separating different surface textures	All except NPCC

see Fig. 5). Crossing of lineaments at angles  $>60^\circ$  in, e.g., Achaia suggests noncoeval production under the assumption that Anderson faulting is applicable. Hence multiple impacts may have been necessary to produce the observed lineaments. Second, like Eros (*Veverka et al.*, 2001), the presence of lineament sets over distances greater than the radius of the asteroid implies that Lutetia may have some structural coherence over such distance scales. Conversely, the age and substantial numbers of large craters should have provoked considerable fracturing. Being able to reconcile these two points would provide a step forward. Finally, the major ridge on Lutetia (*Sèquana*) has topographic relief of more than 10 km. The base of the ridge shows evidence of old slides that have produced relatively sharp discontinuities in the surface reflectance arising from abrupt changes in slope. Although gravity is weak, some deformation of this feature under its own weight may occur, particularly if the structural strength is as low as that of lunar regolith (e.g., *Arslan et al.*, 2010). A quantitative analysis may provide knowledge of the strength of the surface material.

**3.1.3. Boulders.** Inside and around the NPCC, there are large numbers of boulders (*Küppers et al.*, 2012). The boulders are up to 250 m in size and are mostly draped over the rim of Gades and extending off in the direction of Etruria (see Fig. 6). On larger objects, boulders are mostly found outside the crater rim of an impact structure. However, the low surface gravity may have played a role in producing a more complex spatial distribution of boulders with respect to the Gades impact. The history of the impact site may complicate this issue. Following the larger Corduba-forming impact, the asteroid, particularly near the NPCC, should have been highly fractured. The Gades impactor struck this fractured material and hence the boulders we see on the surface have probably been shocked and modified by impact at least twice.

Assuming that boulders are broken down with time by micrometeorite impacts [other processes such as thermal fatigue may also contribute (*Delbo et al.*, 2014)], together

with assumptions about the impact rates, this can be used to constrain the surface age of the NPCC with values of  $\sim 300$  m.y. being suggested (*Küppers et al.*, 2012). From the relative positioning of the boulders and the landslides inside Gades (see Fig. 6), some boulders may have been buried by the landslides, suggesting that the landslides occurred later. The landslides do not appear to have carried boulders to the lowest part of Gades, suggesting a rather weak flow.

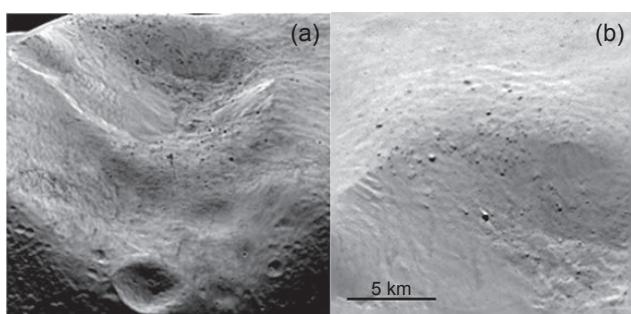

**3.1.4. Landslides and local material motion.** The interior of Gades in the NPCC of Lutetia shows evidence of three landslides (named Danuvius, Gallicum, and Sarnus Labes). Davunius Labes seems to be a debris slide or avalanche about 10 km wide with several lobes of 200-m scale relief at its base (see Fig. 6). The surface appearance of the debris is mottled, possibly indicating a poorly sorted mixture of particle sizes and not a uniform regolith. However, the strong forward scattering of the surfaces of Danuvius and especially Gallicum, noted in *Thomas et al.* (2012), indicates low macroscopic roughness at subpixel scales ( $\sim 100$  m). This, together with the absence of boulders on the surfaces of the landslides, indicates that the landslides are some of the most recently produced surfaces on Lutetia.

The major ridge on Lutetia (*Sèquana*) has topographic relief of more than 10 km. It would form part of the rim of Massilia crater, although we note that it is linear rather than curved. The base of the ridge shows evidence of old slides that have produced relatively sharp discontinuities in the surface reflectance arising from abrupt changes in slope. Although gravity is weak, some deformation of *Sèquana* under its own weight may also have occurred, particularly if the structural strength is as low as that of lunar regolith (e.g., *Arslan et al.*, 2010). Finally, *Vincent et al.* (2012) have investigated asymmetric craters with flow-like features on Lutetia and concluded that flow of fine material is widespread, including within the Narbonensis region, where flow is primarily directed toward the center of a local gravitational well. This forms a plausible explanation for the lower apparent age of the surface within the Massilia structure.

## 3.2. Crater Populations and Surface Ages

The surface of Lutetia shows abundant impact craters, the spatial distribution of which appear highly variable across the surface. The geometry of the flyby resulted in variable spatial resolution and illumination conditions that did not allow a uniform detection of craters across the imaged surface. The best conditions were achieved for the Achaia, Baetica, Narbonensis, and (partially) Noricum regions, and for these areas estimates of the ages have been computed.

Achaia exhibits the highest crater density (Fig. 2b). The overall distribution of craters revealed 157 craters larger than  $\sim 0.6$  km. The largest crater is called Nicaea and measures about 22 km across. A remarkable feature is the presence of a sharp kink in the cumulative crater SFD at crater sizes between 4 and 7 km. The presence of the kink can have several explanations, such as a similar inflection in the impactor SFD. Although the impactor SFD is not well constrained at

**Fig. 6.** (a) Nonlinear enhanced (unsharp masking) version of the central portion of image taken by NAC showing the NPCC. The Gades impact crater is toward the top. The lobate smooth material in the crater center comes from the Davunius Labes landslide. (b) Boulders distributed over the rim of Gades in the NPCC. The largest visible is about 250 m in width. Credit: ESA/Rosetta/MPS for OSIRIS Team MPS/UPD/LAM/IAA/SSO/INTA/UPM/DASP/IDA.

the corresponding impactor sizes (~0.5 km), comparison with crater SFDs from other asteroids (e.g., Vesta, Gaspra) make this interpretation unlikely (see the chapter by Marchi et al. in this volume). Other processes seem more likely. Examples would include preferential erasure of craters smaller than ~7 km, or a change of the target mechanical properties with depth (Marchi et al., 2012).

Noricum exhibits a similarly high crater density; however, at closest approach the region was seen under a grazing angle; which may affect the detection of craters. A total of 76 craters larger than 0.6 km were mapped (Marchi et al., 2012). Noricum is also characterized by significant topography variations (Thomas et al., 2012), possibly due to impact sculpting, but these large concavities were not included in the crater SFD due to inconclusive evidence. These factors may explain why the Noricum crater SFD appears distorted if compared with that of Achaia.

Narbonensis corresponds to the floor of the largest impact structure on Lutetia, Massilia crater. Most of this region has a high slope with respect to the local gravity and many craters show clear evidence of rim slumping (Vincent et al., 2012). A total of 47 craters larger than 0.6 km were mapped, and the overall crater density is somewhat lower than that of Achaia/Noricum, implying a lower crater retention age (Marchi et al., 2012). It is a matter of debate whether the Narbonensis crater SFD is representative of the formation age of Massilia, or rather indicates a younger age due to internal resurfacing (e.g., because of mass wasting). A related important issue is the degree of crater erasure that the formation of Massilia may have triggered on surrounding terrains. A possibility is that the formation of Massilia was so intense that it caused significant erasure of craters in the Achaia and Noricum regions, both via seismic shaking and ejecta burial. In this case, given that regions appear roughly spatially uniform, the erasing must have been on a global scale, and therefore the age of Achaia/Noricum would indicate the formation age of Massilia, while Massilia's floor appears younger. This would imply post-formation resurfacing. Support for this interpretation may come from the degraded and shallow appearance of Nicaea and other large craters in Achaia, which require significant infilling with loose material to explain their shallow depths. If one assumes that all the craters larger than 7 km pre-date Massilia and survived its formation, then smaller craters may post-date Massilia. Alternatively, Massilia may not have significantly affected the Achaia/Noricum crater populations and their crater retention ages would pre-date Massilia. In this case, the kink in the crater SFD (Fig. 2b) could be the result of a layered structure, with increasing target strength with depth (Sierks et al., 2011; Marchi et al., 2012).

Baetica is the youngest region and shows very few small impact craters. The region appears to have been produced by the formation of three superposed large impact structures with a subsequent smaller impact. The stratigraphically oldest of them is a 34-km crater called Corduba. Crater measurements were performed only on a subregion using the highest spatial resolution. A total of 62 craters in the range 0.2–1 km were mapped (Marchi et al., 2012). The resulting crater SFD

shows a remarkably flat slope when compared with Achaia (and its extrapolation to smaller sizes), or other asteroids such as Vesta (see the chapter by Marchi et al. in this volume). A possible explanation for such behavior includes a shallower slope of the impactor SFD or erasure of small craters caused by mass wasting given the high gravitational slope of this terrain.

The formation of Corduba was investigated in detail using SPH simulations (Jutzi et al., 2013). It was found that ejecta accumulation may have triggered some crater erasure in nearby regions, including Achaia and Narbonensis, because of ejecta accumulation. The predicted size of buried craters on Achaia depends on the impact geometry, but is generally below or comparable to the range of crater sizes studied here (<0.6 km), and could potentially explain the shallow slope of Achaia crater SFD below 4 km if compared with the production function. A more significant accumulation of ejecta is predicted within Narbonensis, which along with rim slumping may have resulted in significant crater erasures.

As briefly discussed for Šteins, the absolute age determination requires some assumptions on the crater-scaling law and mechanical properties of the target. The latter has an important role given that all the craters analyzed formed in the so-called strength regime, and therefore the final crater size is sensitive to the target strength. Furthermore, the crater density on the oldest regions is such that crater obliteration processes may play a role. Here we revise the age estimates published by Marchi et al. (2012). In particular, we have implemented an improved model for the time-dependence of the impact flux in the past following O'Brien et al. (2014) and improved crater-scaling laws. Concerning the latter, we implemented two cases: a hard rock case and a rubbly material case. Both crater-scaling laws are from Holsapple and Housen (2007). In the case of hard rock, we assumed a typical strength of  $2 \times 10^7$  Pa (Asphaug et al., 1996), while for the rubbly material case, we adopted  $2 \times 10^6$  Pa, i.e., one-tenth that of the assumed competent rocks (note that this is higher than what assumed for Šteins, but lower values are also plausible). The first set of fits was performed assuming a uniform target, and only considering craters larger than 8 km. The resulting age is ~3.7 Ga for both scaling laws. We also implemented a case of a two-layered target, as discussed in Marchi et al. (2011, 2012). We considered cases both with and without crater obliteration. The resulting ages are ~2.6 and 3.3 Ga, respectively. The best fits (Fig. 3b) are achieved for an assumed thickness of the top layer of ~2.5 km. Despite the improved quality of the fit resulting from the two-layer model, there is still a mismatch for craters smaller than ~3 km. It is important to realize that the slope of the model curve depends on the assumed strength and density profiles with depth, which are assumed to be linearly increasing from the surface to the bottom of the top layer (2.5 km). It is therefore conceivable that a different choice of profile may improve the quality of the fit. A similar age estimate applies to Noricum, given the similar crater density. Under the same assumptions of uniform target structure, Narbonensis has an age of ~1 Ga. The age of Baetica is highly uncertain given the very shallow

slope, which does not match the assumed production function for the crater SFD. Also, it seems plausible that this region is constituted by a thick layer of regolith (with no layering), for which rubbly material models with low strength values could be more appropriate. Possible values range from tens of millions of years to 100 m.y., depending on which size range is used for the best fit as well as on the assumed tensile strength of the regolith. The given age limits correspond to  $2 \times 10^5$  and  $2 \times 10^6$  Pa, respectively.

### 3.3. Composition

The VIRTIS observations of Lutetia showed flat featureless spectra in the visible and near-infrared (*Coradini et al.*, 2011). VIRTIS has two channels: VIRTIS-M for hyperspectral images in the wavelength 250–5100 nm with a spatial resolution of 250 mrad and VIRTIS-H, a higher-resolution spectrometer from 2000 to 5000 nm with a spectral resolution of 3000 ( $\lambda/\Delta\lambda$ ) and a spatial resolution of  $1.74 \times 0.58$  mrad. VIRTIS-M obtained hyperspectral images of the surface with a spatial resolution varying from 12 km to about 1 km. VIRTIS-M and VIRTIS-H did not identify any spectral features associated with OH at 3000 nm or any feature associated with organic material at 3300–3600 nm (*Coradini et al.*, 2011). The flat and featureless visible and near-infrared spectra obtained during the flyby do not allow discrimination between a carbonaceous and/or enstatite nature, although mid-infrared observations by the Spitzer Space Telescope obtained a few years before with different viewing geometry are more in favor of carbonaceous chondrites (*Barucci et al.*, 2008). The 3000-nm band was not observable by the VIRTIS instrument on the visible 50% of the Lutetia's surface (*Coradini et al.*, 2011), although the other surface of the asteroid, not visible to Rosetta, shows the hydration feature (*Rivkin et al.*, 2011). *Barucci et al.* (2012) assembled all the available data that are diagnostic of composition, with the aim of gathering all the pieces of the Lutetia composition puzzle. From analysis of all the data from ultraviolet to mid-infrared and including polarimetric data, it is evident that Lutetia has a complex composition that can be explained with local variations connected to different composition and different surface textures (structure and regolith). Analogies with existing meteorites remain inconclusive. The surface is probably composed of different chondritic-like materials. Some regions in the southern hemisphere seem to be dominated by carbonaceous chondrites with the presence of aqueous altered materials, while the northern hemisphere could be similar to a mixture of enstatite and carbonaceous chondrites (*Barucci et al.*, 2012). The complicated surface composition associated with the complex structures and history may be explained by collisions of objects with different composition.

The Alice ultraviolet spectrometer observed Lutetia from 70 to 205 nm (*Stern et al.*, 2011). No gas emission was observed around the object and the spectra show a precipitous drop between 180 and 160 nm, which is the strongest feature detected in the spectra. No similar feature has been observed in any asteroid so far, and its interpretation is particularly

difficult because of the lack of laboratory data at these wavelengths. A tentative model with 77% EH5 chondrite and 7.7% each of anorthite, H<sub>2</sub>O frost, and SO<sub>2</sub> frost has been proposed by *Stern et al.* (2011), although the authors were cautious, as other materials could be also consistent with the ultraviolet feature.

Seven other instruments [Rosetta Orbiter Spectrometer for Ion and Neutral Analysis (ROSINA), Cometary Sampling and Composition experiment (COSAC)/Philae, Ptolemy/Philae, Alice, MIRO, OSIRIS, Rosetta Plasma Consortium (RPC)] were switched on during the flyby to search for an exosphere, and, even if none of the attempts gave a detection, stringent upper limits have been found by *Altweiss et al.* (2012) for CO ( $<1.7 \times 10^{25}$  molecules s<sup>-1</sup>) and by *Gulkis et al.* (2012) for H<sub>2</sub>O ( $<4.3 \times 10^{23}$  molecules s<sup>-1</sup>), providing the limit of the possible presence of volatiles on Lutetia's surface. MIRO was used to search for H<sub>2</sub>O, CO, CH<sub>3</sub>OH, and NH<sub>3</sub>, but none of the molecules were detected. The MIRO team estimated an upper limit for the column density of water of  $<5 \times 10^{11}$  molecules cm<sup>-2</sup> and concluded that a layer of ice could not exist at depths less than 4 m.

### 3.4. Thermal Inertia

The spectral emission beyond 3500 nm can be used to estimate the surface temperature. Variations between 170 and 245 K with some correlation with topographic features were found. A thermal inertia of  $20\text{--}30 \text{ J m}^{-2} \text{ K}^{-1} \text{ s}^{-1/2}$  has been computed using VIRTIS observations (*Coradini et al.*, 2011). MIRO (*Gulkis et al.*, 2012) estimated a value of  $<20 \text{ J m}^{-2} \text{ K}^{-1} \text{ s}^{-1/2}$  in the upper surface layer (a few centimeters). The combination of VIRTIS and MIRO data allowed *Keihm et al.* (2012) to model the surface roughness, adding 50% fractional coverage of hemispherical mini-craters. An extremely low thermal inertia value was also computed on the basis of Spitzer Space Telescope (*Barucci et al.*, 2008) and Herschel Space Observatory (*O'Rourke et al.*, 2012) observations. The interpretation of the ensemble (combination) of the thermal observations confirm the existence on the surface of a significant amount of small-scale roughness with a surface layer of high porosity.

### 3.5. Internal Structure

The relatively high density of Lutetia [ $3.4 \pm 0.3 \text{ g cm}^{-3}$  (*Pätzold et al.*, 2011)] has led to speculation that Lutetia may be partially differentiated (*Weiss et al.*, 2012). The OSIRIS observations provide no meaningful constraints on this hypothesis. In the model of the NPCC impact in *Jutzi et al.* (2013), the asteroid was modeled with an internal core to establish whether this would influence the model results. The depth of the “mantle” and the magnitude of the inferred damage (fracturing) of this layer was sufficient to damp waves passing through the mantle so that reflections from the modeled core were of little account. Hence, it appears that any further constraints on the putative core will require a follow-up mission with an orbiter and/or lander.

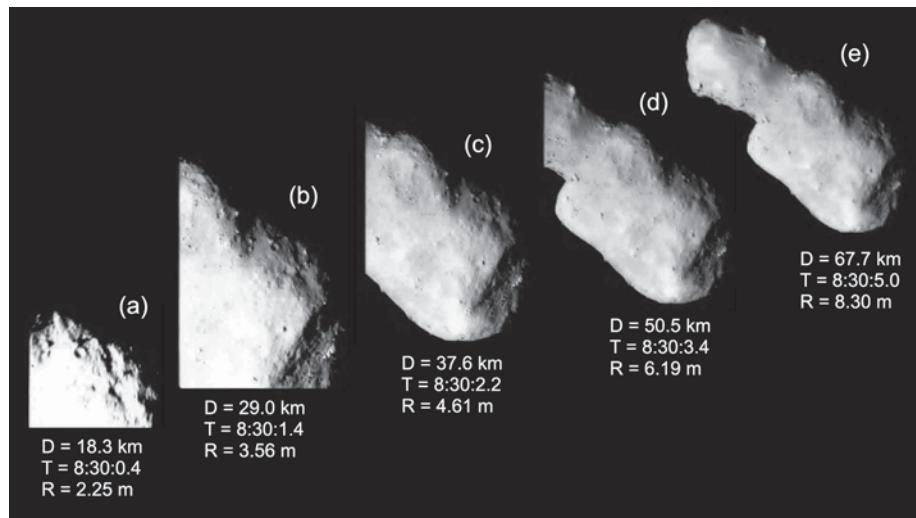

The density of Lutetia is the highest of any measured asteroid density (Britt *et al.*, 2002) and it is similar to that of the differentiated asteroid (4) Vesta. Considering the possibility of a surface layer of significant porosity (as can be deduced from the thermal inertia properties), the bulk density of Lutetia's materials would exceed the mean value of known chondritic meteorites. Weiss *et al.* (2012) analyzed the porosity constraints and suggested that Lutetia could have experienced an early thermal metamorphism and that it could have a partially differentiated metallic core overlain by a primitive chondrite crust. No magnetic field signature associated to Lutetia was detected, which allowed Richter *et al.* (2012) to derive a global upper limit of the magnetic field strength to be <1 nT. This is not in contradiction with the Weiss *et al.* (2012) conclusions, as this measurement does not establish whether Lutetia has remnant magnetization.

#### 4. (4179) TOUTATIS

The approach and observations of Toutatis were relatively short because of the high relative velocity of the spacecraft. Furthermore, the geometry of the asteroid encounter was not optimal. Imaging during the inbound trajectory was not prioritized because the Sun-Toutatis-Chang'e-2 phase angle of 143.6° was considered to be too large. The side of the asteroid facing the probe was mostly shadowed as Chang'e-2 approached, and the best views were expected only after the probe passed by the asteroid. Therefore, Chang'e-2 completed an attitude adjustment approximately 1 h ahead of the flyby to prepare for outbound imaging. Thus, Chang'e-2 adjusted the camera's optical axis to lie antiparallel to the direction of the relative velocity vector between the probe and Toutatis.

Rather than use its high-resolution lunar-mapping camera, which was designed to operate in "push-broom" mode, scanning a wide swath of the lunar surface as it passed directly below, a small engineering CMOS camera was utilized for imaging. This was originally designed to monitor the deployment of solar panels on the spacecraft and to image other objects. The color imaging camera has a  $1024 \times 1024$ -pixel detector, and a field of view of  $7.2^\circ \times 7.2^\circ$ . The asteroid came into the field of view several seconds after closest approach. At first, Toutatis was mostly blocked from view by the solar array, but seconds later, the asteroid moved out from behind the array. The entire imaging procedure lasted approximately 25 min. Five snapshots per second were captured. Figure 7 shows several outbound images of Toutatis. Figure 7e, which was the first panoramic image, was taken at a distance of 67.7 km at a resolution of 8.30 m, whereas Fig. 7a, which was the third in a sequence of images, was shot at an imaging distance of 18.3 km at a local resolution of 2.25 m (Huang *et al.*, 2013).

Three-dimensional models based on delay-Doppler radar measurements (Hudson *et al.*, 2003; Busch *et al.*, 2012; Takahashi *et al.*, 2013) were adopted to determine the attitude of Toutatis during the approach phase. Based on the attitude of the probe and its camera, the relative position between the asteroid and the probe, and optical images, in combination with previous models (Hudson *et al.*, 2003; Busch *et al.*, 2012; Takahashi *et al.*, 2013), the direction of the principal axis was found to be directed toward ecliptic coordinates  $250^\circ \pm 5^\circ$ ,  $63^\circ \pm 5^\circ$ . The size of Toutatis was derived from the visible cross-sectional area. Its maximum length and width of  $(4.75 \times 1.95 \text{ km}) \pm 10\%$ , respectively, have been measured (Huang *et al.*, 2013).

**Fig. 7.** Outbound images of (4179) Toutatis acquired on December 13, 2012, during the Chang'e-2 flyby, indicative of the spacecraft being away from the asteroid [from (a) to (e)]. The left side of Toutatis is blocked by the solar panel in (a) through (d). The imaging distance (D), epoch of flyby (T, UTC), and resolution of each image (R) are shown for each snapshot. Adapted from Huang *et al.* (2013).

#### 4.1. Surface Structures

The spacecraft collected over 400 optical images. The highest-resolution optical image has a resolution that is significantly better than the resolution of the known radar model (Busch *et al.*, 2012; Takahashi *et al.*, 2013), and many detailed features have been newly observed on its surface.

Images from Chang'e-2 show that Toutatis is shaped like a ginger root and consists mainly of a head (small lobe) and a body (large lobe), in agreement with previous radar observations. The detailed similarities and differences between the radar model and Chang'e-2's images are discussed in Zou *et al.* (2014). The observations during Chang'e-2's flyby have revealed several interesting discoveries (Huang *et al.*, 2013): the existence of a large crater-like depression in the body (800 m), the sharply perpendicular silhouette in the neck region that connects the head and body, boulders, and surface regolith.

From the large crater and the ridge around it, Toutatis may have suffered from one or more large impacts. The interior of Toutatis could be therefore very likely be fractured — a rubble-pile structure. The highly porous internal structure could prevent the asteroid from catastrophically disintegrating owing to its high attenuation of shock wave. In this sense, Toutatis may reassemble itself into a weak aggregate of large fragments through a heavy impact or successive smaller impacts. Large interior voids could help damp the collisional energy and further resist larger collisions in the formation scenario.

More than 200 boulders scattered across its surface have been counted (Fig. 7), a large portion of which are identified on the large lobe. They have dimensions ranging from 7 to 64 m, with an average of ~18 m. Approximately 90% of the boulders are less than 30 m in diameter. The largest boulder, along with other large boulders, are mainly distributed near the neck region. The boulders are usually suggested to be non-escaping ejecta that have reimpacted the asteroid's surface (Scheeres *et al.*, 1998).

Evidence suggests that Toutatis is likely to be covered with a regolith layer (Huang *et al.*, 2013). Redistribution of surface regolith was observed in two craters at the neck area. The upper regolith approximate to the craters is fine grained, whereas the lower appears to be relatively coarse, and many fragments are present (see Fig. 7). Such properties of the regolith may arise from the inclined terrain and the orientation of gravity (Scheeres *et al.*, 1998). The average terrain looks a bit smoother than that of Itokawa.

#### 4.2. Surface Age

Toutatis was partially imaged at varying scale (from ~2 m/pixel to ~8 m/pixel), significantly higher than Šteins and Lutetia. However, the overall quality of the pictures is somewhat degraded because they were captured with the monitoring camera. In addition, the low solar phase angle was not favorable for topographic studies. As result, only a few impact craters can be discerned with high fidelity.

However, a number of shallow depressions have been identified and catalogued as impact craters (Huang *et al.*, 2013; Zou *et al.*, 2014). These features appear almost rimless and very shallow, possibly indicating significant regolith movement. A total of 50–70 crater-like features have been mapped (Huang *et al.*, 2013; Zou *et al.*, 2014) on the large lobe, the largest of which is about 0.4–0.5 km across. A few larger craters have been proposed, but their existence appears inconclusive with current imaging. To compute the cumulative crater SFDs (Fig. 2c) we used the improved list of craters presented by Huang *et al.* (2013), for the whole body and the large lobe. Interestingly, the crater SFDs have shallow slopes, resembling that of Šteins, indicating that crater erasure may also be at work on Toutatis.

Here we apply target properties similar to those used for Šteins (a valid assumption given that both objects have a similar size and appear to be covered by loose material). As for the impact rate, we considered the average impact condition for main-belt asteroids. The reason for this choice is that the time spent by Toutatis on near-Earth orbits is typically several orders of magnitude smaller than the time spent in the main belt, hence most — if not all — of the observed craters were formed via collisions within the main belt. The resulting cratering age, for rubbly material and a strength of  $2 \times 10^6$  Pa, is ~1.6 Ga, supporting the validity of our assumption.

#### 4.3. Possible Formation Scenarios

Asteroid (25143) Itokawa is considered to be a contact binary formed by two or more smaller asteroids that have stuck together. Its surface shows few impact craters but is studded with boulders, which, along with its low density, implies that Itokawa may have formed from fragments that have coalesced over time (Michel and Richardson, 2013). Compared with Itokawa (see the chapter by Yoshikawa *et al.* in this volume), Toutatis is composed of two major lobes, suggesting a contact binary and possibly a rubble-pile structure. Several formation mechanisms have been proposed to produce these bifurcated bodies. One model assumes that the two major lobes were previously two separate objects moving at a very low relative speed, and that collision produces the contact binary (Fujiwara *et al.*, 2006). Another scenario assumes that the two components of a binary asteroid system could recombine through the binary YORP effects (Steinberg and Sari, 2011).

### 5. COMPARISON WITH PREVIOUS FLYBY TARGET ASTEROIDS

At the time of writing, seven other asteroids have been visited by spacecraft with fast flybys: (951) Gaspra, (243) Ida (with its satellite Dactyl), (253) Mathilde, (9969) Braille, (2486) Masursky, and (5535) Annefrank. In this discussion, we do not make comparisons with the three asteroids visited by orbital or sample return missions, namely (433) Eros [see detailed description by Cheng (2002)], (4) Vesta (see the

chapter by Russell et al. in this volume) and (25143) Itokawa (see the chapter by Yoshikawa et al. in this volume).

The asteroids in our chosen subset are different from each other in their physical properties (see Table 2). All have been targets of opportunity on missions devoted to other technological or other scientific objectives. It is clear that most of the information collected during a fast flyby is deduced by the analysis of images: the object's shape (usually partial), its rotational properties, its global and regional surface morphology, its age, and some assessment of the geological history. If the flyby geometry is favorable and more data are available (e.g., a very good estimate of the volume), then mass, density, and porosity can be estimated. These results, with possible analogies with meteoritic material, may provide some hints on asteroid internal structure. Visible and near-infrared spectroscopy provide information on surface composition and mineralogy. When adequate spectral coverage is obtained around closest approach, it is also possible to look for compositional heterogeneity of the asteroid.

In this section we compare the information obtained from all the performed asteroid flybys, underlying their importance in unraveling the nature of each individual object, their similarities and dissimilarities, and analyzing how these data can contribute to the understanding of the evolution of the asteroid population.

Spacecraft observations, even at large distances, allow investigation of the rotational properties of an asteroid, including rotation period, pole orientation, and bulk shape. The rotation periods of the flownby asteroids show a large excess of slow rotators with respect to the typical rotation period distribution of intermediate-sized asteroids ( $10 < D < 40$  km) (Fulchignoni et al., 1995). They do not reproduce a Maxwellian distribution, as is seen with larger asteroids, which would indicate that the population has reached a collisional equilibrium (Fulchignoni et al., 1995). Seven of these asteroids (out of ten) have a rotational period ranging from 4 h to 15 h and three of them (30% of the sample) are slow and/or complex rotators: Mathilde, with a period of 17.4 d (Mottola et al., 1995); Braille, with a period of 9.43 d (Oberst et al., 2001); and Toutatis, with a rotation period of 5.4 d and a precession period of 7.4 d (Takahashi et al., 2013). Pravec et al. (2002) discussed the possible causes of the excess of slow rotators in the size range of these bodies, but no definitive solution to this problem has been given. Their bulk shapes, obtained by various lightcurve inversion methods (Kaasalainen et al., 2002; Carry et al., 2012), are good approximations of the real shape as obtained by direct images, thereby validating the technique. The rotational properties of these asteroids deduced from Earth-based observations have a precision comparable to that obtained during the flyby. It indicates that the inversion of asteroid photometric lightcurves obtained by groundbased observations is a powerful tool for the characterization of the asteroid nature, giving precise information on its dynamical behavior and hints regarding its size and coarse shape (if it is convex).

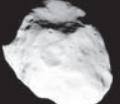

The 10 asteroid flybys covered objects varying in size by more than 2 orders of magnitude, from a little bit more than

1 km (Dactyl, Braille) to more than 100 km (Lutetia), and their shapes are quite irregular. The larger bodies (Mathilde and Lutetia) exhibit more spherical bulk profiles, although large craters modify strongly their surface and limb profiles (see the chapter by Marchi et al. in this book). The mid-sized asteroids, Gaspra and Ida (and possibly also Masursky), have elongated shapes, which can be described by a triaxial ellipsoid. Annefrank, Braille, and Toutatis have very elongated shapes and seem to have a rubble-pile structure, which is probably the result of their collisional origin and subsequent history. The diamond shape of Šteins could have been the consequence of its rotational behavior, dominated by the YORP effect, which forces the migration of the regolith from the polar regions toward the equator. This shape is similar to that of several other small asteroids, particularly among the primaries of small asteroid binaries. Dactyl is very small and quite spherical, as are most of the secondary bodies in asteroid binary/multiple systems.

Mass, volume, and consequently bulk densities are known with good precision only for Ida (thanks to the presence of its satellite Dactyl); Mathilde (Yeomans et al., 1997) and Lutetia were large enough to produce a detectable velocity change observable via the Doppler effect on the radio signal during the flyby. Consequently it has been possible to have an estimate of their micro- and/or macroporosities by comparison of their densities with densities of assumed meteorite analogs and some hints on their internal state. For the other asteroids, it is only possible to estimate some of those parameters based on (1) comparison of their surface composition (obtained by spectroscopy) with the composition of possible meteorite analogs, (2) their reconstructed shapes, and (3) hints on their porosity obtained by the surface morphology (presence of regolith, crater sizes, and depths) and possible analogies with known small bodies [e.g., Itokawa (see Abe et al., 2006)].

Some hints on global geology have been given only for Gaspra (Carr et al., 1994), the Ida-Dactyl system (Sullivan et al., 1996; Veverka et al., 1996b), and Mathilde (Thomas et al., 1999), as the other three flownby asteroids have only obtained images at poor resolution. The surface of Gaspra shows several facets separated by ridges. The effects of impacts dominate the surface of Ida. Very large craters are the dominating character of Mathilde (Chapman et al., 1999); their diameters are equal or greater than the average radius of the asteroid itself. These observations were the first to suggest that asteroids containing a large fraction of porosity may be stronger against impacts than nonporous ones, so that they can survive the energy required to form such big craters (for an explanation on the influence of porosity in impact events, see the chapter by Jutzi et al. in this volume). Grooves and lineaments that have topographic expressions of troughs or aligned rows of pits have been recognized on Gaspra and Ida. The grooves could mark in surface debris the presence, in the deeper interior, of fractures reactivated by subsequent impacts. There are suggestions of structures such as faults or layers on Mathilde but only two features have been clearly recognized: (1) one definite linear feature, a 20-km-long

TABLE 2. Characteristics of asteroids visited by flybys.

Asteroid Flyby Date (mm-dd-yyyy)	Space Mission	Flyby Distance (km)	D (km)	Rotation	Albedo	Spectral Type	Density (g cm <sup>-3</sup> )	Oldest Surface Age (G.y.)	Shape

marking (west from the large Karoo crater), that has a step-like topography on the order of 200 m, and (2) a curving slightly brighter, marking runs over 20 km wide (south from near the crater Otago) and 1.3–2 km across, suggesting either the direct exposure of a layer or the indirect effects of cratering exposing different materials. Neither feature appears to be the same type of feature as the more subtle grooves on Gaspra and Ida (for additional comments, see the chapter by Marchi et al. in this volume).

Isolated positive relief features as large as 150 m are probably ejecta blocks related to large impacts, such as those found on Eros, Lutetia, Vesta, and Toutatis. Extrapolation

of successful ejecta scaling laws to other asteroids suggests that blocks ~15 and 70 m across could be present on Dactyl and Gaspra (Lee et al., 1996) respectively. Evidence for the presence of debris on the surface (e.g., chute depths, grooves, swallowing of the largest degraded craters, and the rounded form of ridges) are present in all these asteroids. Estimates of the average depth of mobile materials suggest that Gaspra is covered with a regolith a few tens to several tens of meters thick, while the thickness of mobile materials on Ida would be 50 m, with a typical thickness for the debris layer ranging from 50 to 100 m (Sullivan et al., 1996). All these geological features have been found, to a greater or lesser extent, on all

asteroids visited by space missions. But the larger the body, the wider the observed effects of its geological evolution.

Looking at surface composition, five out of the ten asteroids considered here belong to the S taxonomic class. The spectral signature of iron-bearing minerals on S-type asteroid (951) Gaspra has been detected by *Carlson et al.* (1992) and *Granahan et al.* (1994) with the Galileo Near Infrared Mapping Spectrometer (NIMS); two spectral units were identified by *Granahan* (2011), both containing a higher relative abundance of olivine than those found in ordinary chondrites, indicating that Gaspra's surface composition could imply bulk materials that have undergone igneous differentiation processes. Recently 2.8- and 3.4- $\mu\text{m}$  spectral features have also been detected on the surface of Gaspra with the reanalysis of the NIMS spectra (*Granahan*, 2014) and interpreted as possibly being due to the presence of structural OH. (243) Ida was identified on the basis of groundbased observations (*Tholen and Barucci*, 1989; *DeMeo et al.*, 2009) as an S-type and Dactyl (*Chapman et al.*, 1995) with a similar but distinct spectrum. *Carlson et al.* (1994), using NIMS, and *Veverka et al.* (1996a), analyzing Galileo Solid State Imager (SSI) color data, observed small color variations both in the blue part of the spectrum and in the depth of the 1- $\mu\text{m}$  pyroxene-olivine band. Two terrains different in color, interpreted as "more processed," or "more weathered," have been recognized on Ida's surface. *Granahan* (2012) revisited the NIMS data of (243) Ida and Dactyl and measured the olivine and pyroxene spectral bands to compare the asteroid spectra with those of meteorites (*Dunn et al.*, 2010), and found that Ida's spectra correspond to measurements of LL chondrites and that of Dactyl correlates to L chondrites. Analyzing 44 images of (5535) Annefrank, *Newburn et al.* (2003) built a phase curve extending to 134°. Flux fell by more than six magnitudes between the extrapolated 0° and 134°. A broadband (470–940 nm) geometric albedo of 0.24 was derived for Annefrank, indicating its appurtenance with the S class. (4179) Toutatis has been extensively observed during its 1992–1993 close encounter with Earth. *Lazzarin et al.* (1994) obtained low-resolution spectra of the asteroid showing a typical behavior of an S-type object with no evidence of surface composition variations. *Reddy et al.* (2012) found that the Toutatis spectrum is consistent with an undifferentiated L-chondrite composition. The only available spectrum of (2486) Masursky obtained in the visible by *Lazzaro et al.* (2004) allowed them to classify it as an S type. *Buratti et al.* (2004) published some spectra of (9969) Braille in the 1.25–2.6- $\mu\text{m}$  region taken during the asteroid flyby. The 0.4–2.5- $\mu\text{m}$  spectrum obtained adding some groundbased observations (*Lazzarin et al.*, 2001; *Binzel et al.*, 2001) to the spacebased ones matches that of the ordinary chondrites and indicates (together with the high albedo,  $p_v = 0.34$ ) the appurtenance of the asteroid to the Q taxonomic type. The main features in the infrared are a 10% absorption band centered at 2  $\mu\text{m}$ , and a reflectance peak at 1.6  $\mu\text{m}$ , suggesting that the asteroid is composed by pyroxene and olivine in a ratio 1:1. The analysis of these spectra suggests also that Braille has a relatively fresh surface, scarcely affected by weathering

processes. In the case of the flyby of (253) Mathilde, only the Multi-Spectral Imager (MSI) and the Radio Science (RSS) instruments acquired data. *Binzel et al.* (1996) have obtained the first spectrum of Mathilde in the visible range by ground observations. *Rivkin et al.* (1997) found Mathilde to have a spectrum consistent with C-class asteroids in the near-infrared, although without the 3- $\mu\text{m}$  water-of-hydration feature commonly (but not always) seen on asteroids of this class. They compare Mathilde with plausible meteorite analogs, and find that the surface of this asteroid is not consistent with a surface composition of common carbonaceous chondritic material. To search for any variation on the asteroid surface, *Doressoundiram et al.* (1997) performed several observations in the visible range showing that Mathilde's surface is homogeneous over almost half of its rotational period. In these last cases of asteroid flybys, the on board instruments did not improve our knowledge of the surface composition.

## 6. CONCLUSIONS

The successful flybys by Rosetta and Chang'e-2 provided precious information on the visited asteroids revealing markedly different bodies. (21) Lutetia, (2867) Šteins, and (4179) Toutatis are different in size, shape, surface morphology, albedo, composition, and history. The three asteroids represent three new complex worlds completely different from previously visited asteroids. The analyzed surfaces have given important constraints on surface evolution and history of the visited bodies. The crater analysis revealed relative ages and provided constraints on their absolute ages and collisional histories, even if at different levels of incertitude. The major limit of flybys is in fact connected with the geometry of the trajectory, which can imply only partial vision of the body, but the velocity of the encounter can also influence and limit the data collection, rapidly changing the viewing geometry. The large size of Lutetia allowed measurement of its density. The images obtained during the Lutetia flyby form an excellent dataset to investigate a wide range of processes on intermediate-sized, irregular-shaped, main-belt asteroids. The production mechanism(s) for lineaments and other surface structures remains a subject for debate. However, recent papers (e.g., *Jutzi et al.*, 2013; *Cremonese et al.*, 2012) suggest that impact modeling has reached a sufficient level of sophistication that processes and mechanisms can be quantitatively assessed rather than speculated about.

In conclusion, Šteins must have suffered a combination of various processes to explain its present physical characteristics, including impacts, seismic shaking, and the YORP effect. Lutetia, with its geological complex surface and high density, seems to be a primordial object, which could have retained a record of early metamorphic and melting processes. Surface material motion appears to be common on Lutetia and could be expected on other intermediate-sized asteroids. All the detailed analyses do not allow us to unveil the real composition of Lutetia, and only a sample return mission will resolve the compositional puzzle of this intriguing object. As for the case of Toutatis, its contact binary shape

allows comparison with Itokawa even though the two bodies have different surface and rotational properties, but the formation mechanisms are still debated. Information about cratering of the surfaces are important contributions from asteroid flybys. Even if the crater analysis was challenging on small objects (like Šteins and Toutatis), crater SFDs can be used to investigate the processes of mass-wasting (some due to cratering itself, such as seismic shaking). Of course the low-quality data imply that the evidence for a rubble-pile nature of these asteroids cannot be conclusive. The generally limited low numbers statistic does not allow for a robust age assessment, but comparative analyses can nevertheless reveal additional details of the evolution of the bodies. On large asteroids (like Lutetia), crater SFDs allow for detailed stratigraphic studies (relative ages of various units) as well as absolute ages, provided the imaging resolution is good enough to obtain robust crater statistics.

Spectral observations give in general appropriate information, but might not allow interpretation of the real composition of the body (in particular, if the targets lack clear, recognizable absorption bands). In fact, from the discussion reported in section 5, it is evident that the information obtained by spectroscopy during a flyby of an asteroid represents a step forward in understanding the degree of homogeneity of the asteroid surface, thanks to the better resolution (e.g., the cases of Gaspra and Ida). However, concerning the asteroid composition, flybys do not seem to allow us to infer composition more accurately than using groundbased observations. Too many microscopic (e.g., space weathering, regolith depth, and size distribution) and macroscopic (e.g., collisions, aging, landslides) effects may affect the behavior of a spectrum, by changing the slope or masking features that reveal the presence of the minerals or processes characterizing an asteroid's composition. Even the search for meteoritic analogs by comparison of the spectra does not guarantee certain answers but only useful indications. Asteroid spectra taken from a distance refer to an average of unknown materials covering a given surface, while the meteorite spectra taken in a laboratory concern small amounts of very well-known, well-characterized materials. The only way to determine the real composition of an asteroid is to analyze the samples collected on its surface by sample return missions, and this is one of the main justifications for sample return missions. Even a very small amount of material analyzed in a laboratory provides fundamental information about the composition and history of the visited objects, as demonstrated by the results of the analysis of the few micrograms returned from the asteroid Itokawa by the Hayabusa mission [see the collection of papers in the *Science*, 333(6046)]. In the next decade, Hayabusa-2 (Japan Aerospace Exploration Agency) and the Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) (NASA) will take samples from the C-type asteroid (162173) 1999 JU<sub>3</sub> and the B-type asteroid (101955) Bennu, respectively, unveiling their chemical and mineralogical nature.

The 3 recent asteroid flyby missions together with the others (for a total of 10 flyby missions), the 2 orbiting ones

[Near Earth Asteroid Rendezvous (NEAR) at Eros and Dawn at Vesta], and the only sample return mission (Hayabusa at Itokawa), represent more than 20 years of “*in situ*” exploration of asteroids. The data collected are precious and of high scientific value, but perhaps the major benefit obtained from these efforts is that they provided us with a ground truth for checking the methods to interpret the groundbased observations, which will allow us to characterize a larger and larger number of asteroids knowing the limit of the possible interpretations at a much lower cost.

# Phobos and Deimos

Scott L. Murchie

*The Johns Hopkins University Applied Physics Laboratory*

Peter C. Thomas

*Cornell University*

Andrew S. Rivkin and Nancy L. Chabot

*The Johns Hopkins University Applied Physics Laboratory*

Phobos and Deimos, the satellites of Mars, occupy a unique place in the solar system. They are the only terrestrial planet satellites besides the Moon, yet have traits in common with low-reflectance bodies more typical of the outer solar system. Understanding their composition, origin, and geologic evolution will provide insights into the earliest stages of terrestrial planet formation. Early exploration by the Viking and Mariner 9 missions, decades before the first “proper” asteroid encounters, hinted at several asteroidal properties yet to be discovered: lower than expected densities, abundant regolith even on relatively small bodies, and complicated geology. The first book in this series, *Asteroids* (1979), had an entire chapter on Phobos and Deimos. We have learned much about these objects in the last 35 years from telescopic and spacecraft observations.

## 1. DISCOVERY AND EXPLORATION

### 1.1. Discovery and Early Groundbased Observations

Once the Galilean satellites of Jupiter were discovered and the Copernican model of the solar system became widely accepted, Mars’ apparent lack of a moon was notable. By the end of the seventeenth century, Saturn was known to have at least five satellites, a number that swelled to seven by the end of the eighteenth century. By 1800 a new planet, Uranus, was discovered and found to have at least two satellites. By 1870, two more uranusian satellites and another saturnian satellite were detected, along with another new planet (Neptune) with its own satellite. Yet Mars remained moonless. Based on numerology, Kepler predicted that Mars should have two satellites, as two made the most sense when interpolating between Earth’s single moon and Jupiter’s four. Jonathan Swift and Voltaire both “predicted” that Mars would have two moons, but their predictions were based on satire (*Hall*, 1878).

Both William Herschel and Heinrich Louis d’Arrest performed unsuccessful searches for martian moons before Asaph Hall, using the U.S. Naval Observatory 26-inch (66-cm) refractor, found first Deimos then Phobos during the excellent Mars apparition of 1877. Because of the primitive state of astrophotography, only visual observations using eyepieces were possible at the time. The satellites were

named for characters in the Iliad, Phobos (Fear) and Deimos (Terror), who are the attendants of the god Ares, the Greek equivalent of the Roman god Mars. Despite searches for additional satellites, using both ground- and spacecraft-based observations, no additional satellites of Mars have been found within its Hill sphere to a diameter of 180 m assuming an albedo of 0.07 (*Sheppard et al.*, 2004).

Given the close proximity of Phobos and Deimos to Mars, positional measurements were typically the only ones undertaken. *Pascu et al.* (2013) compiled and reviewed these measurements as well as other early observations. A focus of early observations was the secular acceleration of Phobos in its orbit (e.g., *Sharpless*, 1945), now known to originate from tidal effects that cause the moon to spiral in toward Mars, which eventually will result in Phobos’ impact (*Burns*, 1978). The first photometric study to estimate the moons’ diameters from their brightnesses, by Edward Charles Pickering of the Harvard College Observatory and reported by *Hall* (1878), suggested diameters of 9 km for Deimos and 11 km for Phobos. These assumed a Mars-like albedo and hence resulted in diameters smaller than the actual values. Just prior to the first spacecraft encounters with the moons, a combination of photoelectric photometry (*Harris*, 1961) and albedo estimates from polarimetry (*Zellner*, 1972) resulted in diameter estimates within 10% of current values (*Zellner and Capen*, 1974).

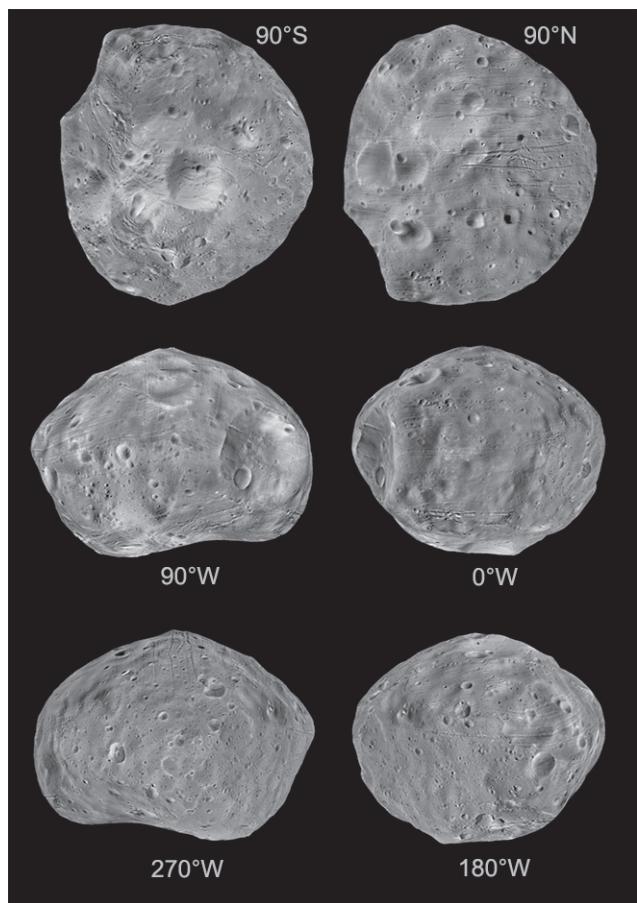

## 1.2. 1969–1980: Exploration by the Mariner and Viking Spacecraft

It was not until the visit of spacecraft to Mars that bulk properties and the physical geology of the moons would become known (Table 1, Figs. 1 and 2). The first image of Phobos, by Mariner 7, was made in silhouette against the martian surface. Smith (1970) found an albedo of 0.065 from those data, at that time the lowest-known albedo in the solar system. The first images resolving surface features, from Mariner 9, established approximate dimensions of the two moons, their heavily cratered surfaces, low albedos, and coverage by regolith (Pollack *et al.*, 1972, 1973). Polarimetric measurements indicated a finely granular regolith (Noland *et al.*, 1973).

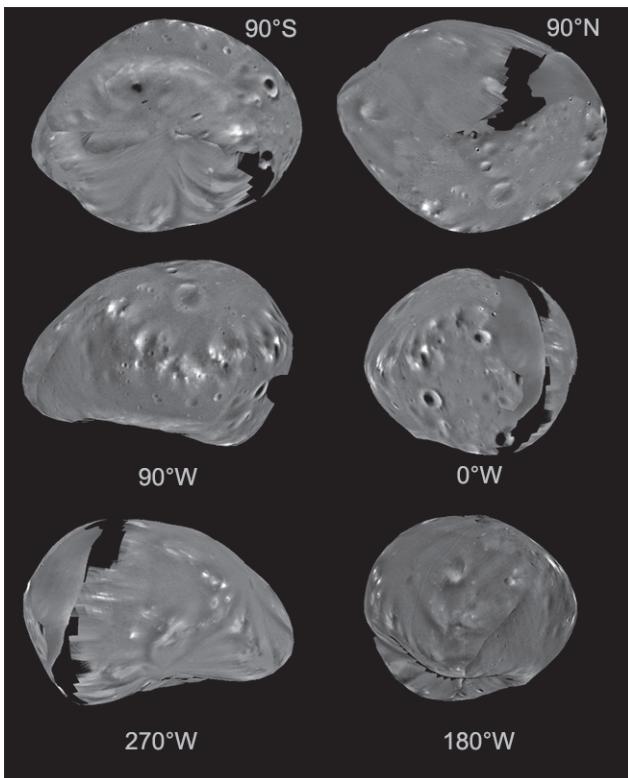

Higher-resolution imaging from close flybys of the moons by the Viking 1 and Viking 2 orbiters revolutionized understanding of both moons (Duxbury and Veverka, 1977), and still provides most of the current knowledge about the physical geology of Deimos. Results through Viking were

thoroughly reviewed by Thomas *et al.* (1992) and Burns (1992). Phobos' surface exhibits rough topography, including craters in a variety of degradation states. One moderately well preserved large crater, Stickney, is about 9.4 km in diameter. Reflectance varies spatially, with brighter materials apparently less affected by “space weathering” being exposed on crater rims (Thomas, 1979). [Space weathering refers to processes that alter the optical properties of regolith over geologic time. On the Moon, this includes darkening accompanied by reddening of the spectrum and weakening of mineral absorptions. It is understood to occur by formation of nanophase metallic iron by redeposition of vapor from micrometeoroid impacts (Hapke, 2001).] Topographic grooves 100–200 m wide, tens of meters deep, and kilometers in length form several subparallel sets, most of which define planes that are nearly parallel to Phobos' intermediate axis (i.e., to the direction of orbital motion) (Thomas *et al.*, 1979). In contrast, Deimos has a markedly smoother surface (Fig. 3) with craters that are more degraded and infilled by regolith (Thomas, 1979). Migration of regolith down slopes has formed elongate streamers (Thomas and Veverka, 1980; Thomas *et al.*, 1996). Grooves have not been recognized on Deimos.

Several spectra of Phobos were acquired at ultraviolet through near-infrared wavelengths by Mariner 9 and Viking, and assembled into a single, composite spectrum

**Fig. 1.** Phobos image mosaic (Stooke, 2011) projected on a shape model from Gaskell (2011). *Upper left:* Southern hemisphere. *Upper right:* Northern hemisphere. *Center left:* Leading hemisphere. *Center right:* Sub-Mars hemisphere. *Lower left:* Trailing hemisphere. *Lower right:* Anti-Mars hemisphere.

**Fig. 2.** Deimos image mosaic projected on shape model, both from Thomas (1993). *Upper left:* Southern hemisphere. *Upper right:* Northern hemisphere. *Center left:* Leading hemisphere. *Center right:* Sub-Mars hemisphere. *Lower left:* Trailing hemisphere. *Lower right:* Anti-Mars hemisphere.

TABLE 1. Current best estimates of global properties of Phobos and Deimos.

	Phobos	Deimos
Orbital semimajor axis	9377 km (2.8 R <sub>Mars</sub> )	23,460 km (7 R <sub>Mars</sub> )
Orbital period	7.66 h	30.3 h
Orbital eccentricity	0.0151	0.0003
Orbital inclination, to Mars' equator	1.093°	0.93°
Rotational period	Synchronous	Synchronous
Size	26.06 × 22.80 × 18.28 km *	15.0 × 12.2 × 10.4 km †
Density	1860 ± 13 kg m <sup>-3</sup> *	1490 ± 190 kg m <sup>-3</sup> ‡
Gravity	3–8 × 10 <sup>-3</sup> m s <sup>-2</sup>	2 × 10 <sup>-3</sup> m s <sup>-2</sup>
Normal reflectance, 0.55 μm	0.071 ± 0.012 §	0.068 ± 0.007 ¶

by Pang et al. (1978). That composite spectrum is flat at wavelengths longer than 0.4 μm but falls off steeply into the ultraviolet. Similarity to the reflectance spectrum of carbonaceous chondrite meteorites drove a long-standing hypothesis that the moons are primitive, carbonaceous bodies captured into orbit around Mars (Pang et al., 1978; Pollack et al., 1978). Alternatively, it has been proposed that the moons accreted in Mars orbit from material like that forming bulk Mars (Burns, 1992), or from ejecta from a large impact with Mars (Singer, 1966; Craddock, 2011), and that they are dark because of extreme space weathering (Britt and Pieters, 1988).

Measurement of the moons' masses, made by tracking perturbations of the Viking Orbiters' trajectories during close flybys, combined with volume estimates from imaging, yielded the first density estimates of 2000 ± 500 kg m<sup>-3</sup> for Phobos and 1900 ± 700 kg m<sup>-3</sup> for Deimos (Veverka and Burns, 1980). Although subsequent data and new analyses improved these values (Table 1), the Viking results clearly showed that Mars' moons are much less dense than the bulk rock making up Mars, requiring that they must be either highly porous, composed of lower-density material, or both.

### 1.3. 1980–2004: Incremental New Understanding

The next phase of exploration included groundbased observations that refined earlier understanding of the moons' properties, a partially failed close rendezvous, and distant observations by other Mars-orbiting or landed spacecraft. Earth-based spectra revealed that the 3-μm H<sub>2</sub>O absorption expected for a hydrated-mineral-bearing carbonaceous composition was undetectable (Bell et al., 1989; Rivkin et al.,

**Fig. 3.** See Plate 16 for color version. Spacecraft exploration reveals global properties of Phobos and Deimos, and basic differences between them. *Top left:* Viking images revealed that Phobos' surface is relatively rough, with well-preserved craters, and parallel topographic grooves. *Top center:* Deimos' surface is smooth with craters infilled by regolith. *Top right:* Multispectral and hyperspectral imaging from Phobos 2, Mars Express, and the Mars Reconnaissance Orbiter (shown, centered on the sub-Mars hemispheres) reveal spatial variations in Phobos' spectral properties, especially associated with Stickney. Deimos' brightness variations are accompanied by less color variation. *Middle:* Phobos simple cylindrical image map and dynamical height, using shape model from Gaskell (2011) and image mosaic from Stooke (2011). Red is high, blue low, with a range of heights of 1.8 km. *Bottom:* Deimos simple cylindrical image map and dynamical heights, using shape model and image mosaic updated from Thomas (1993). Red is high, blue low, with a range of heights of 1.9 km.

2002), and that disk-integrated spectra of Deimos (*Grundy and Fink*, 1992) and Phobos (*Murchie and Zellner*, 1994) were featureless and much redder than previously thought. In hindsight, the shape of the composite spectrum of *Pang et al.* (1978) was a result of mixing shorter wavelengths that covered a more red-sloped part of Phobos and longer wavelengths covering a much less red part of Phobos (*Murchie and Erard*, 1996).

The Phobos 2 mission (*Sagdeev and Zakharov*, 1989) was to have conducted proximity measurements of Phobos' chemical composition, but the spacecraft was lost after its first month of distant observations, before closest approach to the moon. Three medium-distance encounters with Phobos that did occur provided the most precise estimate of density to date (*Avanesov et al.*, 1991). During those encounters, color imaging returned by the Videospectrometric Camera (VSK) (*Avanesov et al.*, 1991) and ultraviolet through near-infrared spectra by the Combined Radiometer and Photometer for Mars (KRFM) (*Ksanfomality et al.*, 1990) and Imaging Spectrometer for Mars (ISM) (*Bibring et al.*, 1989) provided the first spatially resolved measurements of spectral properties of a low-reflectance body. Phobos' surface was revealed to be heterogeneous, with a "redder unit" occupying most of the surface, and a "bluer unit" associated with Stickney (Fig. 3). The two units differ mainly in spectral slope, and any mineral absorptions are weak. The 3- $\mu\text{m}$  absorption remained undetected even with improved spatial resolution (*Murchie et al.*, 1991; *Murchie and Erard*, 1996). The red spectral slopes of the two bodies, plus weak to absent 3- $\mu\text{m}$  absorptions, are more consistent with D-type asteroids than with carbonaceous chondrites (*Rivkin et al.*, 2002).

Measurements by Mars Global Surveyor and Mars Pathfinder added to the growing understanding of the moons. Images from the Mars Orbiter Camera, comparable to the best from Viking, revealed a high spatial density of blocks just east of Stickney, where ejecta from that crater are predicted to be thickest (*Thomas et al.*, 2000). Thermal emission spectrometer (TES) measurements revealed a nearly blackbody spectrum from 10 to 30  $\mu\text{m}$ , possibly with weak superimposed silicate features (*Roush and Hogan*, 2000, 2001; *Glotch et al.*, 2015). Whole-disk spectra of both moons from the Imager for Mars Pathfinder (*Murchie et al.*, 1999) confirmed the red-sloped spectra of both moons, and identified a 0.7- $\mu\text{m}$  absorption that they suggested could be due to Fe-bearing minerals.

#### 1.4. Beginning in 2004: Exploration by Mars Express and Mars Reconnaissance Orbiter

Knowledge of Phobos and Deimos was revolutionized again by the Mars Express and Mars Reconnaissance Orbiter (MRO) missions. During multiple close flybys of Phobos, Mars Express (*Witasse et al.*, 2013) acquired nearly global coverage with the High Resolution Stereo Camera (HRSC) (*Neukum et al.*, 2004; *Jaumann et al.*, 2007) and the Observatoire pour la Mineralogie, l'Eau, les Glaces et l'Activité (OMEGA) (*Bibring et al.*, 2004) imaging spectrometer, at

multiple viewing geometries that support derivation of the photometric properties of the surface over a broad wavelength range (*Fraeman et al.*, 2012). Additional spectral information came from the thermal infrared Point Fourier Spectrometer (PFS) (*Giuranna et al.*, 2011). The MaRS radio science experiment further improved the accuracy of mass determination, which, combined with a refined global volume estimate from HRSC, yields a density estimate for Phobos with a precision of <1% (Table 1). From low Mars orbit, MRO conducted several observing sessions dedicated to the moons. By virtue of its very high spatial resolution, the High-Resolution Imaging Science Experiment (HiRISE) (*McEwen et al.*, 2007) obtained the highest-resolution color imaging of the moons to date in three broad bands from 0.4 to 1.0  $\mu\text{m}$ . The Compact Reconnaissance Imaging Spectrometer for Mars (CRISM) (*Murchie et al.*, 2007) collected hyperspectral imaging of Phobos complementary to the OMEGA data, and the first spatially resolved hyperspectral measurements of Deimos.

Results from Mars Express and MRO frame the current debates about the composition, geological processes, and origin of the moons, as described in the following sections. In particular, the complexity of the grooves on Phobos frustrates simple explanation of their origins (*Ramsley and Head*, 2013b; *Murray and Heggie*, 2014). Similarly, spectral features are weak and have been interpreted as resulting from dissimilar compositions corresponding to the range of hypotheses for the moons' origins (*Giuranna et al.*, 2011; *Fraeman et al.*, 2012, 2014).

#### 1.5. Relationship to Themes of Solar System Exploration

The origin and evolution of the martian moons provides insight into fundamental questions regarding formation of the terrestrial planets and the geology of asteroidal bodies. For example, questions from Planetary Science Decadal Survey (*Squyres et al.*, 2011) include: (1) What were the initial stages, conditions, and processes of solar system formation? (2) What governed the supply of water to the terrestrial planets? (3) What were their primordial sources of organic matter? (4) What processes have controlled the surface evolution of small bodies?

Table 2 lists five possible origins for Phobos and Deimos, resulting from capture (*Pollack et al.*, 1978) or *in situ* formation hypotheses (*Burns*, 1992; *Craddock*, 2011). Each origin corresponds to a distinct range of compositions, some of which are in the meteorite collection and some of which have only been modeled. If either Phobos or Deimos is a captured carbon- or water-rich body, then that moon may be a sample of the population of bodies that provided carbon and volatiles to the accreting terrestrial planets; such a result would address the second and third Decadal Survey questions. However, capture does not necessarily imply a carbon-rich composition, or even the same origin for Phobos and Deimos. Alternatively, if Phobos or Deimos originated by capture of an ordinary chondrite, that finding would provide new

TABLE 2. Proposed origins for Phobos and Deimos and predicted compositions.

Hypothesis	Corresponding Composition	Elemental Abundances	Mineral Abundances
Capture of organic- and water-rich outer main belt or outer solar system body	Ultraprimitive; Tagish Lake is best-known analog *	High C, S, H, Zn/Mn; composition possibly distinct from known meteorites	Abundant phyllosilicates; carbonates and organic phases; anhydrous silicate phases rare
	Primitive; like CI or CM †	Medium C, S, H; may grade into other carbonaceous chondrite types — if so, distinguishable with Al/Mn, Zn/Mn	Abundant phyllosilicates; low carbonates; medium organics; olivine and Al-rich grains
Capture of organic-, water-poor outer solar system body	Anhydrous silicates plus elemental C ‡	High C, low H; Mg/Fe ratio ~2–4; bulk composition unlike any meteorite analogs	Anhydrous, medium Fe (20–40%) pyroxene; possibly abundant amorphous C or graphite
Capture of inner solar system body	Ordinary chondrites †	Very low C, H; Mg/Si ~0.8–1, Al/Si ~0.05–0.1; low Zn/Mn, Al/Mn; common composition in meteorite collections	Low carbonates, phyllosilicates; pyroxene, olivine in range of known meteorites
Coaccretion with Mars	Bulk Mars; like ordinary chondrites, but an SNC-derived composition §	Very low C, H; Mg/Si, Al/Si, Fe/Si indicative of bulk Mars; Zn/Mn, Al/Mn like ordinary chondrites	Anhydrous silicates with Fe, Mg expected for bulk Mars; low abundance of C-bearing phases
Accretion disk from giant impact on Mars	Impactor material; mixed with martian crust or mantle, like SNC meteorites ¶	Extremely low H; volatile depletions such as in C, S, K/Th; other elements depend on mix of Mars and impactor material; high Al/Si, Ca/Si indicate evolved igneous materials	Anhydrous phases; a primitive impactor would suggest abundant olivine, possibly C phases; any surviving Mars material is basaltic consistent with many datasets for Mars

insight into how space weathering affects the link between common meteorites and D-type bodies. Formation by coaccretion with Mars would provide access to a building block of Mars, whereas formation from a large impact would sample Mars' earliest crust plus the impactor material. Whatever the moons' origins, addressing this question also addresses the first Decadal Survey question, and characterizing geological processes on Phobos and Deimos addresses the last.

## 2. PHYSICAL GEOLOGY

The two martian moons differ from one another in appearance, and each has fundamental surface characteristics that remain poorly understood. There was an early expectation that the moons were exemplary of the geology of small bodies in general (Veverka and Burns, 1980), but that expectation has been only partially met, due in part to the moons' distinct features compared with features observed on asteroids (see the chapters by Yoshikawa et al., Russell et al., and Barucci et al. in this volume). Yet the fundamental influences on all the bodies are similar: impact cratering,

orbital mechanics and evolution, low gravity, rotational accelerations, thermal cycling, and solid-body mechanical properties. One of the fundamental questions about Phobos' and Deimos' history is, given their similar environments, why does geology of their surfaces appear so different?

### 2.1. Basic Appearance

Phobos is modestly elongated (Table 1), heavily cratered, and distinctively marked with patterns of elongated depressions, termed grooves (Fig. 1). The largest crater, Stickney, is ~9.4 km in diameter, ~0.85× the satellite's mean radius. This size is within the normal range for the largest craters on small objects (Thomas, 1999; Morrison et al., 2009). The depth of the crater at present is about 1 km, but a large debris accumulation in the center is probably over 400 m thick (Thomas, 1998). Depth-to-diameter ratios of Phobos' craters appear to be generally 0.2 or less (Thomas et al., 1979; Basilevsky et al., 2014; Kokhanov et al., 2014). The differences between crater morphologies on small objects and the Moon are still not well established (Morrison et al.,

2009; Basilevsky *et al.*, 2014), in part because evaluation of crater degradation states on small objects is not well defined.

Deimos presents a surface whose smoothness contrasts greatly with the cratered and grooved roughness of Phobos (Fig. 2). Albedo features are conspicuous on ridges and some crater rims, further distinguishing its appearance from that of Phobos. It is even more irregularly shaped than Phobos, with a large concavity centered on the south pole (Thomas, 1998).

## 2.2. Shape, Density, and Internal Porosity

The dimensions of Phobos are well known, but Deimos' are less so. Willner *et al.* (2014) used a set of 665 surface control points on Phobos from HRSC and Viking Orbiter images to generate a spherical harmonic function up to degree and order 17 to describe Phobos' shape. Their best-fit triaxial ellipsoid dimensions (diameters) are  $a = 26.06$  km,  $b = 22.80$  km,  $c = 18.28$  km; the full shape model has a volume of  $5742 \pm 35$  km<sup>3</sup>. These numbers compare closely to the previous dimensions and volume obtained by Duxbury (1989, 1991) and Thomas (1989). Uncertainty in Deimos' volume and shape result from limited coverage and poor resolution of the trailing hemisphere and southern latitudes (Fig. 2). Its ellipsoidal fit dimensions are reported by Thomas (1993) as  $a = 15.6$  km,  $b = 12.0$  km, and  $c = 10.2$  km with a volume of  $1017 \pm 130$  km<sup>3</sup>, the latter obtained directly from the shape model.

Phobos' overall shape is elongated, with the long axis aligned with Mars. Stickney creates a large concavity in the leading part of the sub-Mars hemisphere (Fig. 1). Due to the eccentricity of Phobos' orbit, the moon librates about its mean position by  $\sim 1^\circ$ ; the exact magnitude of that libration is affected by internal density structure. If Phobos' interior is homogeneous, then a libration in longitude of  $1.10^\circ$  is predicted; however, increased porosity beneath Stickney due to impact fracturing could result in a libration up to  $1.24^\circ$  (Rambaux *et al.*, 2012). Previous determinations each have uncertainties of  $0.1^\circ$ – $0.2^\circ$ , and differ from each other by a larger amount than the difference between the two predictions (Duxbury, 1991; Willner *et al.*, 2014; Oberst *et al.*, 2014). Even the most recent and presumably accurate determination,  $1.09^\circ + 0.10^\circ$  (Oberst *et al.*, 2014), is insufficient to distinguish models of interior porosity. In the future, more accurate measurement of libration in longitude may provide a window into heterogeneity in Phobos's interior structure.

Deimos' shape can be described as having several rounded facets (Fig. 2). Ridges at the edges of the facets form gravitational highs, and the centers of the facets are gravitationally low (Fig. 3), creating regional slopes (Thomas, 1993; Thomas *et al.*, 1996). High southern latitudes lie in a major concavity, possibly a highly degraded crater whose ejecta reaccreted onto the moon and created the smooth surface (Thomas *et al.*, 1996; Thomas, 1998).

Although Phobos is low in density compared to mafic mineral assemblages and the bulk terrestrial planets, it is significantly denser than Deimos. Pätzold *et al.* (2013) used

mass determined from Mars Express' flyby of Phobos on March 3, 2010, at 77 km distance, and the global volume from Willner *et al.* (2010), to derive a bulk density of  $1862 \pm 20$  kg m<sup>-3</sup>. They were unable to solve for the second-degree gravity field to constrain internal heterogeneity. The best current mass for Deimos (Jacobson, 2010), divided by the best Viking-era volume estimate (Thomas, 1993), yields a bulk density of  $1490 \pm 190$  kg m<sup>-3</sup>,  $2\sigma$  below Phobos's density. In section 3.4 potential implications for the moons' density difference are discussed. Both densities are lower than those of nearly all analog materials, and substantial internal porosity is probably present at least within Deimos (Rosenblatt, 2011; Murchie *et al.*, 2013).

## 2.3. Gravitational Environment

Small asteroids and small bodies commonly have non-intuitive vectors for surface acceleration. These result from their irregular shapes; rapid spin, which enhances centripetal force; low mass, which decreases gravity; and especially in the case of Phobos, tidal effects. Determining what is "upslope" or "downslope" is best accomplished by calculating potential energies over the surface (Vanicek and Kakiwsky, 1986; Thomas, 1993). One measure of relative height, dynamical height, is obtained by dividing potential energy by acceleration. In the case of Phobos, as it spirals toward Mars, the longer ends (pointing toward and away from Mars,  $0^\circ$  and  $180^\circ$  longitude) become conspicuous gravitational lows due to tides and rotational accelerations (Fig. 3) (Thomas, 1993; Shi *et al.*, 2012). Escape velocities near those locations are also highly directionally dependent, less than  $3$  m s<sup>-1</sup> toward the east, but over  $9$  m s<sup>-1</sup> to the west (Thomas, 1993). Deimos, orbiting much farther from Mars, experiences less effect from tides and rotational accelerations.

## 2.4. Regolith Properties

Having formed on small objects without atmospheres or internal activity, the regoliths of the two moons are expected to be the product of impacts and redistribution of their ejecta over geologic time. Nearly all ejecta from craters on Phobos and Deimos either reimpact the satellites directly [that fraction being a function of strength, which affects ejecta velocity (Asphaug and Melosh, 1993)], or escape to Mars orbit and reaccumulate over time (Soter, 1971; Ramsley and Head, 2014). An important question has been the abundance of Mars ejecta in Phobos' regolith (Chappaz *et al.*, 2013; Ramsley and Head, 2013a, 2014). Chappaz *et al.* (2013) and Ramsley and Head (2013a) calculated that Mars ejecta may constitute a few parts per million to a few hundred parts per million of Phobos' regolith, most having accreted later in Phobos' evolution as it has spiraled to lower altitudes. The presence of at least a few centimeters of low thermal inertia material, indicated by surface temperatures determined from Viking Orbiter thermal infrared measurements (Lunine *et al.*, 1982), is consistent with fine-grained, unconsolidated regolith.

Crater morphology reveals evidence for layering in Phobos' regolith. Layering is directly exposed in one crater wall (Thomas, 1979). Crater floor morphologies [e.g., flat floors, concentric craters (Quaide and Oberbeck, 1968)] suggest depths to discontinuities of a few to several tens of meters in some areas of Phobos (Thomas et al., 2000). Basilevsky et al. (2014) used similar criteria to map crater morphology with Mars Express images, and found that the depth to discontinuities varies greatly over short distances. These and MARSIS radar sounder data (Heggy et al., 2014) suggest that Phobos' regolith varies in modest ways horizontally and that it gradationally merges at greater depths with a more solid, but likely still porous object.

Large ejecta blocks are found on both moons. The largest on Phobos may be an ~85-m boulder near the crater Stickney; Deimos has a poorly resolved block ~150 m across. Basilevsky et al. (2014) noted that the surface density of large blocks (from a variety of source data) approximates that on some lunar terrains, and that mapping of both obvious blocks and mounds interpreted as blocks reveals an association with specific craters. Lee et al. (1986) found that large blocks are more widespread on Deimos than on Phobos, and typify the surface seen in the highest-resolution images (Fig. 3). The sizes of the large blocks are within ranges expected for the possible source craters, and likely were formed by similar excavation and fragmentation phenomena as lunar ejecta blocks. The abundance of smaller blocks on Phobos is known only for the region near Stickney imaged at high resolution, and it is comparable to the number density and size-frequency distributions of blocks on Eros and Itokawa (Ernst et al., 2015).

Phobos' regolith exhibits color as well as albedo variations, whereas Deimos' regolith has albedo variations but little color variation (Murchie et al., 1991; Thomas et al., 2011); both bodies are a factor of 2 lower in reflectance than even the most space-weathered lunar mare materials (sections 3.1, 3.2). Phobos' greatest color variation is associated with the crater Stickney (Fig. 3), a "bluer" region that includes most of the crater, the ejecta to the east, and less distinct lobes to the northwest and southwest (Patsyn et al., 2012; Pieters et al., 2014). These locations correspond to predicted locations of the thickest ejecta from Stickney (Thomas, 1998). The rest of the surface is a "redder unit," and close to the color exhibited by Deimos. Phobos has some brighter crater rims, and accumulations of relatively dark material on the floors of some craters. Deimos' albedo features are mostly streamers that taper downslope from crater rims and blocks on the regional gravitational highs at ridge crests (Fig. 3) (Thomas et al., 1996). These albedo features exhibit little color contrast from the darker surroundings, but are up to 30% brighter than the rest of Deimos' surface. It is likely that some of the elevated reflectances are related to lesser space weathering of more freshly exposed regolith, particularly on Phobos' bright crater rims and in Deimos' streamers. The detailed processes by which space weathering operates on Mars' moons depends on the composition of the starting material, which is debated

(section 3.2). However, it is unlikely that Phobos' redder material results from space weathering of the bluer material: Space weathering is understood to weaken mineral absorptions (Hapke, 2001), and absorptions present at 0.65 and 2.8  $\mu\text{m}$  in the redder material are weaker or absent in the bluer material (section 3.2).

Deimos exhibits clear evidence for widespread motion of material down regional slopes: brighter streamers trending down gravitational slopes, asymmetric ponded material within craters concentrated on their downslope sides, and more blocks and small craters on higher terrain (those at lower elevations having been buried). Deimos has perhaps the largest recognized crater of any small body relative to body size, the south polar concavity with a diameter of ~10 km (Thomas, 1989; Morrison et al., 2009). The estimated volume of this crater is  $43 \pm 20 \text{ km}^3$  on an object with a surface area  $520 \text{ km}^2$ . In comparison, Stickney's initial volume was  $50 \pm 15 \text{ km}^3$  on an object with a surface area of  $1600 \text{ km}^2$  (Thomas, 1998). Nearly all crater ejecta should have eventually reaccreted on Deimos. At present, an uneven distribution of craters larger than 350 m indicates uneven blanketing or other degradation of craters. The simplest explanation, consistent with the topographic slopes, is concentration of reaccreted ejecta into lower areas by mass wasting, yielding thicknesses up to 200–400 m in gravitational lows (Fig. 14 of Thomas, 1998). Deimos' globally uniform appearance suggests that the south polar cratering event does not date to Deimos' earliest history: If the cratering event was that old, then downslope movement of regolith might have exposed substrate in topographically higher regions, which would then have accumulated a high density of small impact craters.

Whereas Deimos exhibits mass wasting on slopes as low as  $2^\circ$ , Phobos' rougher surface has only localized examples of mass wasting. The most obvious are on the western interior slope of Stickney (Thomas et al., 2000; Basilevsky et al., 2014), which is at the angle of repose and has few superposed small craters and numerous downslope albedo streamers. On the floor of Stickney is a hummocky mound several hundred meters in thickness that is probably a debris slide formed substantially after Stickney's formation, judging from its well-preserved hummocks and few superposed craters. As noted in section 2.3, the gravitational slopes on Phobos are changing as it approaches Mars; Stickney's western slope has probably increased with time, encouraging further and future mass movement. Other mass movement on Phobos is observed in smaller craters (Basilevsky et al., 2014) and in some grooves.

Both martian moons have been observed by Earth-based radar. Busch et al. (2007), using Arecibo observations at 13-cm wavelength, measured radar albedos of  $0.056 \pm 0.014$  for Phobos, consistent with a recalibrated value of  $0.049 \pm 0.01$  for Phobos found by Ostro et al. (1989), and  $0.021 \pm 0.006$  for Deimos. Both radar albedos are low: Phobos is near the low end of asteroid radar albedos and Deimos has the lowest detected radar albedo in the solar system to date. Given the radar albedos, a near-surface density and porosity can be calculated if a composition is assumed;

*Busch et al.* (2007) considered lunar soils and dehydrated low-grade carbonaceous chondrites, and for each used grain densities of  $2700 \text{ kg m}^{-3}$ . Phobos' near-surface bulk density was estimated to be  $1600 \pm 300 \text{ kg m}^{-3}$ , indicating a near-surface total porosity of  $40 \pm 10\%$ , while for Deimos the values are  $1100 \pm 300 \text{ kg m}^{-3}$  and  $60 \pm 10\%$ .

## 2.5. Crater Densities and Surface Ages of the Moons

Crater densities on Phobos have been studied by *Thomas and Veverka* (1980), *Thomas* (1998), and *Schmedemann et al.* (2013, 2014). Studies of crater density on irregular objects must deal with geographic variations in image quality and lighting, effects of differing slopes, and relief of the substrate that can affect crater shape and size. Crater degradation on small objects may involve seismic shaking induced by impacts (*Richardson et al.*, 2005). *Schmedemann et al.* (2014) found spatial variations in crater density on Phobos, and possibly discontinuities in the cratering record (kinks in the cumulative crater density curves), which they hypothesized to be created by seismic shaking or ejecta emplacement events. Absolute ages are model-dependent: If Phobos has experienced the expected crater flux at Mars' orbit since its earliest history, then the oldest surface may approach 4.3 Ga and Stickney may be as old as 4.2 Ga. Model ages for grooves are younger than Stickney, consistent with the observation that grooves cross-cut Stickney and its ejecta, but their absolute age probably exceeds 3 Ga. The role of secondaries is unclear: *Ramsley and Head* (2014) interpreted it to be significant, whereas *Schmedemann et al.* (2014) did not. The antapex (around  $270^\circ\text{W}$  longitude) lacks significant grooves and has been suggested to have less regolith than other areas (*Thomas*, 1998), perhaps relating both to deposition of ejecta near Stickney, and to disturbance near Stickney's antipode. A global crater catalog of Phobos has been compiled, and is likely close to complete for craters  $>50 \text{ m}$  in diameter (*Bandeira et al.*, 2014).

Deimos' distinct morphology indicates a different history of crater modification from that on Phobos. Despite smoothing of the surface by deposition or reaccumulation of a large amount of ejecta (section 2.4), there remains a high density of large craters (*Thomas*, 1998) not very different from that on Phobos. However, although rims of larger craters are visible for counting, crater interiors have been largely filled by debris (*Thomas*, 1998). The uneven geographic distribution of smaller craters on Deimos, with fewer small craters near the center of the topographic facets, indicates greater burial by debris in gravitational lows (Fig. 16 of *Thomas*, 1998).

## 2.6. Grooves on Phobos

Viking Orbiter views of Phobos revealed linear, often parallel depressions 100–200 m wide, extending up to several kilometers (*Veverka and Burns*, 1980). Several spacecraft missions later, these features remain without consensus explanations. Similar but not identical features have been found on small icy satellites (*Morrison et al.*, 2009), and on

small asteroids including (951) Gaspra (*Veverka et al.*, 1994), (243) Ida (*Sullivan et al.*, 1996), (433) Eros (*Buczkowski et al.*, 2008), and (21) Lutetia (*Thomas et al.*, 2012). A large fraction of Phobos' grooves fall into at least four parallel sets, whose normals are close to the plane defined by the long and short axes of Phobos (*Thomas et al.*, 1979; *Murray et al.*, 1994). Some grooves cut other grooves, and many cut crater rims, including Stickney's. They traverse a wide range of angles with respect to local slope directions. Many have a pitted appearance, although some have straight rims with no apparent pitting. Many are "shoulder-to-shoulder." Raised rims appear to bound some grooves, although the shoulder-to-shoulder groove spacing in some places and subtle reflectance variations make rim topography difficult to characterize. Interior slopes are typically well below angles of repose. A few wide, shallow grooves are the clearest examples of linear arrays of discrete pits (D grooves of *Thomas et al.*, 1979).

Hypotheses for the origin of the grooves include secondary cratering from Phobos impacts (*Veverka and Duxbury*, 1977; *Head and Cintala*, 1979), secondary cratering from Mars impacts (*Murray et al.*, 1994, 2014), cratering from debris in Mars orbit (*Schultz and Crawford*, 1989; *Kikuchi and Miyamoto*, 2014), tracks formed by rolling ejecta blocks (*Wilson and Head*, 2005; *Duxbury*, 2011; *Hamelin*, 2011; *Ramsley and Head*, 2013b), and fractures of the body of Phobos into which regolith has drained or from which regolith has been ejected by degassing of water from the interior (*Thomas et al.*, 1979; *Weidenschilling*, 1979; *Horstman and Melosh*, 1989). The grooves show a variety of morphologies, which could be evidence that their formation involved more than a single mechanism. The range of groove morphologies observed in different materials and dynamical environments of asteroids and icy satellites (*Buczkowski et al.*, 2008; *Morrison et al.*, 2009; *Thomas et al.*, 2012) suggests that multiple formation mechanisms act throughout the solar system. One common feature in all models of groove formation, however, is a requirement for loose regolith, to tens of meters in depth, where grooves occur.

None of the hypotheses for groove formation is overwhelmingly supported for all of Phobos' grooves by existing observations. Secondary cratering from Mars theoretically could explain some grooves' alignments (*Murray et al.*, 1994), but the close spacing of the grooves, the even spacing of similarly sized pits along the grooves, and the large area of coverage by grooves cannot obviously be explained by secondary cratering from impacts many thousands of kilometers away (*Ramsley and Head*, 2013b). A few distinct, wide grooves do have morphologies consistent with secondary crater chains, and have orientations that match predicted ejecta patterns from Stickney (*Thomas*, 1998), but most grooves do not. Impacts from debris in orbit about Mars might be consistent with some patterns (*Schultz and Crawford*, 1989; *Kikuchi and Miyamoto*, 2014), but this hypothesis is not well developed theoretically. Rolling ejecta blocks can form somewhat similar aligned markings, but there is no explanation for the consistent parallel patterns of grooves instead of meandering paths deflected

by topography that are typical of lunar boulder tracks, or for the paths traversing all slope angles [especially apparent east of Stickney; see Fig. 10 of Thomas (1998)]. Some grooves, especially those crossing the northern polar region, have morphologies (straight walls, nearly constant widths) suggestive of graben, as do some grooves on saturnian satellites with similar body-related patterns (Morrison et al., 2009). Other grooves consist of regularly spaced chains of similarly-sized pits consistent with drainage of loose regolith into underlying fractures (Horstman and Melosh, 1989). Tidal stretching has been a favored source of stress to generate fractures underlying grooves (Soter and Harris, 1977; Weidenschilling, 1979; Morrison et al., 2009). Mechanical modeling based on the real shape of Phobos and on a layered or gradational regolith is needed to test a possible origin by fracturing.

## 2.7. Surface and Orbital Environment

The surface environments of Phobos and Deimos are strongly affected by their location in Mars orbit. At the surface, at noon near the subsolar point, surface temperature may exceed 350 K at perihelion, but only reach 270 K when Mars is at aphelion (Giuranna et al., 2011). Modeling predicts that nighttime surface temperature depends on latitude and season, typically cooling to 100 K before dawn, although temperatures during polar night may reach 60 K. The diurnal thermal wave penetrates to less than 1 cm, and at depth the average temperature is near 230 K (Kuhrt and Giese, 1989). Unlike the Moon and Mercury, Phobos and Deimos do not have polar craters that are permanently shadowed and  $\leq 100$  K in temperature over geologic time. On geologic timescales, Mars' obliquity is chaotic, ranging between  $0^\circ$  and  $60^\circ$  (Laskar and Robutel, 1993). For the moons' low orbital inclinations to Mars' equator, orbit inclination reckoned from Mars' equator of date is subject only to small variations — in other words, as Mars' obliquity varies, the moons' orbits track the equator (Gurfil et al., 2007). Thus, presently cold polar regions were subjected to prolonged heating by insolation in the past (Laskar et al., 2004). This history also affects the moons' ability to have retained internal ice that has been hypothesized to have been present at the moons' formation (e.g., Rosenblatt, 2011): At all latitudes, any initial pore-filling ice will have ablated to a depth of between hundreds of meters to over 3 km, depending on typical pore size (Fanale and Salvail, 1989).

The regolith environment may be even more exotic, with the moons predicted by theory to reside in a "dust belt" (Soter, 1971). No direct measurement provides confirmation that such a belt exists, so the details of dust belt density and morphology are based on models. Observations by the Hubble Space Telescope place upper limits on the optical depths (Showalter et al., 2006). Modeling predicts that much of the ejecta from small impacts on the moons will exceed the escape velocity of either moon and remain in Mars orbit. Larger particles will follow Keplerian trajectories and eventually reimpact the parent moon, whereas the orbits of

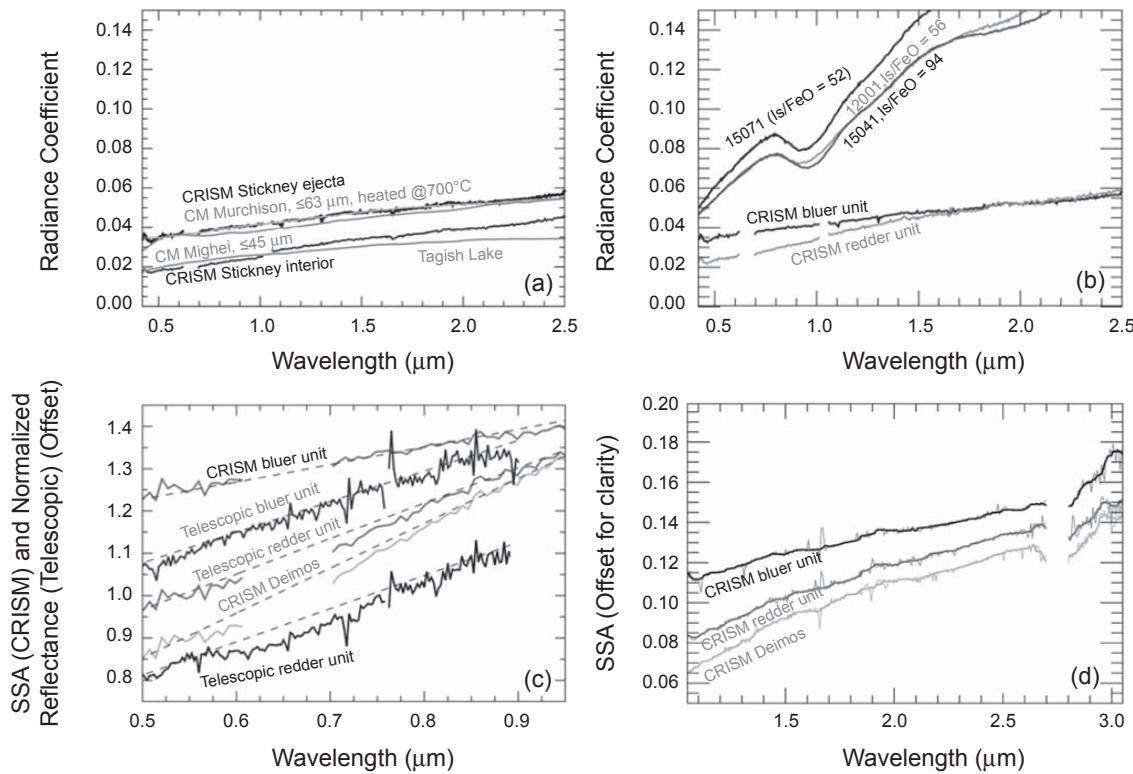

smaller particles will be perturbed by solar radiation pressure, and become asymmetric about Mars. Small particles originating from Phobos are perturbed toward the Sun, and those originating from Deimos are perturbed away from the Sun. In addition, grains from Deimos will oscillate about size-dependent Laplace planes, creating a vertically asymmetric ring. For the Deimos ring, interaction between the two asymmetries gives rise to a time-dependent structure that varies with martian season. The smaller particles eventually either impact Mars or are lost from the Mars system (Horanyi et al., 1990, 1991; Kholshevnikov et al., 1993; Juhasz and Horanyi, 1995; Sasaki, 1996; Hamilton, 1996; Krivov and Hamilton, 1997; Makuch et al., 2005; Krivov et al., 2006; Zakharov et al., 2014).

## 3. COMPOSITION, ORIGIN, AND ORBITAL EVOLUTION

The compositions of Phobos and Deimos are interesting in themselves, but more importantly, they help to constrain the moons' origins. At the present time, remote measurements can provide two major constraints on the moons' composition, their overall reflectance and spectral continuum, and the presence of absorption or emission features diagnostic of particular minerals.

### 3.1. Constraints from Reflectance

Comparisons of the visible to near-infrared reflectances of Phobos and Deimos with analog materials have been hampered over the years by comparison of dissimilar quantities, e.g., geometric albedo and bidirectional reflectance measured in the laboratory, or single-wavelength measures of reflectance that do not include an assessment of the spectral continuum. Mars Express/OMEGA and MRO/CRISM observations have overcome these challenges because they cover hundreds of wavelengths, and the OMEGA data cover a range of geometries that allows derivation of an accurate photometric correction to the geometry at which analog materials are commonly observed in the laboratory, i.e., incidence angle  $i = 30^\circ$ , emergence angle  $e = 0^\circ$ , and phase angle  $\alpha = 30^\circ$  (Framan et al., 2012). Figures 4a,b compare corrected spectral reflectance of Phobos to examples of the two broad classes of proposed composition, carbon-rich materials exemplified by low-grade carbonaceous chondrites, and space-weathered mafic assemblages exemplified by mature lunar mare soils. Reflectance and spectral slope are closely comparable to low-grade, carbon-rich CI and CM carbonaceous chondrites, and are particularly well matched by samples of the CM chondrite Murchison that have been heated by laser pulses to simulate the effects of space weathering (Hiroi et al., 2003). Pajola et al. (2013) were able to model the spectrum of the redder unit by adding a component of Mg-rich glass to the Tagish Lake ungrouped, phyllosilicate-rich carbonaceous chondrite. In contrast with the close match in reflectance and spectral slope with primitive carbonaceous materials, Phobos and Deimos are a factor of 2 darker than even the most space-weathered

**Fig. 4.** CRISM spectral reflectance measurements of Phobos and Deimos. Uncertainty in the data is typically  $\pm 1\%$  near  $0.7\text{ }\mu\text{m}$  and  $\pm 3\%$  near  $3\text{ }\mu\text{m}$  (Fraeman et al., 2014). (a) Reflectance of bluer unit corrected to  $i = 30^\circ$ ,  $e = 0^\circ$ ,  $\alpha = 30^\circ$  compared with meteorite analogs measured at the same geometry. Stickney ejecta and heated Murchison overplot each other. Adapted from Fraeman et al. (2012). (b) Redder and bluer units compared with mature lunar mare soils. Is/FeO is magnetic susceptibility divided by Fe content expressed as FeO, and is proportional to the extent of space weathering. Adapted from Fraeman et al. (2012). (c) CRISM spectra of redder and bluer units covering the  $0.65\text{-}\mu\text{m}$  feature, compared with telescopic spectra that reproduce the absorption. Adapted from Fraeman et al. (2014). (d) Spectra corrected for thermal emission extending to  $3.1\text{ }\mu\text{m}$ , showing the  $2.8\text{-}\mu\text{m}$  OH absorption. Adapted from Fraeman et al. (2014).

lunar mare soils, making space-weathered Mars crustal material unsuitable as a spectral analog despite the similarity in spectral continuum slope. Phobos and Deimos are also much darker, and much redder, than shock-darkened ordinary chondrites, which have been suggested as compositional analogs to several low-reflectance planetary surfaces (Britt and Pieters, 1988; Gillis-Davis et al., 2013).

### 3.2. Constraints from Spectral Features

Constraining the compositions of Phobos and Deimos from weak mineral spectral signatures requires accurate calibration of remote spectral measurements, confirmation of the mineral signatures in multiple datasets, and determining the diagnostic character of the signatures. In ISM spectra taken from Phobos 2, upward curvature in the  $1\text{-}\mu\text{m}$  region in a ratio spectrum of bluer to redder material resembles an absorption due to olivine or possibly pyroxene. Such a feature would be consistent with less-red material having experienced less lunar-like space weathering and having a stronger mineral signature (Murchie and Erard,

1996; Gendrin et al., 2005). Disk-integrated observations of the moons acquired from Mars' surface by the Imager for Mars Pathfinder showed no evidence for the  $1\text{-}\mu\text{m}$  feature, and indicated instead a broad, shallow feature near  $0.7\text{ }\mu\text{m}$  (Murchie et al., 1999) comparable to that seen in some low-albedo asteroid spectra (Vilas et al., 1994). Subsequent OMEGA and CRISM data do not reproduce detection of a  $1\text{-}\mu\text{m}$  absorption due to olivine or pyroxene (Fraeman et al., 2012, 2014) or detect a feature due to  $\text{H}_2\text{O}$  at  $3\text{ }\mu\text{m}$  (Fraeman et al., 2012).

However, CRISM data do reveal spectral features in both units (Fraeman et al., 2014). Deimos and the redder unit on Phobos both exhibit a broad, shallow absorption centered near  $0.65\text{ }\mu\text{m}$  — the feature detected earlier in Mars Pathfinder data — but the feature is absent from Phobos' bluer unit. The strength of this feature is highly correlated with visible color observed by HiRISE and CRISM. The  $0.65\text{-}\mu\text{m}$  absorption is reproduced in telescopic spectra dominated by the redder unit, but absent in telescopic spectra dominated by the bluer unit (Fig. 4c). Both units also exhibit a sharp absorption near  $2.8\text{ }\mu\text{m}$  (Fig. 4d) attributable to OH (Clark

*et al.*, 1990); the feature is strongest on Deimos and weakest in Phobos' bluer unit. Spectrally, Phobos and Deimos belong to the “Pallas group” described in the chapter by Rivkin et al. in this volume. With more complete wavelength coverage, the false detection of olivine from ISM spectra is now recognizable as the artifact of ratioing a bland bluer unit spectrum to a redder unit spectrum with a 0.65- $\mu\text{m}$  absorption having a longer-wavelength shoulder near 1  $\mu\text{m}$ .

One interpretation of these absorptions, consistent with the reflectance and spectral slope characteristics described in section 3.1, is a composition rich in phyllosilicate that has been desiccated of molecular  $\text{H}_2\text{O}$ . In particular, phyllosilicate-rich CM carbonaceous chondrites exhibit an OH feature like that observed at 2.8  $\mu\text{m}$  as well as an absorption due to Fe in phyllosilicate near 0.7  $\mu\text{m}$  (*Cloutis et al.*, 2011; *Takir et al.*, 2013; see also the chapter by Rivkin et al. in this volume). Phobos' and Deimos' Fe feature is centered closer to 0.65  $\mu\text{m}$ , possibly suggesting a different desiccated phyllosilicate, such as Fe-bearing nontronite (*Fraeman et al.*, 2014). That interpretation would be consistent with an origin of the moons that includes primitive material. However, alternate interpretations involving anhydrous minerals consistent with other proposed origins cannot be entirely excluded. Curvature in the spectrum near 0.65  $\mu\text{m}$  might result from Rayleigh scattering by a mixture of microphase and nanophase Fe in the right proportion that is formed by space-weathering processes (*Clark et al.*, 2012). The OH feature near 2.8  $\mu\text{m}$  is similar in its reflectance minimum to an OH feature observed on the Moon (*Clark*, 2009; *Peters et al.*, 2009; *Sunshine et al.*, 2009) and attributed to anhydrous reaction of implanted solar wind protons with oxygen in silicate minerals (*McCord et al.*, 2011), although the lunar feature is considerably broader than that observed on Phobos, Pallas, or CM meteorites.

Thermal infrared spectra complement the mineral detection capabilities of visible to near-infrared spectra. However, their analysis is complicated by the need to ratio to a blackbody spectrum, and the fact that Phobos' and Deimos' thermal emissions are not well fit by an ideal blackbody (*Lynch et al.*, 2007). *Giuranna et al.* (2011) calculated emissivity spectra from TES and PFS data whose footprints cover large segments of Phobos, assuming an areal mixture of blackbody spectra representing three different surface temperatures (shaded surfaces, low and high thermal inertia solar-illuminated surfaces). Selected regions exhibit apparent emissivity features consistent with phyllosilicate, although features in other spectra resemble those due to feldspathoid minerals. *Giuranna et al.* favored the feldspathoid interpretation, and a composition of highly evolved Mars crustal material. Difficulties in this interpretation include the lack of feldspathoid-rich meteorite analogs, the dominance of basaltic compositions in Mars' crust (*McSween et al.*, 2009), the lack of detection of feldspathoids on Mars despite detection of over 30 other minerals (*Viviano-Beck et al.*, 2014), and the possibility of artifacts from assuming a mixture of surfaces with discrete temperatures. More recently, using TES data, *Glotch et al.* (2015) modeled thermal emissivity

from TES data covering the redder unit using a surface with many different temperatures. They find evidence for bound molecular water and carbonate, which if correct would be diagnostic of primitive carbonaceous compositions, and for silicate consistent with the desiccated phyllosilicate inferred from visible to near-infrared reflectance.

Regardless of precise compositions, the contrast in spectral properties between the bluer and redder units provides information on three-dimensional structure within Phobos. Inside Stickney, either redder or bluer material is exposed in different locations (*Thomas et al.*, 2011). The heterogeneity inside Stickney led *Basilevsky et al.* (2014) to suggest that at depth Phobos consists of a rubble of discrete bluer and redder blocks as proposed by *Murchie et al.* (1991). Alternatively, the interior may be relatively coherent as suggested by average density if a CM-chondrite-like composition is assumed (section 3.4), with the bluer material that is relatively “pristine” chemically having zones and pockets of hydration into redder material richer in phyllosilicates, which exhibit 0.65- $\mu\text{m}$  and 2.8- $\mu\text{m}$  absorptions.

### 3.3. Comparison with D-Type and Related Asteroids

The spectra of martian satellites are consistent with low-reflectance, outer-belt D-class asteroids, which also dominate the Trojan asteroid region. This similarity was first noted for Deimos by *Grundy and Fink* (1992), and for Phobos by *Murchie and Erard* (1996), who found that most of Phobos' surface has a spectrum similar to that of Deimos, although the area near Stickney has a flatter spectral slope. *Rivkin et al.* (2002) combined 1.65–3.5- $\mu\text{m}$  spectra from the Infrared Telescope Facility (IRTF) with shorter-wavelength Phobos 2 data, and interpreted D-class asteroids to best match Deimos and Phobos' redder unit, whereas Phobos' bluer unit is more similar to P- or T-class asteroids.

The weak absorptions observed on Phobos and Deimos are also consistent with those observed on low-reflectance asteroids. Absorptions near 0.7  $\mu\text{m}$  on low-reflectance asteroids have been attributed to Fe-bearing phyllosilicates, which are usually accompanied by absorptions due to OH or  $\text{H}_2\text{O}$  near 3  $\mu\text{m}$  (*Vilas and Gaffey*, 1989; *Vilas et al.*, 1993; *Vilas*, 1994; *Rivkin et al.*, 2002). Mineralogical interpretations for the asteroids most similar to Phobos and Deimos having absorptions near 0.65  $\mu\text{m}$  without an accompanying feature near 0.9  $\mu\text{m}$  remain uncertain (*Jarvis et al.*, 1993; *Vilas et al.*, 1994). Many low-reflectance asteroids also display an absorption centered near 2.8  $\mu\text{m}$ , and these features can be grouped qualitatively into three classes (see the chapter by Rivkin et al. in this volume): (1) Ceres-type, with symmetric absorption minima near 3.0 and 3.3  $\mu\text{m}$ , possibly attributable to brucite (*Milliken and Rivkin*, 2009); (2) Themis-type, with an absorption minimum near 3.1  $\mu\text{m}$  attributable to water frost (*Rivkin and Emery*, 2010; *Campins et al.*, 2010); and (2) Pallas-type, having a checkmark-shaped absorption with a minimum near 2.8  $\mu\text{m}$  attributable to OH-bearing phases (*Rivkin et al.*, 2011). Phobos' and Deimos' features group with those of the (2) Pallas class.

### 3.4. Implications for Internal Structure

Given a compositional determination for either Phobos or Deimos, and a measurement of the moon's average density, the approximate internal structure of the moon can be inferred. As the extent of fracturing of an asteroidal body increases and its mechanical coherence decreases, internal structure transitions through four classes described by *Wilkison et al.* (2002) and *Britt et al.* (2002): coherent, with minimal macroporosity; fractured but mechanically coherent, with up to 20% macroporosity; heavily fractured, with 20–30% macroporosity; and loosely consolidated or rubble pile, with  $\geq 30\%$  macroporosity. For small bodies whose internal pressures are smaller than the mechanical strength of the constituent materials, additional porosity (microporosity) occurs as pores or microfractures between individual mineral grains within mechanically coherent chunks. The macroporosity is needed to infer interior structure. [Definitions of density and porosity of meteorites and asteroids used here follow those of *Britt and Consolmagno* (2003) and *Consolmagno et al.* (2008). Grain density is defined as the density of the solid phase of a meteoritic or asteroidal material, excluding voids. Bulk density is the density of a porous meteoritic material, and differs from grain density due to the presence of pores and microfractures between grains. Macroporosity is the volume percent of an asteroidal body occupied by fractures between mechanically coherent chunks, not including pores between grains within those chunks (microporosity). Total porosity of an asteroidal body is the sum of macroporosity and microporosity.]

Inferred internal structures inferred for Phobos and Deimos depend strongly on the composition assumed. CM meteorites, arguably the closest spectral analog to the moons, have a bulk density (including pores and microfractures) of  $2250 \pm 80 \text{ kg m}^{-3}$ , and a grain density (for the solid phase only) of  $2900 \pm 80 \text{ kg m}^{-3}$  (*Consolmagno et al.*, 2008). Using this CM bulk density, *Murchie et al.* (2013) calculated a macroporosity for Phobos of  $17 \pm 4\%$ , placing it in the fractured but coherent category, and a macroporosity for Deimos of  $34 \pm 11\%$ , consistent with a rubble pile. A more porous structure for Deimos would be consistent with its south polar concavity having originated from an impact that partially shattered the moon, followed by reaccretion of the fragments to explain the smooth surface (*Thomas*, 1996). The derived macroporosity for Deimos is comparable with typical values for fragmental lunar mare regolith at tens of centimeters to meter depth, 35–38% (*Mitchell et al.*, 1972), where overburden pressure is comparable to that in the martian moon interiors. *Andert et al.* (2010) used a slightly lower grain density to estimate a total porosity for Phobos of  $30 \pm 5\%$ . Andert et al. equated this result with a loosely consolidated interior, but that interpretation did not allow for partitioning of total porosity into microporosity and macroporosity, only the latter of which is relevant for internal structure.

*Rosenblatt* (2011) considered what macroporosities would correspond with differing compositional interpretations of

existing spectral measurements. For example, if the moons are dominated by Mars crustal material (*Craddock*, 2011; *Giuranna et al.*, 2011) or shock-darkened ordinary chondrite (*Britt and Pieters*, 1988), macroporosity for Phobos could be in the range of 25–47% and for Deimos in the range 41–58%. Rosenblatt speculated that the higher porosities would be unrealistic and require portions of the void spaces to be filled by water ice. However, an explanation for the geochemically unexpected combination of anhydrous silicates with a large fraction of ice — two components expected to have condensed in different parts of the solar system — was not proposed.

Interpretation of geologic surface features on the martian moons, and in particular the grooves on Phobos, also has the potential to provide insights into internal structure. The formation mechanisms for Phobos' grooves are actively debated, as discussed in section 2.6. Models that invoke extensive fracturing, if correct, would indicate mechanical coherence consistent with that implied by a CM-chondrite-like composition. In contrast, continuous fracturing over kilometers would be inconsistent with the rubble-pile structure required by mafic or ordinary chondritic compositions.

### 3.5. Orbital Evolution and Formation Mechanisms

Any hypothesis for the origin of Phobos and Deimos must be consistent with the dynamics of the moons' orbital evolution. Reconciling empirical observations of the moons' properties with predictions of orbital dynamical models has proven challenging. A primitive carbonaceous composition, if that interpretation is correct, could have resulted from formation in the solar nebula at heliocentric distances beyond Mars' orbit (*Pollack et al.*, 1978), migration toward the inner solar system as proposed by some dynamical models [namely the Nice model (*Tsiganis et al.*, 2005; *Gomes et al.*, 2005)], and capture into Mars orbit. Capture requires special circumstances such as drag from an extended protoatmosphere (*Hunten*, 1979; *Pollack et al.*, 1979; *Sasaki*, 1990).

Circularizing an initially eccentric orbit after capture, and reducing orbital inclination to the present near-equatorial orbit, can be achieved by tidal processes in the case of Phobos over the last 4.6 G.y. However, this requires a high tidal dissipation rate that is difficult to reconcile with a largely coherent Phobos. Instead, the interior would need to be highly fragmented, or have a substantial fraction of ice to increase the tidal dissipation rate (*Lambeck*, 1979; *Mignard*, 1981; *Rosenblatt*, 2011; *McCarthy and Castillo-Rogez*, 2011). In the case of Deimos, tidally induced orbital changes are probably too slow to account for evolution of an eccentric, inclined orbit over the last 4.6 G.y. (*Lambeck*, 1979; *Szeto*, 1983), unless there was enhanced tidal dissipation due to internal ice (*Rosenblatt*, 2011). Alternatively, drag in the protoatmosphere, particularly efficient in circularizing an orbit, may have played a role. This scenario requires a very early capture, a suitable density of the protoatmosphere to prevent the captured asteroid from impacting Mars (*Sasaki*, 1990), and an extent of the protoatmosphere beyond the current orbit of Deimos.

The moons' present orbits are thought to have evolved considerably once in the equatorial plane. Because Phobos orbits inside a synchronous orbit, it exhibits acceleration along its orbit resulting from the solid body tides raised by Phobos in Mars (e.g., Burns, 1992), by about  $1.27 \times 10^{-3}$  deg yr $^{-2}$  (Lainey et al., 2007; Jacobson, 2010). Phobos' orbit thus decays by about 20 cm yr $^{-1}$ . Former moons orbiting well inside Phobos already will have impacted Mars. The interpretation of elongated martian impact craters being formed by obliquely impacting former moons is debated (Schultz and Luz-Garihan, 1982; Bottke et al., 2000; Chappelow and Herrick, 2008). The same mechanism is expected to cause Deimos' orbit to recede away from Mars, because Deimos orbits beyond a synchronous orbit. When Phobos' and Deimos' orbits are integrated backward in time, inevitably the moons must once have been in close proximity, raising the possibility that they both formed near a synchronous orbit (Rosenblatt and Charnoz, 2012), or even are fragments of a single captured object (Singer, 2007; Rosenblatt, 2011).

Formation of Phobos and Deimos in orbit around Mars avoids the challenges of explaining the orbital evolution of captured objects. Phobos and Deimos could have coaccreted with Mars (Safronov et al., 1986), which would account for the current near-equatorial and near-circular orbits of both moons. However, this hypothesis implies that Phobos and Deimos would have ordinary-chondrite-like or bulk-Mars-like compositions, which is hard to reconcile with their low densities and spectral properties. One hypothesis that may be reconcilable with many observed properties of the moons is that they formed from a hot, circumplanetary accretion disk formed by the impact of a large carbonaceous body on Mars (Craddock, 2011; Rosenblatt and Charnoz, 2012; Canup and Salmon, 2014). Crater scaling relations identify the Daedalia, Chryse, and newly recognized Borealis (Andrews-Hanna et al., 2008) basins on Mars as the most plausible records of that impact (Craddock, 2011). The 4.3-Ga estimated crater age of the Borealis basin (Frey, 2010) agrees with the observed crater density on Phobos (Sche medemann et al., 2014). Material from the impactor could have dominated the accretion disk. Even if a carbonaceous impactor caused the moons' low reflectances, heating of the material should have driven off molecular water, explaining the lack of a strong 3-μm absorption at present (Craddock, 2011). Rosenblatt and Charnoz (2012) examined several different scenarios for satellite formation from such an accretion disk, in a strong-tide regime close to the Roche limit and in a weak-tide regime further out. They concluded that formation in a strong-tide regime would have formed bodies whose dynamic lifetime against reimpact on Mars is much less than the moons' age, so that such a mechanism cannot have formed the moons. In contrast, formation in a weak-tide regime between the Roche limit and synchronous orbit may have been capable of forming the satellites. They suggested that Phobos and Deimos may be the last two remnants of such bodies formed near the synchronous distance to Mars, other now extinct moons having since impacted Mars.

#### 4. OUTSTANDING QUESTIONS FOR FUTURE STUDY

After Mars Express, four key uncertainties remain about Phobos and Deimos for which resolution is required to answer high-level science questions. First, what are the moons' compositions, and how does that constrain the moons' origins? Some remote measurements are highly suggestive of a CM-carbonaceous-chondrite-like composition, but alternative interpretations of the moons' low reflectance and weak spectral features cannot be ruled out based on existing data. Sample return answers this question definitively using major and minor elements and isotopes to link the moons to particular reservoirs. Short of sample return, future remote or *in situ* spacecraft measurements could also provide key compositional information to address the fundamental question of the moons' origins. As shown in Table 2, a diagnostic set of measurements would be elemental abundances, particularly measurements that would constrain abundances of H, C, S, and major and minor elements exhibiting a range of volatilities (e.g., Zn, Mn, and Al). Another diagnostic measurement set would be of mineralogy with a focus on phases whose abundances differ greatly between proposed compositions, particularly olivine, pyroxene, phyllosilicate, and carbonate. The ambiguity of detection of these phases in existing measurements suggests that new measurements should include fresh, non-space-weathered surfaces, or should resolve single mineral grains to enhance spectral signatures of minor phases. The presence of molecular water, hydroxylated minerals, or subsurface ice is a critical test of models of the moons' formation: A high content of water or hydroxyl in minerals (or water-equivalent H) is consistent with capture of a primitive body, but is probably inconsistent with formation *in situ*. For *in situ* formation, either the source material was low-water (ordinary chondrite, martian crust) or it accreted from a circumplanetary disk from which water was baked out.

Second, what is the relationship of Phobos to Deimos? In part this depends on their origins — if formed in Mars orbit, they are related, but if captured, they could be either unrelated or fragments of a single body that was disrupted during capture (Singer, 2007; Rosenblatt, 2011). In addition, the moons' closer proximity earlier in their history and regolith exchange between the moons via the hypothesized dust belts raises the possibility that Phobos' redder unit could be derived from Deimos. Testing these hypotheses requires modeling as well as compositional measurements of both moons.

Third, what is the moons' deep structure and could there be deep water ice? The two most important new groups of measurements would be composition of both moons to estimate internal macroporosity, and volume of Deimos to reduce the uncertainty in its average density. Higher-degree gravity coefficients for both moons would also be useful. Given the likelihood that any internal ice has ablated to a depth of 1 km or greater, near-surface detection of it by shallow radar sounding may not be feasible. Alternatively, heterogeneity in the filling of deep pores by water ice may be detectable by measuring the amplitude of Phobos' forced

libration and the second-order coefficients of the nonspherical part of the gravity field (Rosenblatt, 2011). Measurement of the forced libration can also be used to test for enhanced macroporosity beneath Stickney due to impact fracturing (Rambaux et al., 2012; LeMaistre et al., 2013).

Fourth, what is the origin of the grooves on Phobos? The global distribution, orientation, and stratigraphic relations of grooves is now relatively well known, but implications of these observables for models of groove origin remain debatable (Ramsley and Head, 2013b; Murray and Heggie, 2014). Given the widespread occurrence of somewhat similar, but varied features on asteroids and on small icy bodies, understanding the way or ways in which grooves form is important for interpreting the evolution of small bodies across the solar system. New tests for models of groove origin may be obtained using high-resolution, meter-scale measurements of groove topography and color. Various models make different predictions about topography of groove rims and floors, and about stratigraphic relations of groove floor and rim materials. Seismic measurements across grooves could determine whether they are surface expressions of fractures at depth.

Many key outstanding scientific questions about the martian moons may be solved by future robotic missions, even before ultimate human exploration of these destinations.

---

Asteroids and meteorites provide key evidence on the formation of planetesimals in the solar system. Asteroids are traditionally thought to form in a bottom-up process by coagulation within a population of initially kilometer-scale planetesimals. However, new models challenge this idea by demonstrating that asteroids of sizes from 100 to 1000 km can form directly from the gravitational collapse of small particles that have organized themselves in dense filaments and clusters in the turbulent gas. Particles concentrate passively between eddies down to the smallest scales of the turbulent gas flow and inside large-scale pressure bumps and vortices. The streaming instability causes particles to take an active role in the concentration, by piling up in dense filaments whose friction on the gas reduces the radial drift compared to that of isolated particles. In this chapter we review new paradigms for asteroid formation and critically compare them against the observed properties of asteroids as well as constraints from meteorites. Chondrules of typical sizes from 0.1 to 1 mm are ubiquitous in primitive meteorites and likely represent the primary building blocks of asteroids. Chondrule-sized particles are nevertheless tightly coupled to the gas via friction and are therefore hard to concentrate in large amounts in the turbulent gas. We review recent progress on understanding the incorporation of chondrules into the asteroids, including layered accretion models where chondrules are accreted onto asteroids over millions of years. We highlight in the end 10 unsolved questions in asteroid formation where we expect that progress will be made over the next decade.

## 1. INTRODUCTION

The solar system contains large populations of pristine planetesimals that have remained relatively unchanged since their formation. Our proximity to the asteroid belt provides astronomers, planetary scientists, and cosmochemists access to extremely detailed data about asteroid compositions, sizes, and dynamics. Planetesimals are the building blocks of both terrestrial planets and the cores of the giant planets, as well as the super-Earths (with various degrees of gaseous envelopes) that are now known to orbit around a high fraction of solar-type stars (Fressin *et al.*, 2013). The formation of planetesimals is thus a key step toward the assembly of planetary systems, but many aspects of the planetesimal formation process remain obscure.

Recent progress in understanding planetesimal formation was triggered by two important realizations. The first is that macroscopic dust particles (millimeter or larger) have poor sticking properties. Laboratory experiments and coagulation models show that it is difficult to form planetesimals by direct sticking of silicate particles, most importantly because particle growth stalls at millimeter sizes where the particles bounce off each other rather than stick (Güttler *et al.*, 2010). While some particle growth is still possible at relatively high collision speeds, due to the net transfer of mass from small impactors onto large targets (Wurm *et al.*, 2005; Windmark *et al.*, 2012a), the resulting growth rate is too low to compete with the radial drift of the particles.

The second important realization is that particles are concentrated to very high densities in the turbulent gas flow.

This idea is not new — *Whipple* (1972) already proposed that large-scale pressure bumps can trap particles, as their radial drift speed vanishes in the pressure bump where the radial pressure gradient is zero. However, the advent of supercomputing led to the discovery and exploration of a large number of particle concentration mechanisms. Large-scale axisymmetric pressure bumps, akin to those envisioned by *Whipple* (1972), have been shown to arise spontaneously in simulations of protoplanetary disk turbulence driven by the magnetorotational instability (*Johansen et al.*, 2009a; *Simon et al.*, 2012). Particle densities reach high enough values inside these pressure bumps to trigger gravitational collapse to form planetesimals with sizes up to several 1000 km (*Johansen et al.*, 2007, 2011; *Kato et al.*, 2012). The baroclinic instability, which operates in the absence of coupling between gas and magnetic field, leads to the formation of slowly overturning large-scale vortices (*Klahr and Bodenheimer*, 2003), which can act as dust traps in a similar way as pressure bumps (*Barge and Sommeria*, 1995).

In the streaming instability scenario the particles play an active role in the concentration (*Youdin and Goodman*, 2005). The relative motion between gas and particles is subject to a linear instability whereby axisymmetric filaments of a slightly increased particle density accelerate the gas toward the Keplerian speed and hence experience reduced radial drift. This leads to a runaway pileup of fast-drifting, isolated particles in these filaments (*Johansen and Youdin*, 2007). The densities achieved can be as high as 10,000× the local gas density (*Bai and Stone*, 2010; *Johansen et al.*, 2012), leading to the formation of planetesimals with characteristic diameters of 100–200 km for particle column densities relevant for the asteroid belt, on a timescale of just a few local orbital periods.

A concern about large-scale particle concentration models is that typically very large particles are needed for optimal concentration (at least decimeter in size when the models are applied to the asteroid belt). Chondrules of typical sizes from 0.1 to 1 mm are ubiquitous in primitive meteorites, but such small particles are very hard to concentrate in vortices and pressure bumps or through the streaming instability. One line of particle concentration models has nevertheless been successful in concentrating chondrules. Swiftly rotating low-pressure vortex tubes expel particles with short friction times (*Squires and Eaton*, 1990, 1991; *Wang and Maxey*, 1993). This was proposed to explain the characteristic sizes and narrow size ranges of chondrules observed in different chondrites (*Cuzzi et al.*, 2001) and leads to the formation of 100-km-scale asteroids from rare high-density concentrations (*Cuzzi et al.*, 2008, 2010). However, the evaluation of the probability for such high-density concentrations to occur over sufficiently large scales depends on scaling computer simulations to the very large separations between the energy injection scale and the dissipation scale relevant for protoplanetary disks; *Pan et al.* (2011) found that the particle clustering gets less contribution from the addition of consecutively larger scales than originally thought in the model of *Cuzzi et al.* (2008, 2010).

Therefore the incorporation of chondrules into the asteroids is still an unsolved problem in asteroid formation. This is one of the main motivations for this review. We refer the readers to several other recent reviews on the formation of planetesimals that provide a broader scope of the topic beyond asteroid formation (e.g., *Cuzzi and Weidenschilling*, 2006; *Chiang and Youdin*, 2010; *Johansen et al.*, 2014).

The review is organized as follows. The first two sections discuss the constraints on asteroid formation from the study of meteorites (section 2) and asteroids (section 3). In section 4 we review laboratory experiments and computer simulations of dust coagulation to illustrate the formidable barriers that exist to planetesimal formation by direct sticking. The turbulent concentration model, in which chondrule-sized particles are concentrated at the smallest scales of the turbulent gas flow, is discussed in section 5. Section 6 is devoted to particle concentration in large-scale pressure bumps and through streaming instabilities. In section 7 we discuss layered accretion models where the chondrules are accreted onto planetesimals over millions of years. Finally, in section 8 we pose 10 open questions regarding the formation of asteroids on which we expect major progress in the next decade.

## 2. CONSTRAINTS FROM METEORITES

Meteorites provide a direct view of the solid material from which the asteroids accumulated, while the crystallization ages of the component particles and the degree of heating and differentiation of the parent bodies give important information about the timescales for planetesimal formation in the solar system.

Meteorites may be broadly classified in two categories (*Weisberg et al.*, 2006): primitive meteorites (also known as chondrites) and differentiated meteorites. Chondrites, which make up 85% of the observed falls, are basically collections of millimeter- and submillimeter-sized solids, little modified since agglomeration and lithification (compression) in their parent bodies. They exhibit nonvolatile element abundances comparable to the solar photosphere's (*Palme and Jones*, 2005). Differentiated meteorites derive from parent bodies that underwent significant chemical fractionations on the scale of the parent body, resulting in the asteroid-wide segregation of an iron core and silicate mantle and crust. In the process, differentiated meteorites have lost not only their accretionary (presumably chondritic) texture, but also their primitive chemical composition; depending on which part of the parent body they sample, some may be essentially pure metal (the iron meteorites) while others are essentially metal-free (the achondrites).

It is among the components of chondrites that the oldest solids of the solar system, the refractory inclusions (*Krot et al.*, 2004; *MacPherson*, 2005), in particular calcium-aluminium-rich inclusions (CAIs), have been identified. Their age of  $4567.3 \pm 0.16$  m.y. (*Connelly et al.*, 2012) marks the commonly accepted “time zero” of the solar system. But the ubiquitous components of chondrites are the eponymous

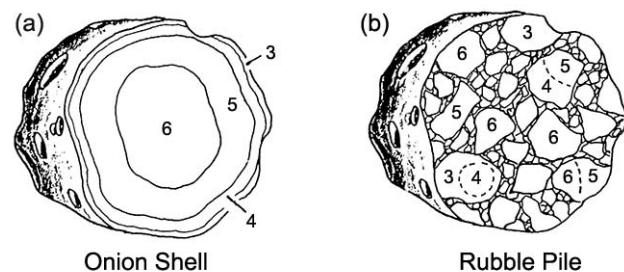

chondrules (*Hewins et al.*, 2005; *Connolly and Desch*, 2004), which are millimeter-sized silicate spherules presumably resulting from transient (and repeated) high-temperature episodes in the disk, but whose very nature remains a longstanding cosmochemical and astrophysical enigma (*Boss*, 1996; *Desch et al.*, 2012). All these components are set in a fine-grained matrix consisting of amorphous and crystalline grains native to the disk as well as rare presolar grains (*Brearley*, 1996). While compositionally primitive, chondrites may have undergone some degree of thermal metamorphism, aqueous alteration, and shock processing on their parent body.

Despite their general petrographic similarity and roughly solar composition, chondrites are actually quite variable, and 14 distinct chemical groups have been recognized so far, each of which is believed to represent a single parent body — sometimes with supporting evidence from cosmic-ray exposure ages (*Eugster et al.*, 2006) — or at least a family of parent bodies formed in the same nebular reservoir (i.e., a compositionally distinctive space-time section of the disk). There are various levels of affinities between these groups (e.g., clans, classes) but we will be content here to distinguish carbonaceous chondrites (henceforth “CCs,” comprising the CI, CM, CO, CV, CK, CR, CH, and CB groups) from noncarbonaceous chondrites [henceforth “EORs,” as they include the enstatite (EH, EL), ordinary (H, L, LL), and Rumuruti (R) chondrite groups]. Carbonaceous chondrites are more primitive in the sense that they have a solar Mg/Si ratio and a  $^{16}\text{O}$ -rich oxygen isotopic composition closer to that of the Sun (e.g., *Scott and Krot*, 2003). Noncarbonaceous chondrites, although poorer in refractory elements, are more depleted in volatile elements, have sub-solar Mg/Si ratios and a more terrestrial isotopic composition for many elements (*Trinquier et al.*, 2009). EORs have generally undergone thermal metamorphism (see Fig. 1), while aqueous alteration has been prevalent in CCs (*Huss et al.*, 2006; *Brearley*, 2003), but again there are exceptions.

## 2.1. Primary Texture and Aerodynamic Sorting

The texture of most chondrites has been reworked by impact fragmentation and erosion on their parent body. However, rare pieces of CM and CO chondrites have been found, referred to as “primary texture” (*Metzler et al.*, 1992; *Brearley*, 1993), which seem to retain the nature of a prebrecciated body. Primary texture appears to consist of nothing but dust-rimmed chondrules of very similar properties, loosely pressed together.

The constituents of most chondrites appear well-sorted by size, with strong mean size differences from one group to another (*Brearley and Jones*, 1998). Whether these differences arise from some regionally or temporally variable bouncing-barrier (*Jacquet*, 2014a), some aerodynamic sorting process (sections 5 and 7), or some aspect of the mysterious chondrule-formation process itself, they provide an important clue to primary accretion. *Hezel et al.* (2008) have emphasized the need for better particle counting statistics, and indeed one recent chondrule size distribution measurement

**Fig. 1.** (a) Initial state of a parent body with a radius of 100 km, which was initially homogeneous throughout, after heating by  $^{26}\text{Al}$ . The proportions of the least (3) to most (6) altered material are constrained by meteorite statistics. (b) The same body after catastrophic fragmentation and reassembly as a rubble pile with some highly altered material now near the surface. This body is then cratered by subsequent impacts, releasing samples of all metamorphic grades (adapted from *Scott and Rajan*, 1981).

taken from Allende, of a far larger sample than analyzed previously (*Fisher et al.*, 2014), points to a distribution substantially broader for that chondrite than previously reported.

Aerodynamic sorting has been suggested often as an important factor in selecting for the contents of primary texture (see *Cuzzi and Weidenschilling*, 2006, for a review). Comparing the aerodynamical friction time of objects of greatly different density, such as silicate and metal grains, shows that their friction times are quite similar in the least-altered meteorites (*Dodd*, 1976; *Kuebler et al.*, 1999), suggesting that asteroids selectively incorporated components with specific aerodynamical properties (we discuss this further in section 3.3).

## 2.2. The Abundance and Distribution of Aluminum-26 and Iron-60

The melting of the parent bodies of differentiated meteorites puts important constraints on the timescale for planetesimal formation in the asteroid belt. While electromagnetic heating (*Sonett and Colburn*, 1968) or impact heating (*Keil et al.*, 1997) have been considered in the literature, the most likely source of planetesimal heating is the decay of the short-lived radionuclides (SLRs)  $^{26}\text{Al}$  (with mean lifetime  $\tau = 1.0$  m.y.) and  $^{60}\text{Fe}$  ( $\tau = 3.7$  m.y.) (*Urey*, 1955). Depending on their respective initial abundance, and on the time of planetesimal accretion, both could have significantly contributed to planetesimal heating. Additionally, short-lived nuclides provide crystallization ages that can be calibrated using a long-lived radionuclide decay system such as Pb-Pb, under the assumption that the short-lived radionuclide was homogeneously distributed in the solar protoplanetary disk.

The content of SLRs in CAIs is usually identified with that of the nascent solar system (*Dauphas and Chaussidon*, 2011). Excesses of  $^{26}\text{Mg}$  linearly correlating with  $^{27}\text{Al}$  content were first observed in an Allende CAI in 1976 (*Lee et al.*,

1976). This isochron diagram demonstrated the presence of  $^{26}\text{Al}$  in the nascent solar system. The CAIs from a diversity of chondrite groups formed with an initial  $(^{26}\text{Al}/^{27}\text{Al})_0$  of roughly  $5 \times 10^{-5}$  (MacPherson *et al.*, 2014). A remarkably tight isochron for CAIs in the CV chondrites was obtained by Jacobsen *et al.* (2008). The deduced  $(^{26}\text{Al}/^{27}\text{Al})_0$  ratio of  $(5.23 \pm 0.13) \times 10^{-5}$  is often considered as the initial value for the solar system and the small dispersion as indicative of a narrow formation interval ( $\leq 40,000$  yr). However, this interpretation should be limited to the region where the unusually large CV CAIs have formed (Krot *et al.*, 2009). This is especially true since many CAIs are known to have formed without any  $^{26}\text{Al}$  (Liu *et al.*, 2012; Makide *et al.*, 2013). This indicates some level of heterogeneity in the  $^{26}\text{Al}$  distribution within the region where CAIs formed (assuming that region was unique, which is supported by the ubiquitous  $^{16}\text{O}$  enrichment of CAIs compared to, e.g., chondrules). Larsen *et al.* (2011) used bulk magnesium isotopic measurements to suggest that the heterogeneity of  $^{26}\text{Al}$  distribution might have reached 80% of the canonical value in the solar protoplanetary disk. However, Kita *et al.* (2013) and Wasserburg *et al.* (2012) argue that the observed variations can be better ascribed to small heterogeneities in the stable isotope  $^{26}\text{Mg}$ .

Although the presence of live  $^{60}\text{Fe}$  in the early solar system was demonstrated almost 20 years ago (Shukolyukov and Lugmair, 1993), the determination of the solar system initial abundance is complicated by the difficulty of obtaining good isochrons for CAIs (Quitté *et al.*, 2007), given their low abundance in Ni. To bypass that difficulty, most measurements were performed on chondrules that are believed to have formed from around the same time as CAIs up to 3 m.y. later (Connelly *et al.*, 2012). High initial  $(^{60}\text{Fe}/^{56}\text{Fe})_0$  ratios were originally reported in chondrules from unequilibrated ordinary chondrites (UOC), which experienced very little heating or aqueous alteration (e.g., Tachibana and Huss, 2003; Mostefaoui *et al.*, 2005; Tachibana *et al.*, 2006). Telus *et al.* (2012) showed that most of these previous data were statistically biased and that most chondrules do not show any Ni excesses indicative of the decay of  $^{60}\text{Fe}$ . The high values obtained in older publications could be due to statistical biases related to low counts (Telus *et al.*, 2012) or to thermal metamorphism, which would have led to the redistribution of Ni isotopes (Chaussidon and Barat, 2009). Recently, improved techniques for measuring bulk chondrules in unequilibrated ordinary chondrites have yielded initial solar system values for  $(^{60}\text{Fe}/^{56}\text{Fe})_0$  of  $\approx 1 \times 10^{-8}$  (Tang and Dauphas, 2012; Chen *et al.*, 2013). This value is consistent with that inferred from Fe-Ni isotope measurements of a diversity of differentiated meteorites (Quitté *et al.*, 2011; Tang and Dauphas, 2012).

In conclusion, it seems that most CAIs formed with an initial ratio  $(^{26}\text{Al}/^{27}\text{Al})_0$  of roughly  $5 \times 10^{-5}$ , which can be considered in a first approximation as the solar system average or typical initial value. Some heterogeneity was undoubtedly present, but its exact level is still unknown. On the other hand, it is likely that the initial  $(^{60}\text{Fe}/^{56}\text{Fe})_0$  of the solar system was lower than  $1 \times 10^{-8}$ , although high levels of  $^{60}\text{Fe}$  (up to  $10^{-6}$ )

have been detected in some components of chondrites. At the time of writing this review, there was no evidence of  $^{60}\text{Fe}$  heterogeneity within the solar protoplanetary disk.

### 2.3. The Origin of Aluminum-26 and Iron-60

The initial solar system ratio  $(^{26}\text{Al}/^{27}\text{Al})_0$  of roughly  $5 \times 10^{-5}$  is well above the calculated average galactic abundance (Huss *et al.*, 2009). This elevated abundance indicates a last-minute origin for  $^{26}\text{Al}$ . Production of  $^{26}\text{Al}$  by irradiation has been envisioned in different contexts (e.g., Lee, 1978; Gounelle *et al.*, 2006), but fails to produce enough  $^{26}\text{Al}$  relative to  $^{10}\text{Be}$  ( $\tau = 2.0$  m.y.), another SLR whose origin by irradiation is strongly supported by experimental data (Gounelle *et al.*, 2013). This leaves stellar delivery as the only possibility for  $^{26}\text{Al}$  introduction in the solar system. Although asymptotic giant branch stars produce elevated amounts of  $^{26}\text{Al}$  (Lugardo *et al.*, 2012), it is extremely unlikely that stars at this evolutionary stage are present in a star-forming region (Kastner and Myers, 1994). Thus massive stars are the best (unique) candidates for the origin of the solar system's  $^{26}\text{Al}$ .

The recently obtained lower estimates for the abundance of  $^{60}\text{Fe}$  (see section 2.2) are compatible with a galactic background origin, independently of whether this is calculated crudely using a box model (Huss *et al.*, 2009), or taking into account the stochastic nature of star formation in molecular clouds (Gounelle *et al.*, 2009). However, if the initial  $^{60}\text{Fe}$  abundance corresponds instead to a much higher  $(^{60}\text{Fe}/^{56}\text{Fe})_0$  ratio of  $\approx 10^{-6}$ , a last-minute origin is needed. Irradiation processes cannot account for  $^{60}\text{Fe}$  production because of its richness in neutrons (Lee *et al.*, 1998). The winds of massive stars can also be excluded, given their low abundance in  $^{60}\text{Fe}$ . In contrast, supernovae are copious producers of  $^{60}\text{Fe}$ , essentially because this SLR is synthesized in abundance during the hydrostatic and explosive phases of such massive stars (Woosley and Heger, 2007). Two astrophysical settings have been envisioned so far. In the first (classical) model (Cameron and Truran, 1977), the supernova ejecta hits a molecular cloud core and provokes its gravitational collapse (Boss and Keiser, 2013) as well as injecting  $^{60}\text{Fe}$  and other SLRs. A newer model injects  $^{60}\text{Fe}$  in an already formed protoplanetary disk (Hester *et al.*, 2004; Ouellette *et al.*, 2007). In either cases, the supernova progenitor mass is in the range  $20\text{--}60 M_{\odot}$ , because too-massive supernovae are extremely rare and very disruptive to their environment (Chevalier, 2000). Alternatively, generations of supernovae could have enriched the gas of the giant molecular cloud, so that the solar protoplanetary disk simply inherited the elevated abundances of the birth cloud (Vasiliadis *et al.*, 2013).

All these models suffer from an important difficulty, namely the overabundance of  $^{60}\text{Fe}$  in supernova ejecta relative to  $^{26}\text{Al}$ . The solar system  $^{60}\text{Fe}/^{26}\text{Al}$  mass ratio was either  $4 \times 10^{-3}$  or 0.4 depending on the adopted initial  $^{60}\text{Fe}$  abundance. In any case, this is well below the  $^{60}\text{Fe}/^{26}\text{Al}$  mass ratio predicted by supernovae nucleosynthetic models whose variation domain extends from 1.5 to 5.5 for a progenitor mass varying between 20 and  $60 M_{\odot}$ . Heterogeneity in

the composition of supernova ejecta has been proposed as a possible solution to that discrepancy (*Pan et al.*, 2012). However, that variability is limited to a factor of 4, which would help resolve the discrepancy only marginally in the case of the (unlikely) high  $^{60}\text{Fe}$  value. Finally, the astrophysical context of any supernova model is difficult to reconcile with observations of star-forming regions (*Williams and Gaidos*, 2007; *Gounelle and Meibom*, 2008). The commonly proposed setting for supernova contamination of a protoplanetary disk or a dense core is similar to that of the Orion Nebula, where disks are seen within a few tenths of parsec of the massive star  $\theta^1\text{ C Ori}$ . The problem with that setting is that, when  $\theta^1\text{ C Ori}$  will explode in 4 m.y. from now, these disks will have long evaporated or formed planets. New disks or cores will have obviously formed by then, but they will be at the outskirts of the 10-pc-wide H $\alpha$  region created by  $\theta^1\text{ C Ori}$  (*Chevalier*, 1999). At such a distance, the quantity of  $^{26}\text{Al}$  delivered into these disks or cores is orders of magnitude lower than the quantity present in the solar system (*Looney et al.*, 2006). In other words, supernova remnants nearby dense phases are extremely rare (*Tang and Chevalier*, 2014). In conclusion, it seems very unlikely that a nearby supernova was close enough to the solar system to provide the known inventory of  $^{26}\text{Al}$ .

If the low value of  $^{60}\text{Fe}$  inferred from chondrites is correct, then the presence of  $^{26}\text{Al}$  remains to be explained. Supernovae can be excluded as they would vastly overproduce  $^{60}\text{Fe}$  (see above). The winds of massive stars have long been known to be  $^{26}\text{Al}$  and  $^{60}\text{Fe}$ -poor (*Arnould et al.*, 1997). In the models of *Gaidos et al.* (2009) and *Young* (2014),  $^{26}\text{Al}$  is injected at the molecular cloud phase by the winds from a large number of Wolf-Rayet stars. The problem with these models is that the Wolf-Rayet phase is followed by the supernova explosion, and therefore they produce a large excess of  $^{60}\text{Fe}$  relative to  $^{26}\text{Al}$  and their respective solar system values. To escape that caveat, *Young* (2014) has argued that Wolf-Rayet stars do not explode as supernovae but directly collapse into black holes. Although this possibility has been theoretically envisioned, the recent observation of a Wolf-Rayet star going supernova shows this is far from being the rule (*Gal-Yam et al.*, 2014). In addition, models considering injection at the global molecular cloud phase cannot account for the observed heterogeneity of  $^{26}\text{Al}$  (see section 2.2).

The last class of models considered injection at the scale of single massive stars. *Tatischeff et al.* (2010) have envisioned a single star that escaped from its parent cluster and interacted with a neighboring molecular cloud, injecting  $^{26}\text{Al}$  through its dense wind. It is compromised again by the proximity of the Wolf-Rayet phase with the supernova phase. In addition, Wolf-Rayet stars are rare. In contrast, *Gounelle and Meynet* (2012) proposed that  $^{26}\text{Al}$  has been injected in a dense shell of mass  $\sim 1000\text{ M}_\odot$  collected by the wind of a massive star. Evolutionary models of rotating stars are used, so the injection in the shell starts as early as the entry of the star onto the main sequence, lasts for some million years, and ends well before the supernova explosion. When the collected shell has become dense enough and gravitationally

unstable, it collapses and a second generation of stars form that contain  $^{26}\text{Al}$ . Detailed calculations have shown that as long as the parent star, called “Coatlicue,” is more massive than  $M_{\min} = 32\text{ M}_\odot$ , the abundance of  $^{26}\text{Al}$  in the shell is equal to or larger than that of the solar system, depending on the mixing efficiency of the wind material with the shell. Because the mixing timescale of the dense shell is comparable to its collapse timescale, a certain level of  $^{26}\text{Al}$  heterogeneity is expected (*Gounelle and Meynet*, 2012), in agreement with observations. This model is in line with observations of induced star formation within dense shells around massive stars (*Deharveng et al.*, 2010). Because it corresponds to a common — although not universal — mode of star formation, it implies that the solar system is not the only of its kind to have formed with  $^{26}\text{Al}$ , and that early differentiation of planetesimals might have been common in exoplanetary systems. *Gounelle* (2014) has estimated that the occurrence of planetary systems that are rich in  $^{26}\text{Al}$  and poor in  $^{60}\text{Fe}$  is on the order of 1%.

#### 2.4. Timing of Planetesimal Accretion

Planetesimal accretion itself cannot be dated directly with radioisotopic systems, since the mere agglomeration of different solids incurs no isotopic rehomogenization between different mineral phases. Thus one can only obtain upper limits with the age-dating of preaccretionary components (for chondrites) and lower limits from that of secondary (parent body) processes.

Important and ever-improving constraints have emerged since the publication of *Asteroids III*. In particular, Hf-W systematics of achondrites and irons have evidenced early differentiation, sometimes contemporaneous (within errors) with refractory inclusion formation (*Kruijer et al.*, 2012). This indicates that planetesimal formation started very early in the evolution of the solar system. Intriguingly, *Libourel and Krot* (2007) ascribed some olivine aggregates in chondrites to this first generation of planetesimals [but see *Whattam et al.* (2008) and *Jacquet et al.* (2012a) for the alternative view that these formed in the protoplanetary disk]. The above evidence for early differentiation is consistent with thermal modeling expectations, as the initial abundance of  $^{26}\text{Al}$  was sufficient to melt planetesimals, so that chondrites had to be accreted later to be preserved to the present day.

Lower limits on chondrite accretion ages may be obtained from phases precipitated during aqueous alteration (see the chapter by Krot et al. in this volume). *Fujiya et al.* (2013) obtained ages of 4562.5–4563.8 m.y. in CI and CM chondrites [recall the accepted age of CAI formation of  $4567.3 \pm 0.16$  m.y. (*Connelly et al.*, 2012)]. As for non-carbonaceous chondrites, recent Mn-Cr dating of fayalite formed during incipient fluid-assisted metamorphism in the least-metamorphosed LL ordinary chondrites yields an age of  $4564.9^{+1.3}_{-1.8}$  m.y. (*Doyle et al.*, 2014). Al-Mg systematics in the mildly metamorphosed H chondrite Sainte Marguerite indicate an age of  $4563.1 \pm 0.2$  m.y. (*Zinner and Göpel*, 2002). Thermal modeling based on  $^{26}\text{Al}$  heating of

the H-chondrite parent body (one of the ordinary chondrite groups) constrained by dating of chondrites of different metamorphic degrees indicate accretion ages ranging from 1.8 to 2.7 m.y. after refractory inclusions (see *Gail et al.*, 2014, and references therein), while *Fujiya et al.* (2013) advocate accretion of CI and CM chondrites 3–4 m.y. after “time zero” based on similar calculations. If  $^{26}\text{Al}$  really is the heat source behind chondrite alteration, then it would indeed make sense that carbonaceous chondrites, little affected by thermal metamorphism, accreted later than their noncarbonaceous counterparts (*Grimm and McSween*, 1993).

Upper limits are provided by the ages of chondrules. In both carbonaceous and noncarbonaceous chondrites, chondrule Pb-Pb ages in individual meteorites span a range of ~4564–4567 m.y. (*Connelly et al.*, 2012), i.e., 0–3 m.y. after refractory inclusions, with younger ages reported by Al-Mg dating for CR (*Kita and Ushikubo*, 2012) and enstatite chondrite (*Guan et al.*, 2006) chondrules. Little correlation is seen between the age of chondrules and their composition (*Villeneuve et al.*, 2012). The significance of Al-Mg ages for chondrules, in particular in relationship with apparently somewhat older Pb-Pb ages (e.g., *Connelly et al.*, 2012), nevertheless remains uncertain.

To summarize, it seems clear that differentiated planetesimals accreted from the outset of the disk evolution while the known chondrites accreted later in the evolution of the disk (~2–4 m.y. after refractory inclusions), as presumably required to escape differentiation, but the exact chronology of chondrite formation and alteration is still in the process of being firmly established.

## 2.5. Accretion of Chondrules Directly After Formation?

*Alexander et al.* (2008) proposed that the retention of sodium, a volatile element, in chondrules during their formation indicated high solid densities in the chondrule-forming regions, up to 7 orders of magnitude above expectations for the solar protoplanetary disk and possibly gravitationally bound (see also *Cuzzi and Alexander*, 2006), although quite in excess of what the proportion of compound chondrules suggest (*Ciesla et al.*, 2004). This raises the possibility that the formation of chondrules and chondrites, respectively, may have been contemporaneous, as also advocated by *Metzler* (2012) based on the existence of “cluster chondrites” comprised of mutually indented chondrules [but see *Rubin and Brearley* (1996) for a criticism of such hot accretion models].

A further argument put forward by *Alexander and Ebel* (2012) is that chondrule populations in different chondrite groups are quite distinct (*Jones*, 2012). Indeed, *Cuzzi et al.* (2010) noted that two populations of particles formed simultaneously at 2 and 4 AU would be well-mixed within 1 m.y. for  $\alpha = 10^{-4}$ . Here  $\alpha$  is the nondimensional measure of the turbulent viscosity and diffusion. Relevant values for protoplanetary disks are discussed further in section 6, but we note here that a value of  $10^{-4}$  corresponds to the conditions that are expected if the mid-plane in the asteroid formation

region is stirred by turbulent surface layers (*Oishi et al.*, 2007). This would suggest that chondrules had to accrete rapidly to avoid homogenization. However, we do not know exactly the turbulence level or original space time separations between chondrule-/chondrite-forming locations, as the asteroid belt may have undergone significant reshuffling (*Walsh et al.*, 2011). Chondrite groups vary significantly in bulk composition. This indicates that there has been no thorough mixing of chondrite components, whatever their individual transformations in the intervening time were, over the whole chondrite-formation timescale. So whatever fraction of that time the period between chondrule formation and chondrite accretion actually represents, it is not to be expected that chondrules should have been well-mixed over the different chondrite-forming reservoirs (*Jacquet*, 2014b).

A link between chondrules and matrix is suggested, in the case of carbonaceous chondrites, by complementarity: The bulk meteorite is solar in some respect (e.g., the Mg/Si ratio), but its separate components (chondrules/matrix/refractory inclusions) are not [chondrules have a typically higher Mg/Si than solar while the converse is true for the matrix (*Hezel and Palme*, 2010)]. Complementarity—if verified, as for at least some elements it may reflect analytical biases or parent-body processes (*Zanda et al.*, 2012)—would indicate a genetic relationship between chondrules and matrix, which would have exchanged chemical elements upon formation, a relationship that would not be predicted, e.g., in an X-wind scenario for chondrule formation (*Hezel and Palme*, 2010) in which chondrules and matrix would have formed in different locations. But it does not require immediate accretion of chondrule and matrix. It only requires chondrules and dust grains to have been transported in a statistically similar way, as was likely the case for a large portion of the disk evolution until accretion. Several batches of chondrule + dust may have contributed to a given chondrite-forming reservoir, again provided they suffered no loss of chondrules relative to dust or vice versa (*Cuzzi et al.*, 2005; *Jacquet et al.*, 2012b). This nonetheless does assume that at the stage of chondrule/matrix agglomeration, there was no bias for or against the incorporation of any component (*Jacquet*, 2014a), which may be an important constraint on the accretion process. The problem is that small dust grains are much harder to incorporate into asteroidal bodies than the macroscopic chondrules, due to their strong frictional coupling with the gas. One could nevertheless envision that chondrules and matrix aggregated together as compound objects (see section 4.2.5) prior to incorporation in asteroidal bodies and/or that matrix-sized dust coagulated with ice into lumps with aerodynamical properties equivalent to chondrules.

So the jury is still out on whether chondrule formation immediately preceded incorporation in a chondrite or not. Given the chondrule age spread of 3 m.y. within individual chondrites (*Connelly et al.*, 2012), as well as the presence of refractory inclusions and presolar grains that would not have survived chondrule-forming events, it is possible that chondrite components did spend up to a few million years as free-floating particles in the gaseous disk prior to accretion.

### 3. CONSTRAINTS FROM THE ASTEROID BELT

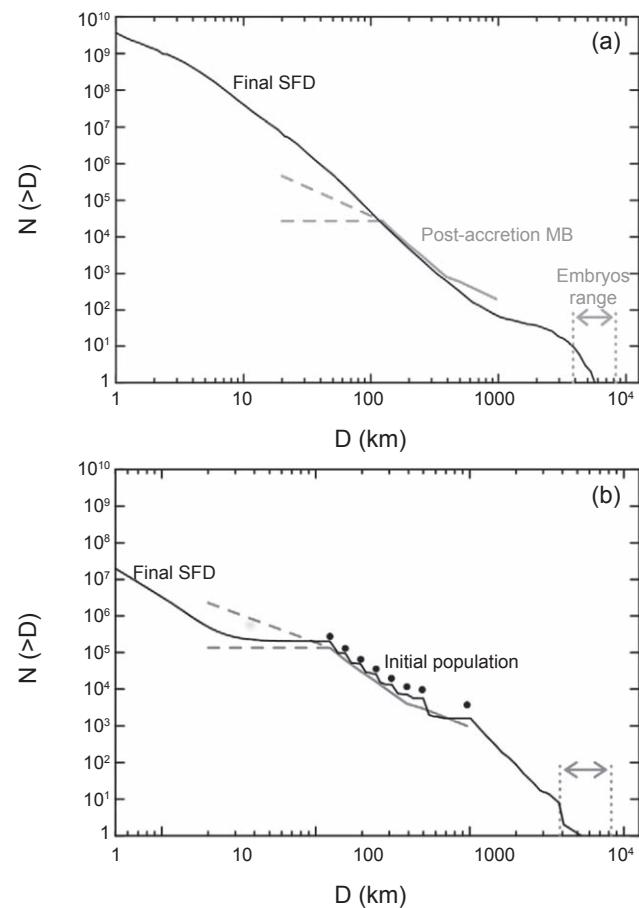

The modern asteroid belt contains only a fraction of its original planetesimal population. However, the shape of the size distribution of the largest asteroids is primordial and gives important insights into the birth sizes of the planetesimals. Asteroid families provide a way to probe whether the asteroids are internally homogeneous or heterogeneous on large scales.

#### 3.1. Asteroid Size Distribution

The observed size distribution of asteroids in the main belt shows a quite steep slope for bodies with diameter  $D > 100$  km and a much shallower slope for smaller bodies (Bottke et al., 2005). A similar change of slope with an elbow at  $D \sim 130$  km is observed in the Kuiper belt population (Fraser et al., 2014).

It was expected that the transition from a steep to a shallower slope is the consequence of the collisional disruption of smaller bodies. However, Bottke et al. (2005) reached the opposite conclusion by examining the collisional evolution of the asteroid belt in detail. They used a number of constraints (the total number of catastrophic asteroid families, the survival of the basaltic crust on Vesta, the existence of only 1–2 major basins on that body, etc.) to conclude that the integrated collisional activity of the asteroid belt had to be less than that of the current main-belt population in a putative timespan of 10 G.y. If one supposes that initially the asteroid belt size distribution had a unique slope (the slope now observed for  $D > 100$  km), such a limited collisional evolution is not sufficient to reduce the slope of the size distribution of objects smaller than 100 km down to the observed value, i.e., to create the observed elbow. Therefore, Bottke et al. (2005) concluded that the elbow at  $D \sim 100$  km is a fossil feature of the primordial size distribution. For the Kuiper belt, the constraints on the integrated collisional activity are not as tight as for the asteroid belt. Nevertheless, models seem to suggest that collisional evolution alone could not create an elbow at diameters larger than 8 km (Pan and Sari, 2005), which is significantly smaller than the observed value.

Morbidelli et al. (2009) failed to produce the elbow at  $D \sim 100$  km in the asteroid belt in collisional coagulation simulations starting from a population of small planetesimals (see Fig. 2). So, having in mind the new models of formation of large planetesimals from self-gravitating clumps of chondrules or larger pebbles and boulders (Johansen et al., 2007; Cuzzi et al., 2008), they proposed that 100 km was the minimal diameter of the original planetesimals. Moreover, not being able to reproduce the current slope of  $D > 100$  km asteroids by mutual collisions between bodies 100 km in size, Morbidelli et al. (2009) argued that these large planetesimals were born with a similar slope. However, as we will see in section 7, the current slope can be reproduced by considering the accretion of chondrule-sized particles by 100-km-scale planetesimals during the gaseous disk phase, a process not considered by Morbidelli et al. (2009).

**Fig. 2.** The cumulative size distribution of asteroids  $N(>D)$ , as a function of asteroid diameter  $D$ , from Morbidelli et al. (2009). These coagulation models started with either (a) kilometer-sized planetesimals or (b) an initial size distribution following the current, observed size distribution of asteroids between 100 and 1000 km in diameter. The gray line shows the current size distribution of asteroids larger than 100 km in diameter. The model with small planetesimals overproduces asteroids smaller than 100 km in diameter (the upper dashed line represents the current size distribution of small asteroids while the lower dashed lines indicates a tighter constraint on the size distribution directly after accretion of the main belt). Starting with large asteroids gives a natural bump in the size distribution at 100 km in diameter, as the smaller asteroids are created in impacts between the larger primordial counterparts.

Weidenschilling (2011) managed to reproduce the elbow at  $D \sim 100$  km in the asteroid belt from collisional coagulation simulations starting from objects 50–200 m in radius. Because of the small size of these objects, collisional damping and gas drag keep the disk very dynamically cold (i.e., with a small velocity dispersion among the objects). Hence, in the simulations of Weidenschilling (2011), the elbow at  $D \sim 100$  km is produced by a transition from dispersion-dominated runaway growth to a regime dominated by Keplerian shear, before the formation of large planetary embryos. However, any external dynamical stirring of the population,

for instance due to gas turbulence in the disk, would break this process. Moreover, these simulations are based on the assumption that any collision that does not lead to fragmentation results in a merger, but 100-m-scale objects have very weak gravity and the actual capability of bodies so small to remain bound to each other is questionable. Finally, we stress that the formation of 100-m-scale bodies is an open issue, in view of the bouncing barrier and meter-sized barrier discussed in section 4.

### 3.2. Snowline Problems

Among the various meteorite types that we know, carbonaceous meteorites (or at least some of them like CI and CM) contain today a considerable amount (5–10%) of water by mass. Evidence for water alteration is widespread, and it is possible that the original ice content of these bodies was higher, close to the 50% value expected from unfractionated solar abundances. Instead, ordinary chondrites contain <2% water by weight (e.g., Jarosewich, 1990; Krot *et al.*, 2009); while ordinary chondrites do show signs of water alteration, it is unlikely that they ever contained 50% water ice by mass. This suggests that the parent bodies of these meteorites (CI and CM vs. ordinary) formed on either side of the condensation line for water, also called the snowline. In other words, the snowline was located in the middle of the asteroid belt at the time when the asteroids formed. Earth is also very water poor (some 0.1% by mass, although uncertain by a factor of ~5), suggesting that the planetesimals in its neighborhood were mostly dry and that water was delivered only by the small amount of planetesimals accreted from farther out (Morbidelli *et al.*, 2000; Raymond *et al.*, 2004; O'Brien *et al.*, 2014). The very dry enstatite chondrites have been proposed to arise from an extinct portion of the asteroid belt located between 1.6 and 2.1 AU from the Sun (Bottke *et al.*, 2012).

The problem with this picture is that chondritic bodies accreted late (2–4 m.y. after CAIs) and that the snowline is expected to migrate toward the Sun with time. The temperature of the disk is set by the equilibrium between heating and cooling. In the inner part of the disk, the heating is predominantly due to the viscous friction of the gas in differential rotation around the Sun, so it is related to the gas accretion rate of the star. The cooling rate is governed by how much mass is in the disk in the form of micrometer-sized grains. In Bitsch *et al.* (2015), the snowline is at 2–3 AU only in the earliest phases of disk evolution when the accretion rate is  $\dot{M} = 10^{-7} M_{\odot} \text{ yr}^{-1}$ , but the snowline migrates to 1–2 AU already after 500,000 yr when the accretion rate drops below  $\dot{M} = 10^{-8} M_{\odot} \text{ yr}^{-1}$ . These models are probably optimistically warm, because it is assumed that the ratio between the mass in micrometer-sized dust and the mass in gas is 1% (this reflects the solar metallicity but planetesimal accretion should eventually decrease the dust content) and account for the heating produced by stellar irradiation by a star more luminous than our early Sun. According to the observation of the accretion rate of stars as a function of age (Hartmann *et al.*, 1998) and photoevaporation models (Alexander and

Armitage, 2006), the accretion rate of the star should drop to  $\dot{M} = 10^{-9} M_{\odot} \text{ yr}^{-1}$  at 2–3 m.y., i.e., at the time of chondrite formation. The fact that there is no sign of primary accretion in the solar system after ~3 m.y. also suggests that the disk disappeared at that time (or that all the solids could have been incorporated into parent bodies at that time — however, accretion of solids is unlikely to reach 100% efficiency). Thus, at the time of chondrite formation, the snowline should have been well inside the inner edge of the asteroid belt, possibly even inside 1 AU. This is at odds with the paucity of water in the ordinary chondrites and in Earth.

A way to keep the disk warm has been proposed recently by Martin and Livio (2012, 2013). In their model, a dead zone in the disk, with low turbulent viscosity, becomes very massive and develops gravitational instabilities that heat the gas. The unlimited pileup of gas in the dead zone, however, could be a consequence of a simplified disk transport model, and is not observed in more complex three-dimensional hydrodynamical calculations (Bitsch *et al.*, 2014). Also, the model of Martin and Livio (2012) predicts a cold region where ice could condense inside the orbit of Earth, which seems inconsistent with the compositions of Venus and Mercury.

A possible way to keep the asteroid belt ice poor, despite freezing conditions, is to stop the inward flow of icy pebbles in a pressure bump. The inward drift of pebbles is caused by friction with the slower-moving gas (this effect is discussed more in section 6.1). Then, when the nebula cooled locally below the ice condensation temperature, there was no water vapor present to condense, and the planetesimals formed there would have a volatile depletion similar to that achieved in a warm disk. Bitsch *et al.* (2014) explored the effects of viscosity transitions at the snowline (as suggested by Kretke and Lin, 2007), but found that only very steep radial gradients in the  $\alpha$  parameter allow the formation of a pressure bump. Lambrechts *et al.* (2014) showed that the formation of a proto-Jupiter of about  $20 M_{\oplus}$  can produce a strong pressure bump just exterior to its orbit. If proto-Jupiter formed at the snowline when the snowline was at the outer edge of the asteroid belt, then its presence would have shielded the asteroid belt and the terrestrial planet region from the flow of icy pebbles, while small silicate dust and chondrules would remain for longer times in the asteroid belt due to their slow radial drift.

### 3.3. Are Asteroids Internally Homogeneous?

The possibility that the asteroids grew incrementally by layered accretion of chondrules (section 7) implies that asteroids are internally heterogeneous, in the most extreme case with a chondritic surface layer residing on a differentiated interior. We discuss here briefly whether such internal heterogeneity is supported by observations of the asteroid belt. Burbine *et al.* (2002) note that 100–150 distinct meteorite parent bodies, three-fourths of them differentiated, are represented in the meteorite collection. However, this sample is biased toward the sturdy irons and against the weaker, never-melted primitive chondrites.

Differentiation is a constraint on formation age. Most studies have suggested that sizeable asteroids forming  $<10^6$  yr after CAIs are almost certain to have thoroughly melted, but those that formed more than 2 m.y. after CAIs may have escaped melting except near their centers. More recent work paints a more complicated picture (see the chapter by Scheinberg et al. in this volume). Specifically, the Allende parent body, source of primitive CV3 chondrites, is thought to have melted near its center, as evidenced by the paleomagnetism detected in these meteorites (*Elkins-Tanton et al.*, 2011); other CV chondrites may show a similar signal (*Weiss et al.*, 2010). This suggests that the CV parent body was differentiated in its interior, but preserved an undifferentiated chondritic layer. Other authors have ascribed the magnetic field in the CV chondrites to impacts (e.g., *Wasson et al.*, 2013).

Modeling of the buoyancy of silicate melts of different composition suggests that, for C-type composition, melt might be dense and remain stable at depth, but for S-type (OC) compositions, and certainly for enstatite compositions, melt is less dense than surrounding material and will rise to manifest on the surface (*Fu and Elkins-Tanton*, 2014). Thus there might be old, centrally melted C-type asteroids such as the Allende parent body, where the evidence for differentiation remains buried, but the lack of evidence for significant surface melting on most S-type asteroids may argue that most of them remain unmelted and undifferentiated throughout (see the chapter by Scheinberg et al. in this volume) (*Weiss and Elkins-Tanton*, 2013).

We can sample the internal properties of asteroids in two ways: from the observed color and albedo distributions of collisionally disrupted asteroids in families (see also the chapters by Nesvorný et al. and Michel et al. in this volume) and from the meteorites that derive from them (see next paragraph). The Near-Earth Object Wide-field Infrared Survey Explorer (NEOWISE) mission has measured the albedos of a large number of asteroids and families, finding a dichotomy in albedo, roughly corresponding to the classical S- and C-types, that is most evident in the outer main belt. Collisional families cover the entire belt, so they avoid the sampling bias that affects meteorites. Many families have internal albedo distributions that are narrower than the global spread of albedos across families. A similar story is told by observations at visual and near-infrared wavelengths (*Mothé-Diniz and Nesvorný*, 2008). This conclusion is nevertheless complicated by the identification of interlopers in (and exclusion from) the asteroid families. Hence there is an inherent tendency to observe low-albedo variations within asteroid families. In contrast, the Eos family and the Eunomia family have unusually large internal variance (*Mothé-Diniz et al.*, 2005, 2008) and the Eunomia family looks like what an internally differentiated S-type might produce (see discussion in *Weiss and Elkins-Tanton*, 2013).

The three ordinary chondrite groups (H, L, and LL) are each thought to derive from a single parent body, based on a clustering of cosmic-ray-exposure ages of chondrites in each group, as if they were excavated by the same few large impacts (*Eugster et al.*, 2006). The thermal history of the

H-chondrite parent body under internal heating by  $^{26}\text{Al}$  was modeled by *Tieloff et al.* (2003), *Monnereau et al.* (2013), and *Henke et al.* (2013), who all concluded it was a roughly 100-km-radius body. Chondrites from all three OC groups show different amounts of thermal alteration from this process, designated as metamorphic grades 3–6. Models imply that the H-chondrite parent, at least, first incurred thermal alteration in an “onion-shell” fashion, with the most strongly heated H5/H6 material heated deep in the interior, and then was catastrophically disrupted and reassembled as a rubble pile (see Fig. 1) (*Taylor et al.*, 1987; *Scott et al.*, 2014). The small fractional abundance of minimally altered chondrites (H3/H4; Fig. 1) constrains the accretion of the H-chondrite parent body to have happened quickly — probably faster than  $3 \times 10^5$  yr (*Henke et al.*, 2013; *Vernazza et al.*, 2014). The constant mass growth rate adopted in *Henke et al.* (2013) is nevertheless not applicable to layered accretion, which results in runaway accretion and deposition of most of the mass toward the end of the growth phase (see further discussion in section 7).

While the major-element chemical compositions, and the oxygen isotopic compositions, of the OC groups differ significantly, there is little or no discernible variation of either chemical or isotopic composition across metamorphic grades in any of the three groups (*Jarosewich*, 1990; *Wood*, 2005; see also Tables 1 and 2 of *Clayton et al.*, 1991). The variation of chondrule size across metamorphic grade is less well studied (A. Rubin, personal communication, 2014).

*Dodd* (1976) demonstrated that the difference in the aerodynamical friction time between metal grains and silicate chondrules can explain silicate-metal fractionation in the ordinary chondrites. In this picture the LL chondrites are underabundant in metal because the parent body was successfully able to accrete large silicate-rich chondrules [the chondrules in the LL chondrites are larger than those in both H and L chondrites (see, e.g., *Nelson and Rubin*, 2002)]. The oxidation of metallic Fe could have happened as the LL-chondrite parent body accreted water-bearing phyllosilicates (*Rubin*, 2005). In the layered accretion model presented in section 7, asteroids will accrete larger and larger particles as they grow. Metal grains had a more restricted size range and hence a relatively small parent body of the H chondrites would accrete mainly small chondrules together with metal grains. A small size of the H-chondrite parent body is further supported by the low fraction of strongly metamorphosed samples that we have from that group (*Dodd*, 1976). A similar story is told for the enstatite chondrites (*Schneider et al.*, 1998): The EH group has more metal and smaller chondrules than the EL group. This aerodynamical size sorting may be evidence of asteroid growth by layered accretion (section 7) or asteroid formation by turbulent concentration (section 5).

#### 4. DUST GROWTH BY STICKING

Now that we have given an overview of some of the constraints from meteorites and asteroids, we can turn to the theoretical models of planetesimal formation. In this section

we discuss the growth of dust by direct sticking; subsequent chapters discuss gravitational instability models.

#### 4.1. Particle-Gas Interaction

The dynamical behavior of a particle in gas depends on both its size and density, as determined by its friction time  $\tau_f$  in the nebula gas (Whipple, 1972; Weidenschilling, 1977a). For particles smaller than the gas molecule mean free path (approximately 10–100 cm in the asteroid-belt region, depending on the uncertain value of the gas density), the friction time is

$$\tau_f = \frac{a\rho_*}{v_{\text{th}}\rho_g} \quad (1)$$

where  $a$  and  $\rho_*$  are the particle radius and density, and  $v_{\text{th}}$  and  $\rho_g$  are the gas thermal speed and mid-plane density. The thermal speed of the gas molecules is in turn connected to the isothermal sound speed through  $v_{\text{th}} = \sqrt{8/\pi c_s}$ . The Stokes number  $St$  is defined as  $St = \Omega\tau_f$ , where  $\Omega$  is the (local) orbital frequency of the protoplanetary disk. The translation from Stokes number to particle size follows

$$a = \frac{(2/\pi)\Sigma_g St}{\rho_*} \approx 80 St f_g(r) \left( \frac{r}{2.5 \text{ AU}} \right)^{-1.5} \text{ cm} \quad (2)$$

Here  $\Sigma_g = \sqrt{2\pi}\rho_g H_g$  is the gas column density and  $f_g(r)$  a parameter that sets gas depletion relative to the minimum mass solar nebula (MMSN) as a function of semimajor axis  $r$ . We set in the second equality  $\rho_* = 3.5 \text{ g cm}^{-3}$ , relevant for chondrules. The Stokes number controls many aspects of dust dynamics. Particles of larger Stokes numbers couple increasingly to larger, longer-lived, and higher-velocity eddies in nebula turbulence, thus acquiring larger relative velocities. Solutions for particle velocities have been developed by Voelk *et al.* (1980) and Mizuno *et al.* (1988), including closed-form analytical expressions by Cuzzi and Hogan (2003) and Ormel and Cuzzi (2007). Importantly, the Stokes number also controls the degree of sedimentation, with the scale height of the sedimented mid-plane layer,  $H_p$ , given by

$$H_p = H_g \sqrt{\frac{\alpha}{St + \alpha}} \quad (3)$$

Here  $H_g$  is the gas scale-height and  $\alpha$  is a measure of the turbulent diffusion coefficient  $D$  normalized as  $D = \alpha c_s H_g$  (see Johansen *et al.*, 2014, for references). Significant sedimentation can occur when  $St \geq \alpha$ . Chondrules of millimeter sizes have a Stokes number of  $St \sim 10^{-3}$ ; hence chondrules will only settle out of the gas if  $\alpha \ll 10^{-3}$ .

#### 4.2. Dust Growth

The study of dust growth has been an extremely active field, both experimentally and numerically, since *Asteroids III*. Subsequent reviews were presented by Dominik *et al.* (2007), Blum and Wurm (2008), and Chiang and

Youdin (2010); the older review by Beckwith *et al.* (2000) is also valuable for basics. Two very recent overview chapters presenting both the basic physics and selected recent highlights are Johansen *et al.* (2014) and Testi *et al.* (2014); for efficiency we build on those chapters and here emphasize specifics relevant to asteroid formation.

**4.2.1. Sticking.** Particles can stick if their relative kinetic energy exceeds certain functions of the surface energy of the material, which depends on composition. At the low relative velocities for small monomers (0.1–10  $\mu\text{m}$ ) under nebula conditions, both ice and silicate particles stick easily and form loose, porous aggregates. The process continues until the aggregates are at least 100  $\mu\text{m}$  in radius. Aggregates can continue to grow and stick at larger velocities, if their open structure is able to deform and dissipate energy (Wada *et al.*, 2009). The entire process of growth beyond roughly 100  $\mu\text{m}$  fluffy aggregates depends on just how much these aggregates can be compacted by their mutual collisions. Recent studies that concentrate on icy particles outside the snowline have argued that the high surface energy of ice prevents significant compaction from occurring (and keeps relative velocities small) until particles have grown to extremely large size — hundreds of meters — with extremely low density (Okuzumi *et al.*, 2012).

**4.2.2. Bouncing.** The surface energies of silicates are much smaller than those of ice, so it is easy for even millimeter-sized silicate particles to compact each other in mutual collisions. Relative velocities large enough to cause compaction and bouncing are acquired by roughly millimeter-sized silicate particles in nebula turbulence. Coagulation modeling by Zsom *et al.* (2010), consistent with experiments (Güttler *et al.*, 2010; Weidling *et al.*, 2012), revealed a bouncing barrier in this size range where growth of silicate aggregates by sticking ceased. This new barrier joins the long-known fragmentation barrier and radial drift barrier, which, even if the bouncing barrier can be breached, tend to frustrate growth in the asteroid-belt region beyond decimeter to meter size (Brauer *et al.*, 2008; Birnstiel *et al.*, 2010, 2011).

**4.2.3. Fragmentation.** A simple critical velocity  $v_{\text{frag}}$  can be used to refer to fragmentation of two comparable masses. This approach has been modified in some treatments to include some mass transfer by a smaller projectile hitting a larger target at high velocity, even if the projectile is destroyed and some mass is ejected from the target (Wurm *et al.*, 2005). An alternate approach is to treat the fragmentation threshold as a critical kinetic energy per unit mass  $Q^*$ , which can be thought of as a critical velocity squared for same-sized particles (Stewart and Leinhardt, 2009). The latter treatment automatically accounts for particle size differences and thus allows accretion of small particles to proceed at collision velocities much higher than the nominal  $v_{\text{frag}} \sim \sqrt{Q^*}$ . Stewart and Leinhardt (2009) treated solids as weak rubble piles, all calibrated using experimental work by Setor *et al.* (2007). These expressions allow for the higher efficiency of low-velocity collisions in fragmentation than for hypervelocity impacts. For particles made of small silicate grains, a value of  $Q^*$  on the order of  $10^4 \text{ cm}^2 \text{ s}^{-2}$  is suggested, with an

associated  $v_{\text{frag}} \sim 1$  to several meters per second, for weak centimeter- to meter-sized aggregates (Schräpler et al., 2012; Stewart and Leinhardt, 2009; Wada et al., 2009, 2013) or even less (Beitz et al., 2011).

**4.2.4. Lucky particles.** The bouncing barrier, in preserving most of the available solids at small sizes, may provide a target-rich environment for growth of much larger “lucky” particles, which experience few, or low-velocity, collisions and avoid destruction while steadily growing from much smaller particles to large sizes (Windmark et al., 2012a,b; Garaud et al., 2013; Drążkowska et al., 2013). However, Windmark et al. (2012a,b) and Garaud et al. (2013) did not include radial drift, which is important because the growth time for these lucky particles greatly exceeds the drift time to the Sun. Drążkowska et al. (2013) removed the radial drift problem with a pressure bump at the edge of a dead zone, and still found that the total number of meter-sized particles they could produce in  $3 \times 10^4$  yr was in the single digits. An isolated particle cannot trigger collective effects such as the streaming instability (section 6), but can only keep growing by sweep-up. Johansen et al. (2008) and Xie et al. (2010) have modeled this “snowball” stage and find that growth in this fashion is extremely slow unless the nebula turbulent  $\alpha$  is very low, because the small feedstock particles are vertically diffused to a low spatial density otherwise.

**4.2.5. Chondrule rims and chondrule aggregates.** The fine-grained component of chondrites is not only found in a featureless background matrix, it is also found rimming individual chondrules and other coarse particles, often filling cavities (Metzler et al., 1992; Brearley, 1993; Cuzzi et al., 2005). The origin of these fine-grained rims has been debated (Lauretta et al., 2006). One school of thought regards them as accretionary rims, swept up as a cooled chondrule moves relative to the gas and entrained dust or small aggregates (MacPherson et al., 1985; Metzler et al., 1992; Bland et al., 2011). Matrix and rims were reviewed in depth by Scott et al. (1984); among many interesting results, they found evidence that rims were accreted as numerous aggregates of variable mean composition, rather than as monomers. Rubin (2011) suggested that carbonaceous chondrites formed in dusty regions of the solar protoplanetary disk and that matrix accumulated into millimeter- to centimeter-sized highly porous dust balls. In this picture, chondrules acquired matrix rims by collisions with these dust balls rather than in collisions with smaller particles.

The accretion of fine-grained rims was modeled by Morfill et al. (1998), Cuzzi (2004), and Ormel et al. (2008). In these models, relative velocities predicted for the nebula environment have been shown to be compatible with sticking and compaction under the theory of Dominik and Tielens (1997); Ormel et al. (2008) added the effects of interchondrule collisions on further compacting the rims. Ormel et al. found that chondrules that had accreted porous rims of dust between collisions could stick more easily because the porous rims acted as shock absorbers, resulting in composite, centimeter- to decimeter-sized objects, depending on the value of  $\alpha$ , formed of rimmed chondrules.

**4.2.6. Gravitational scattering barrier.** There is one further barrier for particles trying to grow incrementally, by sticking, to kilometer-sized and larger. This gravitational scattering barrier arises because, in turbulence, nebula gas has small density fluctuations associated with pressure and vorticity. These density fluctuations, primarily on large scales, scatter growing planetesimals to achieve high relative speeds (Laughlin et al., 2004; Nelson and Papaloizou, 2004; Nelson and Gressel, 2010; Yang et al., 2012). The random velocities acquired by 1–10-km-scale planetesimals in this way are sufficient to put them into an erosive, rather than accretionary, regime throughout most of the solar system for a range of the most plausible  $\alpha$  values (Ida et al., 2008; Stewart and Leinhardt, 2009). Ormel and Okuzumi (2013) found that planetesimals need to have radii of 100 km or more to be able to undergo runaway accretion.

Overall, the barriers to formation of 100-km-scale asteroids by incremental growth by sticking appear formidable. For these reasons, a number of models have arisen that avoid these problems with a leapfrog process in which 10–1000-km-scale asteroids form directly from smaller particles stuck at one of these barriers.

## 5. TURBULENT CONCENTRATION

The leapfrog model, sometimes referred to as turbulent concentration (TC) or turbulent clustering, can in principle make 10–100-km-radius planetesimals directly from chondrule-sized particles. The turbulent concentration model was motivated originally by laboratory and numerical experiments that showed dense particle clusters forming spontaneously in isotropic turbulence, in which the most intense clustering was seen for particles with friction time  $\tau_f$  equal to the Kolmogorov (or smallest eddy) timescale (Squires and Eaton, 1990, 1991; Wang and Maxey, 1993; Eaton and Fessler, 1994). It was realized that this condition was very closely satisfied under canonical nebula conditions by the very chondrule-sized particles that make up the bulk of primitive chondrites (Cuzzi et al., 1996, 2001).

### 5.1. A Brief History of Turbulent Concentration Models

What remains uncertain and a subject of current study, as with many properties of turbulence, is just how the laboratory experiments and numerical simulations translate into actual nebula conditions. The flow regime is described by its turbulence Reynolds number  $Re = UL/v = \alpha c_s H_g/v$ , where  $U$  and  $L$  are some typical velocity and length scale of the flow, and  $v$  is the molecular viscosity. All current experiments and simulations are run at  $Re$  far smaller than likely nebula values. Cuzzi et al. (2001) noticed that the volume fraction of dense clumps increased with increasing  $Re$  and suggested a scaling that would map the behavior to the much higher values of  $Re$  relevant for turbulence in protoplanetary disks.

Hogan and Cuzzi (2007) showed that mass-loading feedback of the particle burden on gas turbulence caused

the concentration process to saturate at a mass loading  $\Phi = \rho_p/\rho_g \sim 100$ , precluding the small, dense clumps advocated by Cuzzi *et al.* (2001). Based on this, Cuzzi *et al.* (2008) advocated gravitational binding and ultimate sedimentation of much larger clumps, on the order of  $10^3$ – $10^4$  km, with  $\Phi \sim 10$ – $100$ . They showed that a long-neglected discovery by Sekiya (1983) precludes genuine, dynamical timescale collapse for dense clumps of chondrule-sized particles under plausible conditions. Particles of these sizes and friction times can only sediment slowly toward the center of their bound clump, on a much longer timescale ( $10^2$ – $10^3$  orbits). Cuzzi *et al.* (2008) suggested a criterion for stability of these bound, yet only slowly shrinking, clumps that led directly to the conclusion that they would preferentially form large planetesimals comparable in size with the mass-dominant 100-km-radius mode advocated for the early asteroid belt by Bottke *et al.* (2005)—thus leaping over the long-troublesome millimeter- to meter- to kilometer-sized barriers. Objects formed in this way are compatible with the primary texture seen in the most primitive unbreciated CM and CO chondrites (Metzler *et al.*, 1992; Brearley, 1993), and would display deep homogeneity of bulk chemical and isotopic properties.

Cuzzi *et al.* (2010) and Chambers (2010) went on to describe an end-to-end primary accretion scenario, combining stability thresholds with calculated probability distributions of clump density, finding that a range of nebula conditions (all implying  $>10\times$  local enhancement of the usually assumed 1% cosmic solids-to-gas ratio within some few  $10^4$  km of the mid-plane) could match the required rate of planetesimal formation and the characteristic mass mode around 100–200-km diameter. Cuzzi *et al.* (2010) gave a number of caveats regarding the built-in assumptions of this model; one caveat regarding scale-dependence of the concentration process has been found to be important enough to change the predictions of the scenario quantitatively (see below). Subsequently, Cuzzi and Hogan (2012) resolved a discrepancy in a key timescale between Cuzzi *et al.* (2010) and Chambers (2010), which makes planetesimal formation  $1000\times$  faster than in Cuzzi *et al.* (2010) [and correspondingly slower than in Chambers (2010)].

## 5.2. New Insights into Turbulent Concentration

The primary issues are whether it is *always* Kolmogorov friction time particles that are most effectively concentrated, and whether the physics of their concentration are scale-invariant. Hogan and Cuzzi (2007) argued by analogy with the observed scale-invariance of turbulent dissipation, which is dominated by Kolmogorov-time vortex tubes (little tornados in turbulence) that the concentration of Kolmogorov-friction-time particles would also be scale-invariant (see also Cuzzi and Hogan, 2012). They developed a so-called cascade model by which to extend the low-Re results to nebula conditions.

The primary accretion scenarios of Cuzzi *et al.* (2010) and Chambers (2010) used this cascade model to generate density-vorticity probability density functions (PDFs) as

a function of nebula scale. Pan *et al.* (2011) ran simulations at higher Re than Hogan and Cuzzi (2007) and found that the clump density PDFs dropped faster than would be predicted by the scale-invariant cascade. They suggested that the physics of particle concentration might indeed be scale-dependent, and that planetesimal formation rates obtained using the Hogan and Cuzzi (2007) cascade might be significantly overestimated.

Ongoing work supports this concern about scale dependence. Cuzzi *et al.* (2014) have analyzed much higher Re simulations (Bec *et al.*, 2010) and found that the cascade measures, called “multiplier distributions,” that determine how strongly particles get clustered at each spatial scale *do* depend on scale at least over the largest decade or so of length scale; i.e., the scale-invariant inertial range for particle concentration and dissipation does not become established at the largest scale, causing little concentration to occur until roughly an order of magnitude smaller scale. Because the cascade process is multiplicative, this slow start means that fewer dense zones are to be found at any given scale size than previously thought.

New, scale-dependent cascades can now be implemented to predict planetesimal IMFs using the approach of Cuzzi *et al.* (2010, 2014). The quantitative implications are not clear as yet, but particles with friction times significantly longer than those of single chondrules are most strongly clustered at length scales most relevant to direct planetesimal formation (see also Bec *et al.*, 2007). Meanwhile, turbulent concentration of small particles may play a critical and as yet unmodeled (in astrophysics) role in formation of aggregates by collisions and sticking (see, e.g., Shaw, 2003; Pan *et al.*, 2011) (section 4). Some combination of these effects probably contributes to observed chondrule size distributions, some (but not all) of which appear broader than previously thought (Fisher *et al.*, 2014; Friedrich *et al.*, 2015; Ebel *et al.*, 2015).

## 6. PRESSURE BUMPS AND STREAMING INSTABILITY

The turbulent concentration mechanism described in the previous section operates on the smallest scales of the turbulent flow (although the vortical structures that expel particles can be very elongated). The dynamical timescales on such small-length scales are much shorter than the local orbital timescale of the protoplanetary disk. In contrast, the largest scales of the turbulent flow are dominated by the Coriolis force, and this allows for the emergence of large-scale geostrophic structures (high-pressure regions in perfect balance between the outward-directed pressure gradient force and the inward-directed Coriolis force).

Whipple (1972) found that particles are trapped by the zonal flow surrounding large-scale pressure bumps. Pressure bumps [in a way azimuthally extended analogs to the vortices envisioned in Barge and Sommeria (1995)] can arise through an inverse cascade of magnetic energy (Johansen *et al.*, 2009a; Simon *et al.*, 2012; Dittrich *et al.*, 2013) in tur-

bulence driven by the magnetorotational instability (*Balbus and Hawley*, 1991). Pressure bumps concentrate primarily large (0.1–10 m) particles that couple to the gas on an orbital timescale (*Johansen et al.*, 2006), reaching densities at least 100× the gas density, which leads to the formation of 1000-km-scale planetesimals (*Johansen et al.*, 2007, 2011). The magnetorotational instability is nevertheless no longer favored as the main driver of angular momentum transport in the asteroid-formation region of the solar protoplanetary disk, since the ionization degree is believed to be too low for coupling the gas to the magnetic field (see review by *Turner et al.*, 2014).

The magnetorotational instability can still drive turbulence (with  $\alpha$  in the interval from  $10^{-3}$  to  $10^{-2}$ ) in the mid-plane close to the star (within approximately 1 AU where the ionization is thermal) and far away from the star (beyond 20 AU where ionizing cosmic rays and X-rays penetrate to the mid-plane). Accretion through the “dead zone,” situated between these regions of active turbulence, can occur in ionized surface layers far above the mid-plane (*Oishi et al.*, 2007), from disk winds (*Bai and Stone*, 2013) and by purely hydrodynamical instabilities in the vertical shear of the gas (*Nelson et al.*, 2013) or radial convection arising from the subcritical baroclinic instability (*Klahr and Bodenheimer*, 2003; *Lesur and Papaloizou*, 2010). The mid-plane is believed to be stirred to a mild degree by these hydrodynamical instabilities or by perturbations from the active layers several scale-heights above the mid-plane, driving effective turbulent diffusivities in the interval from  $10^{-5}$  to  $10^{-3}$  in the mid-plane. The inner and outer edges of this “dead zone,” where the turbulent viscosity transitions abruptly, are also possible sites of pressure bumps and large-scale Rossby vortices that feed off the pressure bumps (*Lyra et al.*, 2008, 2009).

## 6.1. Streaming Instability

The low degree of turbulent stirring in the asteroid-formation region also facilitates the action of the streaming instability, a mechanism where particles take an active role in the concentration process (*Youdin and Goodman*, 2005; *Youdin and Johansen*, 2007; *Johansen and Youdin*, 2007). The instability arises from the speed difference between gas and solid particles. The gas is slightly pressure-supported in the direction pointing away from the star, due to the higher temperature and density close to the star, which mimics a reduced gravity on the gas. The result is that the gas orbital speed is approximately 50 m s<sup>-1</sup> slower than the Keplerian speed at any given distance from the star. Solid particles are not affected by the global pressure gradient — they would move at the Keplerian speed in the absence of drag forces, but drift radially due to the friction from the slower-moving gas. The friction exerted from the particles back onto the gas leads to an instability whereby a small overdensity of particles accelerates the gas and diminishes the difference from the Keplerian speed. The speed increase in turn reduces the local headwind on the dust. This slows down the radial drift of particles locally, which leads to a runaway process

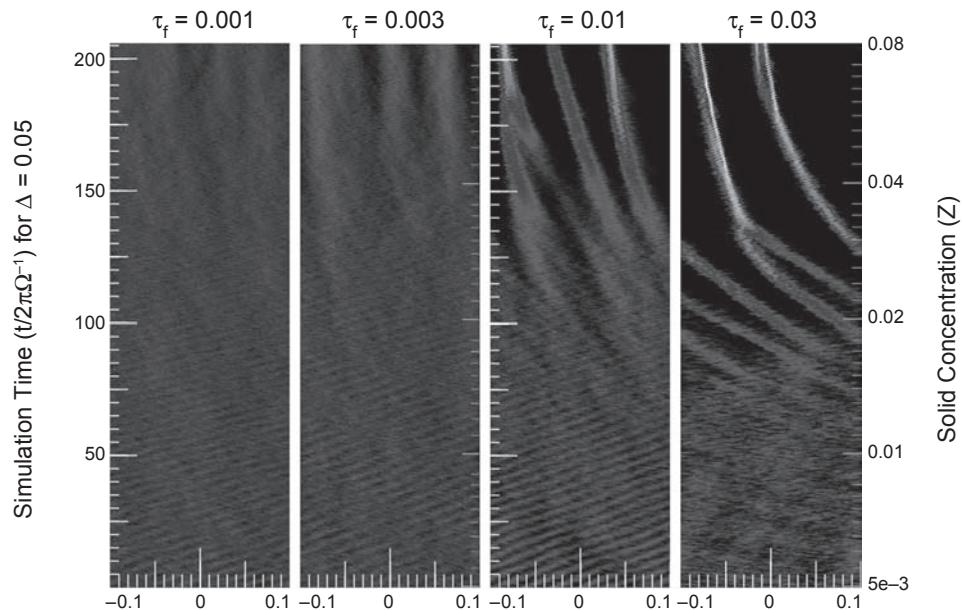

where isolated particles drift into the convergence zone and the density increases exponentially with time. This picture is a bit simplified, as *Youdin and Goodman* (2005) and *Jacquet et al.* (2011) showed that the streaming instability operates only in the presence of rotation, i.e., the instability relies on the presence of Coriolis forces. This explains why the instability occurs on relatively large scales of the protoplanetary disk where Coriolis forces are important, typically a fraction of an astronomical unit, and operates most efficiently on large particles with frictional coupling times around one-tenth of the orbital timescale (typically decimeter sizes at the location of the asteroid belt).

## 6.2 Computer Simulations of the Streaming Instability

Computer simulations that follow the evolution of the streaming instability into its nonlinear regime show the emergence of axisymmetric filaments with typical separations of  $0.2 \times$  the gas scale-height (*Yang and Johansen*, 2014) and local particle densities reaching several thousand times the gas density (*Bai and Stone*, 2010; *Johansen et al.*, 2012). These high densities trigger the formation of large planetesimals (100–1000 km in diameter) by gravitational fragmentation of the filaments (*Johansen et al.*, 2007), although planetesimal sizes decrease to approximately 100 km for a particle column density comparable to that of the solar protoplanetary disk (*Johansen et al.*, 2012).

An important question concerning planetesimal formation through the streaming instability is whether the process can operate for particles as small as chondrules in the asteroid belt. In Fig. 3, we show numerical experiments from *Carrera et al.* (2015) on the streaming instability in particles with sizes down to a fraction of a millimeter. The streaming instability requires a threshold particle mass loading  $Z = \Sigma_p/\Sigma_g$ , where  $\Sigma_p$  and  $\Sigma_g$  are the particle and gas column densities, to trigger the formation of overdense filaments (*Johansen et al.*, 2009b; *Bai and Stone*, 2010). The simulations in Fig. 3 start at  $Z = Z_0 = 0.01$ , but the particle mass-loading is continuously increased by removing the gas on a timescale of 30 orbital periods. This was done to identify how the critical value of  $Z$  depends on the particle size. The result is that overdense filaments form already at  $Z = 0.015$  for centimeter-sized particles, while large chondrules of millimeter sizes require  $Z = 0.04$  to trigger filament formation. Chondrules smaller than millimeters do not form filaments even at  $Z = 0.08$ .

A lowered gas column density may thus be required to trigger concentration of chondrule-sized particles by the streaming instability. It is possible that the solar protoplanetary disk had a lower gas density than what is inferred from the current mass of rock and ice in the planets (which multiplied by 100 gives the MMSN), if the planet-forming regions of the nebula were fed by pebbles drifting in from larger orbital distances (*Birnstiel et al.*, 2012). In this picture the growing planetesimals and planets are fed by drifting pebbles, so that the current mass of the planets was achieved by the integrated capture efficiency of the drifting solids; this

**Fig. 3.** Space-time plots of particle concentration by streaming instabilities, from Carrera et al. (2015), with the x-axis indicating the radial distance from the center of the simulation box and the y-axis the time (on the left) and the dust-to-gas ratio (on the right). The four columns show particle sizes 0.8 mm ( $\tau_f = 0.001\Omega^{-1}$ ), 2.4 mm ( $\tau_f = 0.003\Omega^{-1}$ ), 8 mm ( $\tau_f = 0.01\Omega^{-1}$ ), and 2.4 cm ( $\tau_f = 0.03\Omega^{-1}$ ). Simulations start with a mean dust-to-gas ratio of  $Z = 0.01$ , but gas is removed on a timescale of 30 orbits (1 orbit =  $2\pi\Omega^{-1}$ ), increasing the dust-to-gas ratio accordingly. While centimeter-sized particles concentrate in overdense filaments already at a modest increase in dust-to-gas ratio to  $Z = 0.015$ , smaller particles require consecutively increasing gas removal to trigger clumping.

allows for gas column densities lower than in the MMSN to be consistent with the current masses of planets in the solar system. The gas will also be removed by accretion and photoevaporation (Alexander and Armitage, 2006). The high mass-loading in the gas could be obtained through pileup by radial drift and release of refractory grains near the iceline (Sirono, 2011).

Turbulence as weak as  $\alpha \sim 10^{-7}$  is necessary to allow the sedimentation of chondrules (with  $St \sim 10^{-3}$ ) into a thin mid-plane layer with scale-height  $H_p = 0.01H_g$  and  $\rho_p \approx \rho_g$  (see equation (2)), the latter being a necessary density criterion for activating particle pileup by streaming instabilities. Very low levels of  $\alpha$  are consistent with protoplanetary disk models where angular momentum is transported by disk winds and the mid-plane remains laminar (Bai and Stone, 2013), except for mild stirring by Kelvin-Helmholtz (Youdin and Shu, 2002) and streaming instabilities (Bai and Stone, 2010).

Weak turbulence also facilitates the formation of decimeter-sized chondrule aggregates (Ormel et al., 2008), which would concentrate much more readily in the gas. Stirring by hydrodynamical instabilities in the mid-plane, such as the vertical shear instability (Nelson et al., 2013), would preclude significant sedimentation of chondrule-sized particles and affect the streaming instability, as well as the formation of chondrule aggregates, negatively. An alternative possibility is that the first asteroid seeds in fact did not form from

chondrules (or chondrule aggregates), but rather from larger icy particles that would have been present in the asteroid-formation region in stages of the protoplanetary disk where the iceline was much closer to the star (Martin and Livio, 2012; Ros and Johansen, 2013). Chondrules could have been incorporated by later chondrule accretion (see section 7).

## 7. LAYERED ACCRETION

The turbulent concentration model and the streaming instability, reviewed in the previous sections, are the leading contenders for primary accretion of chondrules into chondrites. However, neither of the two are completely successful in explaining the dominance of chondrules in chondrites: The turbulent concentration models may not be able to concentrate sufficient amounts for gravitational collapse, while the streaming instability relies on the formation of chondrule aggregates and/or gas depletion and pileup of solid material from the outer parts of the protoplanetary disk. In the layered accretion model the chondrules are instead accreted onto the growing asteroids over millions of years after the formation of the first asteroid seeds — those first seeds forming by direct coagulation from a population of 100-m-sized planetesimals as envisioned in Weidenschilling (2011) or by one or more of the particle concentration mechanisms described in the previous sections.

## 7.1. Chondrule Accretion

Chondrules are perfectly sized for drag-force-assisted accretion onto young asteroids. The ubiquity of chondrules inside chondrites, and their large age spread (Connelly et al., 2012), indicates that planetesimals formed and orbited within a sea of chondrules. Chondrules would have been swept past these young asteroids with the sub-Keplerian gas. The gas is slightly pressure-supported in the radial direction and hence moves slower than the Keplerian speed by the positive amount  $\Delta v$  (Weidenschilling, 1977b; Nakagawa et al., 1986). The Bondi radius  $R_B = GM/(\Delta v)^2$  marks the impact parameter for gravitational scattering of a chondrule by an asteroid of mass  $M$ , with

$$\frac{R_B}{R} = 0.87 \left( \frac{R}{50 \text{ km}} \right)^2 \left( \frac{\Delta v}{53 \text{ m s}^{-1}} \right)^{-2} \left( \frac{\rho_*}{3.5 \text{ g cm}^{-3}} \right) \quad (4)$$

Here we have normalized by  $\Delta v = 53 \text{ m s}^{-1}$ , the nominal value in the MMSN model of Hayashi (1981), and used the chondrule density  $\rho_* = 3.5 \text{ g cm}^{-3}$  as a reference value. Chondrules with friction time comparable to the Bondi timescale  $t_B = R_B/\Delta v$  are accreted by the asteroid (Johansen and Lacerda, 2010; Ormel and Klahr, 2010; Lambrechts and Johansen, 2012). The accretion radius  $R_{\text{acc}}$  can be calculated numerically as a function of asteroid size and chondrule size by integrating the trajectory of a chondrule moving with the sub-Keplerian gas flow past the asteroid. The accretion radius peaks at  $R_{\text{acc}} \approx R_B$  for  $t_f/t_B$  in the range from 0.5 to 10 (Lambrechts and Johansen, 2012). Accretion at the full Bondi radius happens for particle sizes

$$a = [0.008, 0.16] \text{ mm} \left( \frac{R}{50 \text{ km}} \right)^3 \left( \frac{\Delta v}{53 \text{ m s}^{-1}} \right)^{-3} \times \left( \frac{r}{2.5 \text{ AU}} \right)^{-3} \left( \frac{\Sigma_g}{\Sigma_{\text{MMSN}}} \right) \quad (5)$$

An asteroid of radius 50 km thus “prefers” to accrete chondrules of sizes smaller than 0.1 mm, corresponding to the smallest chondrules found in chondrites. At 100 km in radius, the preferred chondrule size is closer to 0.2 mm, a 200-km-radius body prefers millimeter-sized chondrules, and larger bodies can only grow efficiently if they can accrete chondrules of several millimeters or centimeters in diameter. Carbonaceous chondrites accreted significant amounts of CAIs and matrix together with their chondrules; Rubin (2011) suggested that matrix was accreted in the form of centimeter-sized porous aggregates with aerodynamical friction time comparable to chondrules and CAIs.

Aerodynamical accretion of chondrules could explain the narrow range of chondrule sizes found in the various classes of meteorites. The model predicts that asteroids accrete increasingly larger chondrules as they grow. This prediction

may be at odds with the little variation in chondrule sizes found within chondrite classes [70% of EH3 and CO3 chondrules have apparent diameters within a factor of 2 of the mean apparent diameters in the group, according to Rubin (2000)]. The least-metamorphosed LL chondrites nevertheless do seem to host on the average larger chondrules (Nelson and Rubin, 2002). More metamorphosed LL chondrites actually show a lack of small chondrules; this could be due to the fact that the smallest chondrules disappeared from the strongly heated central regions of the parent body.

## 7.2 Chondrule Accretion Rates

The accretion rate of chondrules (and other macroscopic particles) is

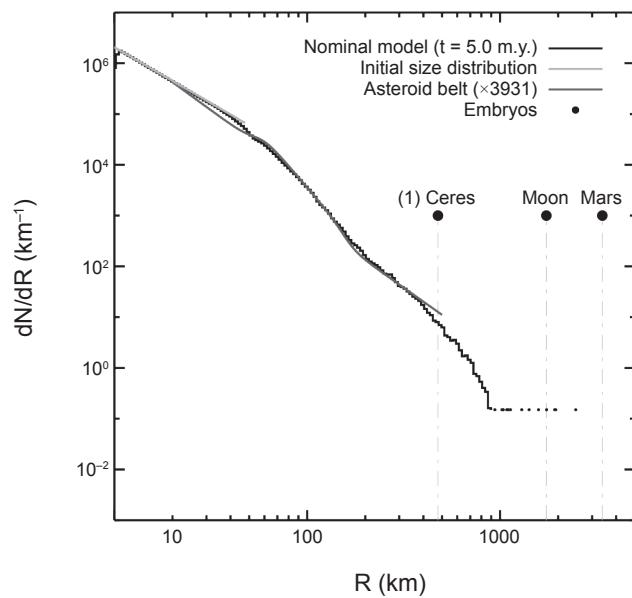

$$\dot{M} = \pi f_B^2 R_B^2 \rho_p \Delta v \quad (6)$$

Here  $f_B$  parameterizes the actual accretion radius relative to the Bondi radius and  $\rho_p$  is the chondrule density. Accretion of chondrules is a runaway process, since  $\dot{M} \propto R_B^2 \propto M^2$  if the optimal chondrule size is present (so that  $f_B = 1$  in equation (6)). The characteristic growth timescale is

$$t_{\text{exp}} = \frac{M}{\dot{M}} = 1.66 \text{ m.y.} \left( \frac{R}{50 \text{ km}} \right)^{-3} \left( \frac{\Delta v}{53 \text{ m s}^{-1}} \right)^3 \times \left( \frac{r}{2.5 \text{ AU}} \right)^{2.75} \left( \frac{\Sigma_g}{\Sigma_{\text{MMSN}}} \right)^{-1} \left( \frac{\rho_*}{3.5 \text{ g cm}^{-3}} \right)^{-1} \quad (7)$$

We assumed here that the chondrules have sedimented to a thin mid-plane layer of thickness 1% relative to the gas scale-height. The strong dependence of the accretion rate on the planetesimal mass will drive a steep differential size distribution of a population of planetesimals accreting chondrules. This is illustrated in Fig. 4, where asteroid seeds with initial sizes from 10 to 50 km in radius have been exposed to chondrule accretion over 5 m.y. The value of the turbulent viscosity is  $\alpha = 2 \times 10^{-6}$ . The resulting differential size distribution (which manifests itself after around 3 m.y. of chondrule accretion) shows a bump at 70 km in radius, a steep decline toward 200 km in radius, and finally a slower decline toward larger asteroids. The shallower decline is caused by the lack of centimeter-sized particles needed to drive the continued runaway accretion of large asteroids (this can be seen as a drop in  $f_B$  in equation (6)). All the features in the size distribution in Fig. 4 are in good agreement with features of the observed size distribution of asteroids that are not explained well in coagulation models (Morbidelli et al., 2009).

Layered accretion of chondrules can readily explain the large age spread of individual chondrules inside chondrites (Connelly et al., 2012), as well as the remnant magnetization of the Allende meteorite (Elkins-Tanton et al., 2011), imposed on the accreted chondrules from the internal dynamo in the

**Fig. 4.** The size distribution of asteroids and planetary embryos after accreting chondrules with sizes from 0.1 to 1.6 mm in diameter for 5 m.y. The original asteroid sizes had sizes between 10 and 50 km in radius (light gray line), here envisioned to form by the streaming instability in a population of decimeter-sized icy particles. The resulting size distribution of asteroids is in good agreement with the bump at 70 km in radius, the steep size distribution from 70 km to 200 km, and the shallower size distribution of larger asteroids whose chondrule accretion is slowed down by friction within their very large Bondi radius. Figure based on Johansen *et al.* (2015).

parent body's molten core. Efficient chondrule accretion requires, as does the streaming instability discussed in the previous section, sedimentation of chondrules to a thin mid-plane layer. The turbulent viscosity of  $\alpha = 2 \times 10^{-6}$  in Fig. 4 is nevertheless significantly larger than the  $\alpha \sim 10^{-7}$  needed to sediment chondrules to a thin mid-plane layer of thickness 1% of the gas scale height; indeed the timescale to grow to the current asteroid population is 3 m.y. in the simulation shown in Fig. 4, about twice as long as in equation (7), but in good agreement with the ages of the youngest chondrules.

## 8. OPEN QUESTIONS

The formation of asteroids is a complex problem that will only be solved through a collective effort from astronomers, planetary scientists, and cosmochemists. Although many details of asteroid formation are still not understood, we hope to have convinced the reader that new insights have been achieved in many areas in the past years. Here we highlight 10 areas of open questions in which we believe that major progress will be made in the next decade:

1. *Short-lived radionuclides.* What is the origin of the short-lived radioactive elements that melted the differentiated parent bodies? Was  $^{26}\text{Al}$  heterogeneous in the solar protoplanetary disk? How did the young solar system

become polluted in  $^{26}\text{Al}$  without receiving large amounts of  $^{60}\text{Fe}$ , an element that is copiously produced in supernovae?

2. *Maintaining free-floating chondrules and CAIs.* How is it possible to preserve chondrules and CAIs for millions of years in the disk before storing them in a chondritic body, without mixing them too much to erase chondrule classes and chondrule-matrix complementarity? What are we missing that makes this issue so paradoxical?

3. *Chondrules vs. matrix.* Why do carbonaceous chondrites contain large amounts of matrix while ordinary chondrites contain very little matrix? Did the matrix enter the chondrites as (potentially icy) "matrix lumps" or on fine-grained rims attached to chondrules and other macroscopic particles?

4. *Initial asteroid sizes.* What is the origin of the steep differential size distribution of asteroids beyond the knee at 100 km? Did asteroids form small as in the coagulation picture, medium-sized as in the layered accretion model, or large as in some turbulent concentration models? Why do Kuiper belt objects, which formed under very different conditions in temperature and density, display a similar size distribution as asteroids?

5. *The origin of asteroid classes.* How is the radial gradient of asteroid composition produced and retained in the presence of considerable preaccretionary turbulent mixing and postaccretionary dynamical mixing? Is asteroid formation a continuous process that happens throughout the lifetime of the protoplanetary disk? What do the different chondrite groups mean in terms of formation location and time?

6. *Dry and wet chondrites.* Why do we have dry chondrites (enstatite, ordinary)? If chondrites form at 2–4 m.y. after CAIs, then the snowline should have been well inside the inner edge of the asteroid belt. Are there overlooked heating sources that could keep the iceline at 3 AU throughout the lifetime of the protoplanetary disk? Or did the asteroid classes form at totally different places only to be transported to their current orbits later?

7. *Internal structure of asteroids.* Does the chondrite and asteroid family evidence suggest that the primary asteroids — before internal heating — are homogeneous, roughly 100-km-diameter bodies composed of a physically, chemically, and isotopically homogeneous mix of chondrule-sized components? Or is internal heterogeneity, as may be the case for the Allende parent body, prevalent?

8. *Turbulent concentration of chondrules.* Under what nebula conditions can vortex tubes over a range of nebula scales concentrate enough chondrules into volumes that are gravitationally bound, at a high enough rate to produce the primordial asteroids and meteorite parent bodies directly? What other roles could turbulent concentration play in planetesimal formation given that the optimally concentrated particle is chondrule-sized under nominal values of the turbulent viscosity?

9. *Streaming instability with chondrules.* Will the conditions for streaming instabilities to concentrate chondrule-sized particles, i.e., gas depletion and/or particle pileup, be fulfilled in the protoplanetary disk? How does an overdense

filament of chondrule-sized particles collapse under self-gravity given the strong support by gas pressure?

10. *Layered accretion.* What is the origin of the apparent scarcity of heterogeneous asteroid families, given that asteroids orbiting within an ocean of chondrules should accrete these prodigiously? What is the thermal evolution of early-formed asteroid seeds that continue to accrete chondrules over millions of years?

**Acknowledgments.** A.J. was supported by the Swedish Research Council (grant 2010-3710), the European Research Council under ERC Starting Grant agreement 278675-PEBBLE2PLANET, and the Knut and Alice Wallenberg Foundation. He would like to thank B. Weiss for stimulating discussions on layered accretion. E.J. wishes to remember his colleague and friend G. Barlet (1985–2014), who as a short-lived radionuclide theorist and chondrule/refractory inclusion specialist would certainly have contributed to the new paradigms discussed herein, true to his attachment to interdisciplinary interactions, but left us far too early. J.C. thanks C. Ormel for a careful reading, and E. Scott, A. Rubin, N. Kita, and G. Wasserburg for helpful comments and references. We would like to thank A. Rubin and an additional anonymous referee for insightful referee reports.

---

The asteroid belt is the remnant of the original planetesimal population in the inner solar system. However, the asteroids currently have orbits with all possible values of eccentricities and inclinations compatible with long-term dynamical stability, whereas the initial planetesimal orbits should have been quasicircular and almost coplanar. The total mass now contained in the asteroid population is a small fraction of that existing primordially. Also, asteroids with different chemical/mineralogical properties are not ranked in an orderly manner with mean heliocentric distance (orbital semimajor axis) as one might expect from the existence of a radial gradient of the temperature in the protoplanetary disk, but they are partially mixed. These properties show that the asteroid belt has been severely sculpted by one or a series of processes during its lifetime. This paper reviews the processes that have been proposed so far, discussing the properties that they explain and the problems with which they are confronted. Emphasis is paid to the interplay between the dynamical and the collisional evolution of the asteroid population, which allows the use of the size distribution or crater densities observed in the asteroid belt to constrain the dynamical models. We divide the asteroid belt evolution into three phases. The first phase started during the lifetime of the gaseous protoplanetary disk, when the giant planets formed and presumably experienced large-scale migrations, and continued after the removal of the gas, during the buildup of the terrestrial planets. The second phase occurred after the removal of the gaseous protoplanetary disk, and it became particularly lively for the asteroid belt when the giant planets suddenly changed their orbits as a result of a mutual dynamical instability and the interaction with the transneptunian planetesimal disk. The third phase covers the aftermath of the giant-planet instability through the present day.

## 1. INTRODUCTION

The asteroid belt helps us in reconstructing the origin and the evolution of the solar system, probably better than the planets themselves. This is because the asteroid belt provides several key constraints that can be used to effectively guide the development, calibration, and validation of evolutionary models. Compared to other small-body populations, such as the Kuiper belt or Oort cloud, the constraints provided by the asteroid belt are probably more stringent, due to the fact that the number and the properties of the asteroids are better known, thanks to groundbased observations, space missions, and meteorite analysis.

The structure of this review chapter is therefore as follows. We start by reviewing in section 2 what the most important observational constraints on the asteroid belt are and what they suggest. Then, in section 3, we will review the main models proposed, from the oldest to the most recent, and from the earliest to the latest evolutionary phases they address. In section 4, we will discuss several implications for asteroid science from our current preferred view of the dynamical evolution of the asteroid belt.

The dynamical evolution of the asteroid belt has already been the object of a review chapter by Petit *et al.* (2002) in the *Asteroids III* book. This review therefore has an important overlap with that chapter. Nevertheless, both our

observational knowledge of the asteroid belt and our theoretical understanding of solar system evolution have improved significantly since the early 2000s, providing an emerging view of a very dynamic early solar system, in which various episodes of planet migration played a fundamental role in sculpting the small-body reservoirs and displacing planetesimals far from their original birthplaces. Thus this chapter will present in greater details models proposed after 2002, focusing on their implications for asteroid science. Moreover, when reviewing models already presented in Petit et al., we will refer to numerical simulations of these models made after the publication of the Petit et al. chapter.

## 2. OBSERVATIONAL CONSTRAINTS ON THE PRIMORDIAL EVOLUTION OF THE ASTEROID BELT

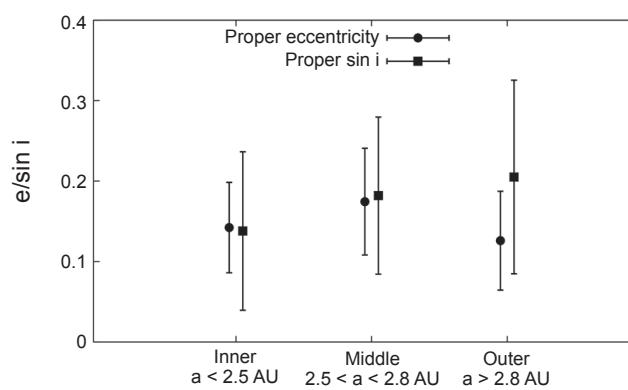

The observational constraints most useful for reconstructing the formation and evolution of the asteroid belt are those related to large asteroids (larger than  $\sim 50$ – $100$  km in diameter). In fact, it has been argued that these asteroids are the most likely to be “pristine” in the sense that they were not generated in large numbers in collisional breakup events of larger parent bodies (Bottke et al., 2005a; see also the chapter by Bottke et al. in this volume), nor have they been affected by gas drag and other nongravitational forces (e.g., the Yarkovsky effect; see the chapter by Vokrouhlický et al. in this volume). Moreover, there is an emerging view that the first planetesimals were big, with a preferred diameter in the range mentioned above (Morbidelli et al., 2009; see also the chapter by Johansen et al. in this volume). Thus, throughout this chapter we will limit our discussion to the properties of large asteroids and refer to smaller asteroids only when explicitly mentioned.

A key major characteristic of the asteroid belt population is the orbital excitation, i.e., the fact that the eccentricities and inclinations of many asteroidal orbits are quite large (e.g., Petit et al., 2002). The median proper inclination of  $D > 100$  km asteroids is  $11^\circ$  and the median proper eccentricity is 0.145. More importantly, the values of eccentricities and inclinations of the largest asteroids are considerably dispersed, with the former ranging between 0 and 0.30, while the latter ranges between  $0^\circ$  and  $33^\circ$  (see Fig. 1). It has been shown that asteroids of modest inclinations ( $i < 20^\circ$ ) fill the entire orbital space available for long-term dynamical stability, although some stable regions are more densely populated than others (Minton and Malhotra, 2009, 2011). The reader should be aware that, whatever the preferred formation mechanism (see the chapter by Johansen et al. in this volume), planetesimals are expected to have formed on circular and coplanar orbits. Thus, one or more dynamical excitation mechanism(s) within the primordial asteroid belt were needed to stir up eccentricities and inclinations to randomly dispersed values. Asteroid eccentricities and inclinations do not show a strong dependence on semimajor axis (Fig. 1).

A second fundamental characteristic of the asteroid belt is the partial mixing of taxonomic classes. Asteroids can be

grouped into many taxonomic classes on the basis of their visual and infrared spectroscopic signatures (Tholen, 1984; Bus and Binzel, 2002; DeMeo et al., 2009). As shown first by Gradie and Tedesco (1982) for the largest asteroids, the inner belt is dominated by S-complex asteroids, many of which are probably related to the meteorites known as ordinary chondrites (Binzel et al., 1996; see also the chapter by Vernazza et al. in this volume). The central belt (2.5–3.2 AU) is dominated by C-complex asteroids, probably related to carbonaceous chondrites (Burbine et al., 2002; see also the chapters by DeMeo et al. and Rivkin et al. in this volume). The Cybeles asteroids (3.2–3.7 AU), the Hilda asteroids (in the 3:2 mean-motion resonance with Jupiter), and the Jupiter Trojan asteroids (in the 1:1 resonance with Jupiter) are dominated by P- and D-type asteroids (see the chapter by Emery et al. in this volume). The C2 ungrouped meteorite “Tagish Lake” has been proposed to be a fragment of a D-type asteroid (Hiroi et al., 2001).

This stratification of the main belt makes intuitive sense in terms of a general view that protoplanetary disks should have temperatures decreasing with increasing distance from the central star. In fact, ordinary chondrites are less abundant in organics and water than carbonaceous chondrites and therefore are more likely to have formed in a warmer part of the disk. The small water content in ordinary chondrites, well below the solar proportion, suggests that these bodies accreted closer to the Sun than the snowline. The fact that some water is nevertheless present is not in contradiction with this statement. A small amount of water could have been accreted by collisions with primitive bodies scattered or drifting into the inner part of the disk. At the opposite extreme, the CI meteorites show no chemical fractionation relative to the solar composition, except H, C, N, O, and all noble gases, suggesting that they formed in a region of

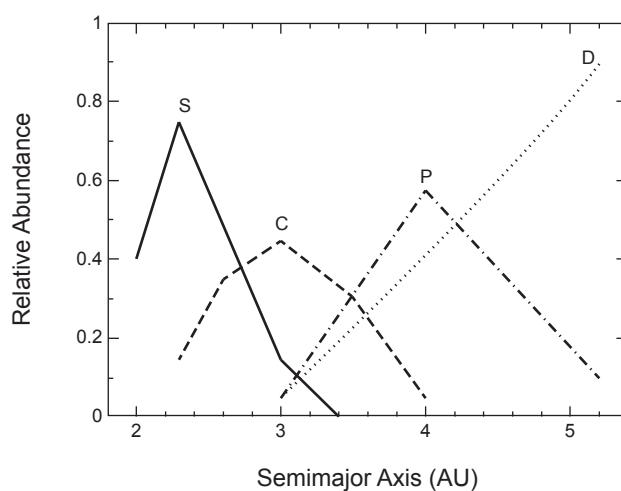

**Fig. 1.** The points show mean proper eccentricity (circles) and mean proper inclination (squares) for the  $D > 100$  km asteroids, divided into three bins of semimajor axis. The error bars show the  $1\sigma$  standard deviation. There is little systematic difference in excitation across the main belt. The slightly increase of inclination from the inner to the outer belt is due to the effect of the  $g = g_6$  secular resonance (see section 3), which most strongly affects high-inclination asteroids in the inner belt.

the disk where the temperature was low enough to allow the condensation of most elements.

As shown in Fig. 2, however, asteroids of different taxonomic types are partially mixed in orbital semimajor axis, which smears the trend relating physical properties to heliocentric distance. The mixing of taxonomic type should not be interpreted as the existence of asteroids of intermediate physical properties between those of adjacent types; instead, it is due to the coexistence of asteroids of different types with various relative proportions at each value of semimajor axis. Some mixing could come from the fact that the thermal and chemical compositional properties of the disk probably changed over time. However, given that no systematic differences in accretion ages is observed among the main group of chondrites (Villeneuve et al., 2009), it is more likely that some mechanism, possibly the same that excited the orbital eccentricities and inclinations, also changed somewhat in a random fashion the original semimajor axes of the bodies, causing the observed partial mixing.

The asteroid belt contains overall very little mass. From the direct determination of the masses of the largest asteroids and an estimate of the total mass of the ring of bodies, which cannot be individually “weighted,” based on the collective gravitational perturbations exerted on Mars, Krasinsky et al. (2002), Kuchynka and Folkner (2013), and Somenzi et al. (2010) concluded that the total mass contained in the asteroid belt is  $\sim 4.5 \times 10^{-4}$  Earth masses ( $M_{\oplus}$ ). This value is very low compared to that estimated to have originally existed in the primordial asteroid belt region by interpolating the mass densities required to form the terrestrial planets and the core of Jupiter at both ends of the belt (Weidenschilling, 1977), which is on the order of  $1 M_{\oplus}$  (within a factor of a few). Thus, the mass in the asteroid belt has potentially been depleted by 3 orders of magnitude compared to these expectations.

**Fig. 2.** The relative distribution of large asteroids ( $D > 50$  km) of different taxonomic types as originally observed by Gradie and Tedesco (1982). Further works by Mothé-Diniz et al. (2003), Carvano et al. (2010), and DeMeo and Carry (2014) demonstrate that the level of mixing increases for smaller asteroid sizes.

We can glean insights into how the primordial belt lost its mass by investigating what we know about its collisional evolution. The collisional history of asteroids is the subject of the chapter by Bottke et al. in this volume, but we report the highlights here that are needed for this discussion. In brief, using a number of constraints, Bottke et al. (2005a) concluded that the integrated collisional activity of the asteroid belt is equivalent to the one that would be produced at the current collisional rate over 8–10 G.y.

This result has several implications. First, it strongly suggests that the 3-orders-of-magnitude mass depletion could not come purely from collisional erosion; such intense comminution would violate numerous constraints. Second, it argues that the mass depletion of the asteroid belt occurred very early. This is because once the eccentricities and inclinations are excited to values comparable to the current ones, for a given body every million years spent in an asteroid belt 1000× more populated brings a number of collisions equivalent to that suffered in 1 G.y. within the current population. For this reason, the third implication is that the dynamical excitation and the mass-depletion event almost certainly coincided. This argues that the real dynamical excitation event was stronger than suggested by the current distribution of asteroid eccentricities. One way to reconcile a massive asteroid belt with this scenario is to assume that more than 99% of the asteroids had their orbits so excited that they left the asteroid belt forever (hence the mass depletion). This would make the eccentricities (and to a lesser extent the inclinations) we see today to be those defined by the lucky survivors, namely the bodies whose orbits were excited the least.

Using these constraints, we discuss in the next section the various models that have been proposed for the primordial sculpting of the asteroid belt.

### 3. MODELS OF PRIMORDIAL EVOLUTION OF THE ASTEROID BELT

#### 3.1. Early Models

The first attempts to explain the primordial dynamical excitation of the asteroid belt were made by Heppenheimer (1980) and Ward (1981), who proposed that secular resonances swept through the asteroid belt region during the dissipation of gas in the protoplanetary disk. Secular resonances occur when the precession rate of the orbit of an asteroid is equal to one of the fundamental frequencies of precession of the orbits of the planets. There are two angles that characterize the orientation of an orbit in space, the longitude of perihelion ( $\omega$ ) and the longitude of the ascending node ( $\Omega$ ), each of which can precess at different rates depending on the gravitational effects of the other planets and nebular gas (if present). The resonances that occur when the precession rates of the longitudes of perihelion of an asteroid (denoted by  $g$ ) and of a planet are equal to each other excite the asteroid’s eccentricity. Similarly, the resonances occurring when the precession rates of the longitudes of node of an asteroid (denoted by  $s$ ) and of a planet are equal to each other

excite the asteroid's inclination. In the case of asteroids in the main belt, the planets' precession frequencies that most influence their dynamics are those associated with the orbits of Jupiter and Saturn. These are called  $g_5$  and  $g_6$  for the longitude of perihelion precession (the former dominating in the precession of the perihelion of Jupiter, the latter in that of Saturn), and  $s_6$  for the longitude of the node precession (both the nodes of Jupiter and Saturn precess at the same rate, if measured relative to the *invariable plane*, defined as the plane orthogonal to their total angular momentum vector).

The dissipation of gas from the protoplanetary disk changes the gravitational potentials that the asteroids and planets feel, and hence changes the precession rates of their orbits. Given that the planets and asteroids are at different locations, they will be affected somewhat differently by this change of gravitational potential and consequently their precession rates will not change proportionally. It is therefore possible that secular resonances sweep through the asteroid belt as the gas dissipates. This means that every asteroid, whatever its location in the belt, first has orbital precession rates slower than the  $g_5$ ,  $g_6$  frequencies of Jupiter and Saturn when there is a lot of gas in the disk, then enters resonance ( $g = g_5$  or  $g = g_6$ ) when some appropriate fraction of the gas has been removed, and eventually is no longer in resonance (its orbital precession frequency being faster than those of the giant planets, i.e.,  $g > g_6$ ) after all the gas has disappeared. The same occurs for the asteroid's nodal frequency  $s$  relative to the planetary frequency  $s_6$ . This sweeping of perihelion and nodal secular resonances has the potential to excite the orbital eccentricities and inclinations of all asteroids.

This mechanism of asteroid excitation due to disk dissipation has been revisited with numerical simulations in *Lemaître and Dubru* (1991), *Lecar and Franklin* (1997), *Nagasawa et al.* (2000, 2001, 2002), *Petit et al.* (2002), and finally by *O'Brien et al.* (2007). *Nagasawa et al.* (2000) found that of all the scenarios for gas depletion they studied (uniform depletion, inside-out, and outside-in), inside-out depletion of the nebula was most effective at exciting eccentricities and inclinations of asteroids throughout the main belt. However, they (unrealistically) assumed that the nebula coincided with the ecliptic plane. Protoplanetary disks can be warped, but they are typically aligned with the orbit of the locally dominant planet (*Mouillet et al.*, 1997). Thus, there is no reason that the gaseous disk in the asteroid belt region was aligned with the current orbital plane of Earth (which was not yet formed). Almost certainly it was aligned with the orbits of the giant planets. Taking the invariable plane (the plane orthogonal to the total angular momentum of the solar system) as a proxy of the original orbital plane of Jupiter and Saturn, *Nagasawa et al.* (2001, 2002) found that the excitation of inclinations would be greatly diminished. Furthermore, since nebular gas in the inside-out depletion scenario would be removed from the asteroid belt region before the resonances swept through it, there would be no gas drag effect to help deplete material from the main-belt region.

The work of *O'Brien et al.* (2007) accounted for the fact that the giant planets should have had orbits significantly

less inclined and eccentric than their current values when they were still embedded in the disk of gas, because of the strong damping that gas exerts on planets (*Cresswell et al.*, 2008; *Kley and Nelson*, 2012). They concluded that secular resonance sweeping is effective at exciting eccentricities and inclinations to their current values only if gas is removed from the inside-out and very slowly, on a timescale of  $\sim 20$  m.y. This gas-removal mode is very different from our current understanding of the photoevaporation process (*Alexander et al.*, 2014), and inconsistent with observations suggesting that disks around solar-type stars have lifetimes of only 1–10 m.y., with an average of  $\sim 3$  m.y. (e.g., *Strom et al.*, 1993; *Zuckerman et al.*, 1995; *Kenyon and Hartmann*, 1995; *Haisch et al.*, 2001).

Earlier studies found that the final eccentricities of the asteroids are quite randomized because two perihelion secular resonances sweep the entire asteroid belt in sequence: first the resonance  $g = g_5$ , then the resonance  $g = g_6$ . The first resonance excites the eccentricities of the asteroids from zero to approximately the same value, but the second resonance, sweeping an already excited belt, can increase or decrease the eccentricity depending on the position of the perihelion of each asteroid at the time of the encounter with the resonance (*Ward et al.*, 1976; *Minton and Malhotra*, 2011). *O'Brien et al.* (2007) found that when Jupiter and Saturn were on orbits initially closer together, as predicted by the Nice model (e.g., *Tsiganis et al.*, 2005), the resonance with frequency  $g_6$  would only sweep part of the outer belt, leading to less randomization of eccentricities in the inner belt. All studies in which the mid-plane of the protoplanetary disk of gas coincides with the invariable plane of the solar system find that the final inclinations tend to have comparable values. This is because there is only one dominant frequency ( $s_6$ ) in the precession of the nodes of Jupiter and Saturn and hence there is only one nodal secular resonance and no randomization of the final inclinations of the asteroids. Clearly, this is in contrast with the observations. For all these problems, the model of secular resonance sweeping during gas removal is no longer considered to be able to alone explain the excitation and depletion of the primordial asteroid belt.

An alternative model for the dynamical excitation of the asteroid belt was proposed by *Ip* (1987). In this model, putative planetary embryos are scattered out of the Jupiter region and cross the asteroid belt for some timescale before being ultimately dynamically ejected from the solar system. If the embryos are massive enough, their repeated crossing of the asteroid belt can excite and randomize the eccentricities and inclinations of the asteroids, through close encounters and secular effects. That scenario has been revisited by *Petit et al.* (1999), who found that, whatever the mass of the putative embryos, the resulting excitation in the asteroid belt ought to be very unbalanced. Excitation would be much stronger in the outer belt than in the inner belt (because the embryos come from Jupiter's region) and it would be much stronger in eccentricity than in inclination. By contrast, the main asteroid belt shows no such trend (see Fig. 1). So, again, this model has since been abandoned. If massive embryos have been

scattered from Jupiter's zone, they must have crossed the asteroid belt very briefly so that their limited effects could be completely overprinted by other processes, such as those discussed below.

### 3.2. Wetherill's Model

The first comprehensive model of asteroid belt sculpting, which linked the evolution of the asteroid belt with the process of terrestrial planet formation, was that proposed by Wetherill (1992) and later simulated in a number of subsequent papers (e.g., Chambers and Wetherill, 1998; Petit et al., 2001, 2002; O'Brien et al., 2006, 2007). In this model, at the time gas was removed from the system, the protoplanetary disk interior to Jupiter consisted of a bimodal population of planetesimals and planetary embryos, the latter with masses comparable to those of the Moon or Mars. Numerical simulations show that, under the effect of the mutual perturbations among the embryos and the resonant perturbations from Jupiter, embryos are generally cleared from the asteroid belt region, whereas embryos collide with each other and build terrestrial planets inside 2 AU. While they are still crossing the asteroid belt, the embryos also excite and eject most of the original resident planetesimals. Only a minority of the planetesimals (and often no embryos) remain in the belt at the end of the terrestrial planet formation process, which explains the mass depletion of the current asteroid population. The eccentricities and inclinations of the surviving asteroids are excited and randomized, and the remaining asteroids have generally been scattered somewhat relative to their original semimajor axes. A series of simulation snapshots demonstrating this process is shown in Fig. 3.

Whereas earlier simulations assumed that Jupiter and Saturn were originally on their current orbits, O'Brien et al. (2006, 2007) performed simulations with Jupiter and Saturn on the low-inclination, nearly circular orbits predicted in the Nice model. The resulting asteroids from a set of simulations with these initial conditions are shown in Fig. 4. Overall, the range of values compare well with those observed for the real asteroids, although the final inclination distribution is skewed toward large inclinations. The reason for this is that it is easier to excite a low-inclination asteroid to large eccentricity and remove it from the belt than it is for a high-inclination asteroid, because the encounter velocities with the embryos are slower and more effective in deflecting the low-inclination asteroid's orbit. Also, with the giant planets on nearly circular orbits, it takes longer to clear embryos from the asteroid belt, allowing more time to excite asteroids to large inclinations.

As noted earlier, the surviving asteroids have their orbital semimajor axes displaced from their original values, as a result of the embryos' gravitational scattering. O'Brien et al. (2007) found that the typical change in semimajor axis is on the order of 0.5 AU (comparable to earlier simulations), with a tail extending to 1–2 AU, and the semimajor axis can be either decreased or increased. This process can explain the partial mixing of taxonomic types. As shown in Fig. 2, the distribution of the S-type and C-type asteroids

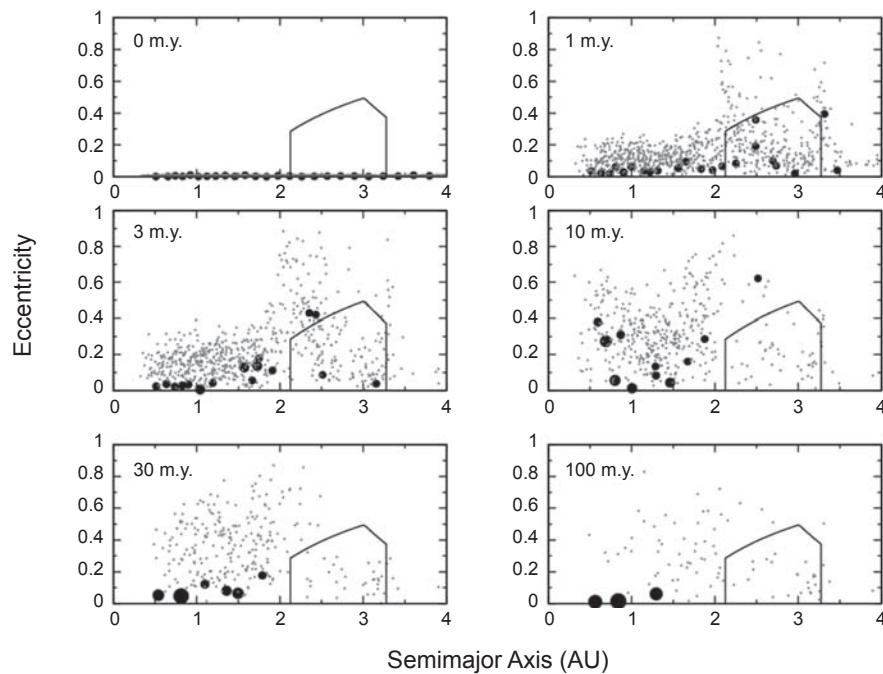

has a Gaussian-like shape, with a characteristic width of ~0.5 AU. Thus, if one postulates that all S-type asteroids originated from the vicinity of 2 AU and all C-type asteroids originated in the vicinity of 3 AU, Wetherill's model explains the current distribution.

### 3.3. The Grand Tack Model

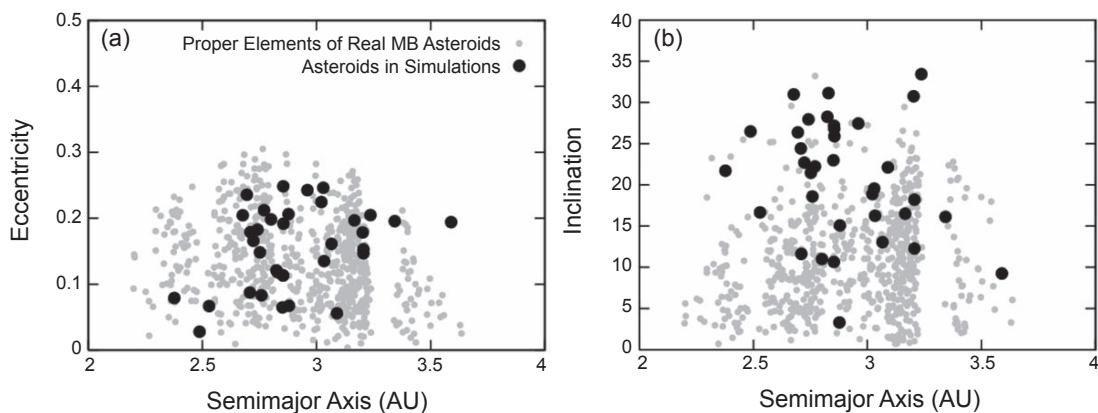

A more recent, alternative model to Wetherill's is the so-called Grand Tack scenario, proposed in Walsh et al. (2011). Initially the Grand Tack scenario had not been developed to explain the asteroid belt, but to answer two questions left open by Wetherill's model: Why is Mars so small relative to Earth? Why is Jupiter so far from the Sun despite planets having a tendency to migrate inward in protoplanetary disks? Nevertheless, this scenario has profound implications for the asteroid belt, as we discuss below.

The Grand Tack scenario is built on results from hydrodynamics simulations finding that Jupiter migrates toward the Sun if it is alone in the gas disk, while it migrates outward if paired with Saturn (Masset and Snellgrove, 2001; Morbidelli and Crida, 2007; Pierens and Nelson, 2008; Pierens and Raymond, 2011; D'Angelo and Marzari, 2012). Thus, the scenario postulates that Jupiter formed first. As long as the planet was basically alone, Saturn being too small to influence its dynamics, Jupiter migrated inward from its initial position (poorly constrained but estimated at ~3.5 AU) down to 1.5 AU. Then, when Saturn reached a mass close to its current one and an orbit close to that of Jupiter, Jupiter reversed migration direction (i.e., it "tacked," hence the name of the model) and the pair of planets started to move outward. This outward migration continued until the final removal of gas in the disk, which the model assumes happened when Jupiter reached a distance of ~5.5 AU. The migration of the cores of giant planets is still not fully understood (see Kley and Nelson, 2012, for a review). Thus, the Grand Tack model comes in two "flavors." In one, Saturn, while growing, migrates inward with Jupiter. In another, Saturn is stranded at a no-migration orbital radius until its mass exceeds  $50 M_{\oplus}$  (Bitsch et al., 2014), then it starts migrating inward and it catches Jupiter in resonance because it migrates faster. Both versions exist with and without Uranus and Neptune. All these variants are described in Walsh et al. (2011); the results are very similar in all these cases, which shows the robustness of the model, at least within the range of tested possibilities. The scheme presented in Fig. 5 has been developed in the framework of the first "flavor."

Assuming that Jupiter formed at the snowline (a usual assumption to justify the large mass of its core and its fast formation), the planetesimals that formed inside its initial orbit should have been mostly dry. It is therefore reasonable to associate these planetesimals (whose distribution is sketched as a dashed area in Fig. 5) with the S-type asteroids and other even dryer bodies (enstatite-type, Earth precursors, etc.). During its inward migration, Jupiter penetrates into the disk of these planetesimals. In doing so, most planetesimals (and planetary embryos) are captured in mean-motion resonances

**Fig. 3.** Snapshots of the evolution of the solar system and of the asteroid belt in a simulation of Wetherill's model performed in O'Brien *et al.* (2006) and assuming Jupiter and Saturn on initial quasicircular orbits. Each panel depicts the eccentricity vs. semimajor axis distribution of the particles in the system at different times, labeled on top. Planetesimals are represented with gray dots and planetary embryos by black circles, whose size is proportional to the cubic root of their mass. The solid lines show the approximate boundaries of the current main belt.

**Fig. 4.** The final eccentricities and inclinations of asteroids in Wetherill's (1992) model (black dots), according to the simulations presented in O'Brien *et al.* (2007). For comparison, the observed distribution of large asteroids is depicted with gray dots.

with Jupiter and are pushed inward, increasing the mass density of the inner part of the disk. However, some 10% of the planetesimals are kicked outward by an encounter with Jupiter, reaching orbits located beyond Saturn that collectively have an orbital ( $a, e$ ) distribution typical of a scattered disk (i.e., with mean eccentricity increasing with semimajor axis). In semimajor axis range, this scattered disk overlaps with the inner part of the disk of primitive bodies (whose distribution is sketched as a dotted area in Fig. 5) that are initially on circular orbits beyond the orbit of Saturn. These bodies, being formed beyond the snowline, should be rich

in water ice and other volatile elements, and therefore it is again reasonable to associate them with C-type asteroids.

After reaching  $\sim 1.5$  AU [this value is constrained by the requirement to form a small Mars and a big Earth (Walsh *et al.*, 2011; Jacobson *et al.*, 2014; Jacobson and Morbidelli, 2014)], Jupiter reverses its migration direction and begins its outward migration phase, during which the giant planets encounter the scattered S-type disk, and then also the primitive C-type disk. Some of the bodies in both populations are scattered inward, reach the asteroid-belt region, and are implanted there as Jupiter moves out of it.

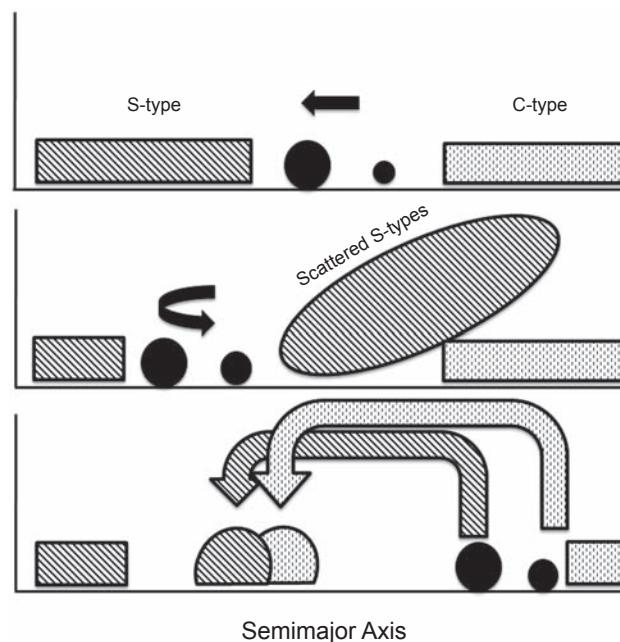

The final orbits of the planetesimals, at the end of the outward migration phase, are shown in Fig. 6. A larger dot size is used to highlight the planetesimals trapped in the asteroid belt region and distinguish them from those in the inner solar system or at eccentricities too large to be in the asteroid belt. Notice that the asteroid belt is not empty, although it has been strongly depleted (by a factor of several hundred relative to its initial population). This result is not trivial. One could have expected that Jupiter migrating through the asteroid belt twice (first inward then outward) would have completely removed the asteroid population, invalidating the Grand Tack scenario. The eccentricities and the inclinations of the particles in the asteroid belt are excited and randomized. The S-type particles (black) are found predominantly in the inner part of the belt and the C-type particles (gray) in the outer part, but there is a wide overlapping region where both are present. This is qualitatively consistent with what is observed.

As discussed above, the Grand Tack scenario solves open problems in Wetherill's model. The small mass of Mars is explained as a result of the disk of the remaining solid material being truncated at  $\sim 1$  AU (Hansen, 2009; Walsh et al., 2011). Fischer and Ciesla (2014) reported that they could obtain a small-mass Mars in a few percent of simulations conducted in the framework of Wetherill's model. However, the rest of the planetary system in these simulations does not resemble

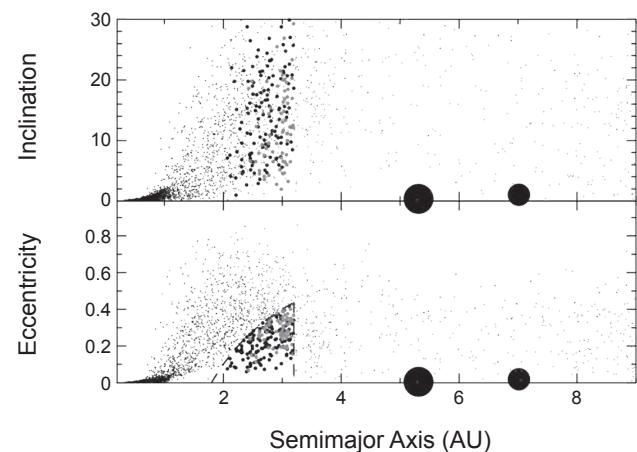

the real terrestrial planet system (Jacobson and Walsh, 2015). For instance, another massive planet is formed in the Mars region or beyond. The outward migration of Jupiter explains why the giant planets in our solar system are so far from the Sun, whereas most giant planets found so far around other stars are located at 1–2 AU. For all these reasons, one can consider the Grand Tack model more as an improvement of Wetherill's model than an alternative, because it is built in the same spirit of linking the asteroid belt sculpting to the evolution of the rest of the solar system (terrestrial planet formation and giant-planet migration, the latter of which was still unknown during Wetherill's time).

It is nevertheless interesting to compare the Grand Tack model and Wetherill's model on the basis of the final asteroid belts that they produce. Comparing Fig. 6 with Fig. 4, it is apparent that the Grand Tack model provides a better inclination distribution, more uniform than Wetherill's, but it produces a worse eccentricity distribution, which is now more skewed toward the upper eccentricity boundary of the asteroid belt.

As we will see in section 3.5, however, the eccentricity distribution can be remodeled somewhat during a later evolutionary phase of the solar system. This is also partially true for the inclination distribution. So, for what concerns the eccentricity and inclination distributions, one might declare a tie in the competition between the two models.

**Fig. 5.** A scheme showing the Grand Tack evolution of Jupiter and Saturn and its effects on the asteroid belt. The three panels show three evolutionary states in temporal sequence. First, the planets migrate inward, then, when Saturn reaches its current mass, they move outward. The dashed and dotted areas schematize the (a,e) distributions of S-type and C-type asteroids respectively. The dashed and dotted arrows in the lower panel illustrate the injection of scattered S-type and C-type asteroids into the asteroid belt during the final phase of outward migration of the planets.

**Fig. 6.** Final semimajor axis, eccentricity, and inclination distribution of bodies surviving the inward and outward migration of Jupiter and Saturn. The black particles were originally placed inside the initial orbit of Jupiter and the gray particles outside the initial orbit of Saturn. The particles finally trapped in the asteroid belt are depicted with larger symbols than the others. The dashed curve in the lower panel shows the approximate boundaries of the asteroid belt inward of the 2:1 resonance with Jupiter. This final distribution was achieved in the simulations of Walsh et al. (2011) accounting only for Jupiter and Saturn (i.e., not including Uranus and Neptune) moving together in the 2:3 resonance, as shown in Fig. 5.

The Grand Tack model makes it conceptually easier to understand the significant differences between S-type and C-type asteroids and their respective presumed daughter populations: the ordinary and carbonaceous chondrites. In fact, in the Grand Tack model these two populations are sourced from clearly distinct reservoirs on either side of the snowline. Instead, in Wetherill's model these bodies would have formed just at the two ends of the asteroid belt, so less than 1 AU apart. Despite such a vast difference in predicted formation locations for these two populations, the debate is open. Some authors (e.g., Alexander *et al.*, 2012) think that bodies formed in the giant-planet region would be much more similar to comets than to asteroids, while others (Gounelle *et al.*, 2008) argue that there is a continuum between C-type asteroids and comets and a clear cleavage of physical properties between ordinary and carbonaceous chondrites. We review the available cosmochemical constraints and their uncertain compatibility with the model in section 3.4.

A clear distinction between the Grand Tack model and Wetherill's model is that the former provides a faster and more drastic depletion of the asteroid belt. This point is illustrated in Fig. 7, which shows the fraction of the initial asteroid population that is in the main-belt region at any time.

The Grand Tack scenario depletes the asteroid belt down to 0.3%, and does so basically in 0.1 m.y. Assuming that the final asteroid belt consisted of one current asteroid belt mass in S-type asteroids and three current asteroid belt masses in C-type asteroids (the reason for 4 $\times$  more total mass in the asteroid belt will be clarified in section 3.6), this implies that the asteroid belt at  $t = 0$  should have contained  $0.6 M_{\oplus}$  in planetesimals (the rest in embryos). Also, a calculation of

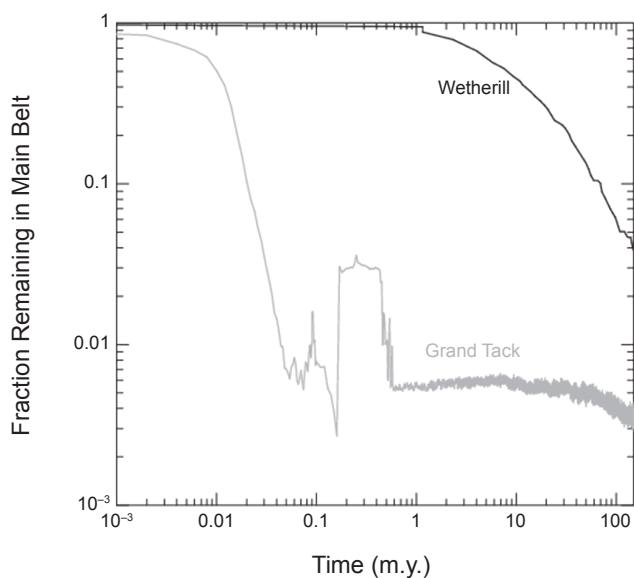

the collision probability of the asteroids as a function of time (both among each other and with the planetesimals outside the asteroid belt) shows that the integrated collisional activity suffered by the surviving asteroids during the first 200 m.y. would not exceed the equivalent of 4 G.y. in the current population. Thus, assuming that the exceeding factor of 4 in the asteroid population is lost within the next 500 m.y. (see sections 3.5 and 3.6), the integrated collisional activity of asteroids throughout the entire solar system age would probably remain within the 10-G.y. constraint described in section 2. In contrast, Wetherill's model depletes the asteroid belt on a timescale of 100 m.y. Also, about 2–3% of the initial population remains in the belt at the end. Thus, to be consistent with constraints on the current population and its integrated collisional activity, the initial mass in planetesimals in the asteroid-belt region should have been no larger than 200 $\times$  the current asteroid-belt mass, or less than one Mars mass (Bottke *et al.*, 2005b).

### 3.4. Are Cosmochemical Constraints Consistent with the Grand Tack Model?

The Grand Tack model predicts that C-type asteroids have been implanted into the asteroid belt from the giant-planet region. Is this supported or refuted by cosmochemical evidence?

Although there is a spread in values, the D/H ratios of carbonaceous chondrites (with the exception of CR chondrites) are a good match to Earth's water (Alexander *et al.*, 2012). Oort cloud comets are usually considered to have formed in the giant-planet region (e.g., Dones *et al.*, 2004). The D/H ratio was measured for the water from seven Oort cloud comets (see Bockelée-Morvan *et al.*, 2012, and references within). All but one [Comet 153P/Ikeya-Zhang (Biver *et al.*, 2006)] have water D/H ratios about twice as high as chondritic. This prompted Yang *et al.* (2013) to develop a model where the D/H ratio of ice in the giant-planet region is high. However, Brasser *et al.* (2007) showed that comet-sized bodies could not be scattered from the giant-planet region into the Oort cloud in the presence of gas drag (i.e., when the giant planets formed), and Brasser and Morbidelli (2013) demonstrated that the Oort cloud population is consistent with an origin from the primordial transneptunian disk at a later time. The recent measurement (Altweig *et al.*, 2014) of a high D/H ratio for the ice of Comet 67P/Churyumov-Gerasimenko, which comes from the Kuiper belt, supports this conclusion by showing that there is no systematic difference between Oort cloud comets and Kuiper belt comets. Care should therefore be taken in using Oort cloud comets as indicators of the D/H ratio in the giant-planet region. Conflicting indications on the local D/H ratio come from the analysis of Saturn's moons. Enceladus' D/H ratio is roughly twice Earth's (Waite *et al.*, 2009), but Titan's D/H ratio is Earth-like (Cousenit *et al.*, 2008; Abbas *et al.*, 2010; Nixon *et al.*, 2012).

Alexander *et al.* (2012) also noticed a correlation between D/H and C/H in meteorites and interpreted it as evidence

**Fig. 7.** The depletion of the asteroid belt in Wetherill's model (black) and Grand Tack model (gray). In the Grand Tack model notice the bump between 0.1 and 0.6 m.y. due to the implantation of primitive objects into the main belt. Overall, the depletion of the asteroid belt is faster and stronger in the Grand Tack model.

for an isotopic exchange between pristine ice and organic matter within the parent bodies of carbonaceous chondrites. From this consideration, they argued that the original water reservoir of carbonaceous asteroids had a D/H ratio lower than Titan, Enceladus, or any comet, again making asteroids distinct from bodies formed in the giant-planet region and beyond. However, a reservoir of pristine ice has never been observed; the fact that Earth's water and other volatiles are in chondritic proportion (Marty, 2012; however, see Halliday, 2013) means that carbonaceous chondrites — wherever they formed — reached their current D/H ratios very quickly, before delivering volatiles to Earth. It is also possible that the D/H ratio measured for comets and satellites might have been the result of a similar rapid exchange between a pristine ice and the organic matter.

Another isotopic constraint comes from the nitrogen isotope ratio. Comets seem to have a rather uniform  $^{15}\text{N}/^{14}\text{N}$  ratio (Rousselot et al., 2014). Even the comets with a chondritic D/H ratio [e.g., Comet Hartley 2 (Hartogh et al., 2011)] have a nonchondritic  $^{15}\text{N}/^{14}\text{N}$  ratio (Meech et al., 2011). The  $^{15}\text{N}/^{14}\text{N}$  ratio, however, is only measured in HCN or  $\text{NH}_2$ , never in molecular nitrogen ( $\text{N}_2$ ). Titan has a cometary  $^{15}\text{N}/^{14}\text{N}$  ratio as well [in this case measured in  $\text{N}_2$  (Niemann et al., 2010)]. Here, again, a few caveats are in order. First, it is difficult to relate the composition of a satellite, born from a circumplanetary disk with its own thermal and chemical evolution, to the composition of bodies born at the same solar distance but on heliocentric orbits. Second, it is unclear whether any comets for which isotope ratios have been measured originate from the giant-planet region, as opposed to the transneptunian disk (Brasser and Morbidelli, 2013). We also point out that hot spots with large  $^{15}\text{N}/^{14}\text{N}$  ratios are found in primitive meteorites (Busemann et al., 2006).

Arguments in favor of an isotopic similarity between carbonaceous chondrites and comets come from the analysis of micrometeorites. Most micrometeorites (particles of  $\sim 100 \mu\text{m}$  collected in the Antarctic ice) have chondritic isotopic ratios for H, C, N, and O [with the exception of ultracarbonaceous micrometeorites, which have a large D/H ratio, comparable to that in the organics of some chondrites, but which constitute only a minority of the micrometeorite population (Duprat et al., 2010)]. Yet according to the best available model of the dust distribution in the inner solar system (Nesvorný et al., 2010), which is compelling given that it fits the zodiacal light observations almost perfectly, most of the dust accreted by Earth should be cometary, even when the entry velocity bias is taken into account. Similarly, from orbital considerations, Gounelle et al. (2006) concluded that the CI meteorite Orgueil is a piece of a comet. Compelling evidence for a continuum between chondrites and comets also comes from the examination of Comet Wild 2 particles returned to Earth by the Stardust mission (e.g., Zolensky et al., 2006, 2008; Ishii et al., 2008; Nakamura et al., 2008).

These considerations suggest that if one looks at their rocky components, comets and carbonaceous asteroids are very similar from a compositional and isotopic point of view, if not in fact indistinguishable.

Finally, it has been argued that if the parent bodies of carbonaceous chondrites had accreted among the giant planets, they would have contained  $\sim 50\%$  water by mass. Instead, the limited hydrous alteration in carbonaceous meteorites suggests that only about 10% of the original mass was in water (A. N. Krot, personal communication, 2014; but see Alexander et al., 2010). However, a body's original water content cannot easily be estimated from its aqueous alteration. Even if alteration is complete, there is a finite amount of water that the clays can hold in their structures. Thus, the carbonaceous parent bodies may have been more water-rich than their alteration seems to imply. In fact, the discoveries of main-belt comets releasing dust at each perihelion passage (Hsieh and Jewitt, 2006), of water ice on asteroids Themis (Campins et al., 2010; Rivkin and Emery, 2010) and Cybele (Licandro et al., 2011; Hargrove et al., 2012), and of vapor plumes on Ceres (Kuppers et al., 2014) show that C-type asteroids are more rich in water than their meteorite counterpart seems to suggest, supporting the idea that they might have formed near or beyond the snowline. Meteorites may simply represent rocky fragments of bodies that were far wetter/icier.

Clearly, the debate on whether carbonaceous asteroids really come from the giant-planet region as predicted by the Grand Tack model is wide open. More data are needed from a broader population of comets. The investigation of main-belt comets, both remote and *in situ*, and the Dawn mission at Ceres will be key to elucidating the real ice content of carbonaceous asteroids and their relationship with classic "comets."

### 3.5. The Nice Model: A Second Phase of Excitation and Depletion for the Asteroid Belt

Figure 7 seems to suggest that after  $\sim 100$  m.y. the asteroid belt had basically reached its final state. However, at this time the orbits of the giant planets were probably still not the current ones. In fact, the giant planets are expected to have emerged from the gas-disk phase in a compact and resonant configuration as a result of their migration in the gas-dominated disk. This is true not only in the Grand Tack model, but in any model where Jupiter is refrained from migrating inside  $\sim 5$  AU by whatever mechanism (Morbidelli et al., 2007).

The transition of the giant planets from this early configuration to the current configuration is expected to have happened via an orbital instability, driven by the interaction of the planets with a massive disk of planetesimals located from a few astronomical units beyond the original orbit of Neptune to about 30 AU (Morbidelli et al., 2007; Batygin and Brown, 2010; Levison et al., 2011; Nesvorný, 2011; Batygin et al., 2012; Nesvorný and Morbidelli, 2012; see also a precursor work by Thommes et al., 1999). In essence, the planetesimals disturbed the orbits of the giant planets and, as soon as two planets fell off resonance, the entire system became unstable. In the simulations, the instability can occur early (e.g., Morbidelli et al., 2007) or late (Levison et al., 2011), depending on the location of the inner edge of the transneptunian disk.

Constraints suggest that in the real solar system the instability occurred relatively late, probably around 4.1 G.y. ago (namely 450 m.y. after gas removal). These constraints come primarily from the Moon. Dating lunar impact basins is difficult, because it is not clear which samples are related to which basin (e.g., *Norman and Nemchin*, 2014). Nevertheless, it is clear that several impact basins, probably a dozen, formed in the 4.1–3.8-Ga period (see *Fassett and Minton*, 2013, for a review). Numerical tests demonstrate that these late basins (even just Imbrium and Orientale, whose young ages are undisputed) are unlikely to have been produced by a declining population of planetesimals, left over from the terrestrial planet accretion process, because of their short dynamical and collisional lifetimes (*Bottke et al.*, 2007). There is also a surge in lunar rock impact ages ~4 G.y. ago, which contrasts with a paucity of impact ages between 4.4 and 4.2 Ga (*Cohen et al.*, 2005). This is difficult to explain if the bombardment had been caused by a population of leftover planetesimals slowly declining over time. The situation is very similar for the bombardment of asteroids, with meteorites showing a surge in impact ages at 4.1 Ga and a paucity of ages between 4.2 and 4.4 Ga (*Marchi et al.*, 2013). Meteorites also show many impact ages near 4.5 Ga, demonstrating that the apparent lack of events in the 4.2–4.4-Ga interval is not due to clock resetting processes. All these constraints strongly suggest the appearance of a new generation of projectiles in the inner solar system about 4.1 G.y. ago, which argues that either a very big asteroid broke up at that time (*Cuk*, 2012) (but such a breakup is very unlikely from collision probability arguments and we do not see any remnant asteroid family supporting this hypothesis), or that the dynamical instability of the giant planets occurred at that time, partially destabilizing small-body reservoirs that had remained stable until then.

Other constraints pointing to the late instability of the giant planets come from the outer solar system. If the planets had become unstable at the disappearance of the gas in the disk, presumably the Sun would still have been in a stellar cluster and consequently the Oort cloud would have formed more tightly bound to the Sun than it is thought to be from the orbital distribution of long-period comets (*Brasser et al.*, 2008, 2012). Also, the impact basins on Iapetus (a satellite of Saturn) have topographies that have relaxed by 25% or less, which argues that they formed in a very viscous lithosphere; according to models of the thermal evolution of the satellite, these basins can not have formed earlier than 200 m.y. after the beginning of the solar system (*Robuchon et al.*, 2011).

For all these reasons, it is appropriate to discuss the consequences of the giant-planet instability on the asteroid belt, after the events described by the Grand Tack or Wetherill's models. In fact, it is important to realize that the model of giant-planet instability (often called the Nice model) is not an alternative to the models described before on the early evolution of the asteroid belt; instead it is a model of the subsequent evolution.

The phase of giant-planet instability is very chaotic and therefore a variety of orbital evolutions are possible. Neverthe-

less, the planetary evolutions can be grouped in two categories. In the first category, Saturn, Uranus, and Neptune have close encounters with each other, but none of them have encounters with Jupiter. Saturn typically scatters either Uranus or Neptune outward and thus it recoils inward. As a result, Uranus and Neptune acquire large eccentricity orbits that cross the transneptunian disk. The dispersal of the planetesimal disk damps the eccentricities of the planets by dynamical friction and drives the planets' divergent migration in semimajor axis (*Tsiganis et al.*, 2005). Thus, the planets achieve stable orbits that are well separated from each other. The orbital separation between Jupiter and Saturn first decreases, when Saturn recoils, and then increases due to planetesimal-driven migration. The timescale for the latter is typically ~10 m.y. The slow separation between the two major planets of the solar system drives a slow migration of secular resonances across the asteroid belt (*Minton and Malhotra*, 2009, 2011) and the terrestrial planet region (*Brasser et al.*, 2009). The problem is that the resulting orbital distribution in the asteroid belt is very uneven, as shown in Fig. 8a, with most asteroids surviving at large inclination (*Morbidelli et al.*, 2010), and the orbits of the terrestrial planets become too excited (*Brasser et al.*, 2009; *Agnor and Lin*, 2012).

In the second category of evolutions, Saturn scatters an ice giant planet (Uranus, Neptune, or a putative fifth planet) inward, thus recoiling outward, and then Jupiter scatters the ice giant outward, thus recoiling inward. The interaction with the planetesimals eventually damps and stabilizes the orbits of the planets. In this evolution, dubbed “jumping-Jupiter,” the orbital separation between Jupiter and Saturn initially jumps, when Saturn recoils outward and Jupiter inward; then there is a final smooth phase of separation, due to planetesimal-driven migration. In the jump, the secular resonances can jump across the asteroid belt (*Morbidelli et al.*, 2010) and across the terrestrial planet region (*Brasser et al.*, 2009) without disrupting their orbital structure (see Fig. 8b).

The jumping-Jupiter evolution also explains the capture of the irregular satellites of Jupiter with an orbital distribution similar to those of the irregular satellites of the other giant planets (*Nesvorný et al.*, 2007, 2014). It can also explain the capture of Jupiter's Trojans in uneven proportions around the L4 and L5 Lagrangian points (*Nesvorný et al.*, 2013; see also the chapter by Emery et al. in this volume). So far, no other model is capable of achieving these results. For all these reasons, simulated solar system evolutions these days are required to show a jumping-Jupiter evolution to be declared successful (*Nesvorný and Morbidelli*, 2012).

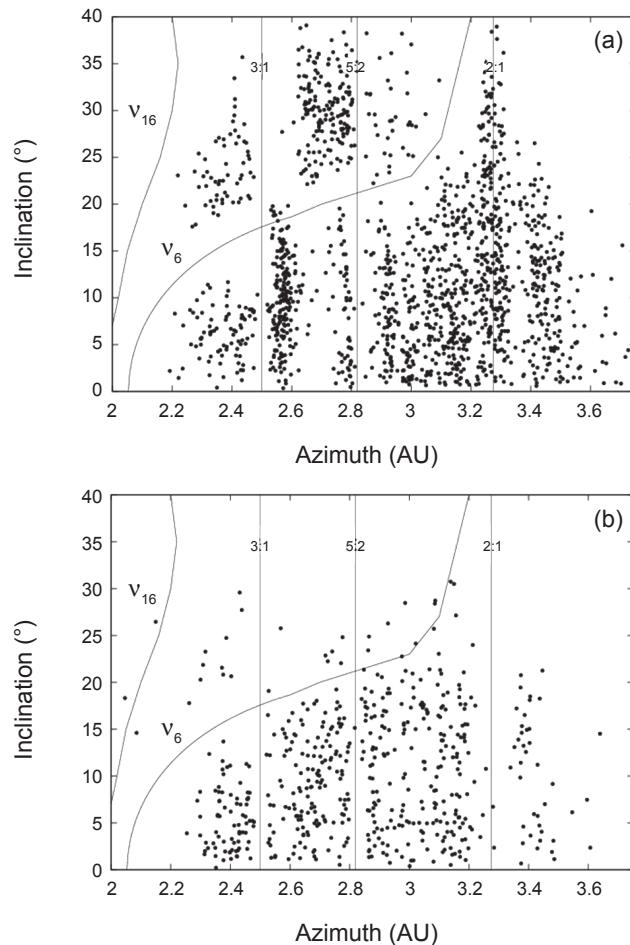

Although it avoids secular resonances sweeping across the asteroid belt, a jumping-Jupiter evolution is not without consequences for the asteroids. The sudden change in the eccentricity of Jupiter (from an initial basically circular orbit, like that observed in hydrodynamical simulations of the four giant planets evolving in the gaseous protoplanetary disk, to one with current eccentricity) changes the forced eccentricity felt by the asteroids in their secular evolution. Consequently, the proper eccentricities of the asteroids are changed. Depending on the value of the longitude of

perihelion when the forced eccentricity changes, the proper eccentricity of an asteroid can decrease or increase. Roughly, 50% of the asteroids are kicked to larger eccentricities and therefore are removed from the asteroid belt. The remaining 50% of the asteroids have their eccentricities reduced. This can potentially reconcile the eccentricity distribution of asteroids at the end of the Grand Tack evolution (see Fig. 6) with the current distribution. Indeed, Minton and Malhotra (2011) showed that the current eccentricity distribution can be achieved starting from a primordial distribution peaked at  $e \sim 0.3$ , similar to that produced by the Grand Tack evolution of Jupiter (Fig. 6). They obtained this result using secular resonance sweeping, but the basic result should hold also for a sudden enhancement of Jupiter's eccentricity. Nevertheless, specific numerical simulations have never been done to demonstrate that the eccentricity distribution of asteroids at the end of the Grand Tack model can be transformed into the current distribution via the jumping-Jupiter evolution [at

the time of this writing, this work is ongoing and seems to give positive results (Deienno and Gomes, personal communication)]. The jump in Jupiter's inclination due to its encounter(s) with another planet should also have partially reshuffled the asteroid inclination distribution, possibly reconciling the final distribution in Wetherill's model (see Fig. 4) with the current one. However, the effects on the inclination during Jupiter's jump seem less pronounced than those on the eccentricity (Morbidelli et al., 2010).

The current inner edge of the asteroid belt is marked by the presence of the secular resonance between the precession frequency of the perihelion of an asteroid and the  $g_6$  planetary frequency. The resonance makes unstable all objects inside 2.1 AU at low to moderate inclinations, which truncates the belt at its current edge. But before the impulsive separation between the inner orbits of Jupiter and Saturn, this resonance was much weaker (because the  $g_6$  mode was less excited in the planetary system, the giant-planet orbits being more circular) and located away from the asteroid belt. Thus, in principle the asteroid belt might have extended closer to Mars before the giant-planet-instability event. Bottke et al. (2012) showed that the destabilization of this extended belt — or “E belt” — could have dominated the formation of impact basins on the Moon, producing 12–15 basins over a 400-m.y. interval. Given the age of the Orientale basin (usually estimated at 3.7–3.8 Ga), this implies that the giant-planet instability and the destabilization of the E belt happened 4.1–4.2 G.y. ago and was responsible for the production of the last dozen lunar basins, known as the Nectarian and post-Nectarian basins. Earlier basins and craters would have to have come from other sources, such as the planetesimals leftover from the terrestrial planet-formation process. The existence of two populations of projectiles, namely the leftover planetesimals dominating the bombardment at early times and the E-belt asteroids dominating the impact rate at a later epoch, should have produced a sawtooth-shaped bombardment history of the Moon (Morbidelli et al., 2012). The E belt should also have caused a long, slowly decaying tail of Chicxulub-sized impacts on Earth, possibly continuing until  $\sim 2$  G.y. ago. Evidence for this long tail in the time-distribution of impacts is provided by the existence of terrestrial impact spherule beds, which are globally distributed ejecta layers created by the formation of Chicxulub-sized or larger craters (Johnson and Melosh, 2012): 10, 4, and 1 of these beds have been found on well-preserved, non-metamorphosed terrains between 3.23 and 3.47 Ga, 2.49 and 2.63 Ga, and 1.7 and 2.1 Ga, respectively (Simonson and Glass, 2004; Bottke et al., 2012).

Moreover, the escape to high-eccentricity orbits of bodies from the main-belt and E-belt regions produced a spike in the impact velocities on main-belt asteroids at the time of the giant-planet instability. Thus, although the impact frequency on asteroids decreased with the depletion of 50% of the main-belt population and 100% of the E-belt population, the production of impact melt on asteroids increased during this event because melt production is very sensitive to impact velocities (Marchi et al., 2013). For this reason, the impact ages of meteorites show a spike at 4.1 Ga like

**Fig. 8.** A comparison between the final (a,i) distribution of asteroids if (a) Jupiter and Saturn migrate slowly away from each other or (b) jump due to them scattering an ice giant planet. In the first case the orbital distribution is inconsistent with that observed, while in the second case it is. From Morbidelli et al. (2010).

the lunar rocks, although for the latter this is due to a surge in the impact rate.

A final consequence of the giant-planet instability on the asteroid belt is the capture into its outer region of planetesimals from the transneptunian disk (Levison *et al.*, 2009). Because Jupiter Trojans are captured in the same event, these last captured asteroids should have had the same source as the Trojans and therefore they should be mostly taxonomic D- and P-types. The probability of capture in the asteroid belt is nevertheless small, so it is unlikely that an object as big as Ceres was trapped from the transneptunian region in this event.

### 3.6. After the Giant-Planet Instability

After the giant-planet instability the orbits of all planets, giants and terrestrial, are similar to the current ones (within the range of semimajor axis, eccentricity, and inclination oscillation provided by the current dynamical evolution). Thus, the asteroid belt has finished evolving substantially under the effect of external events such as giant-planet migration or instability.

The asteroid belt thus entered into the current era of evolution. Asteroids became depleted at the locations of unstable resonances (mean-motion and secular) on time-scales that varied from resonance to resonance. In this way, the asteroid belt acquired its current final orbital structure. In this process, it is likely that another ~50% of the asteroids were removed from the belt, most of them during the first 100 m.y. after the giant-planet instability (Minton and Malhotra, 2010). Combining this 50% with the 50% loss during the instability itself is the reason that we require that the primordial depletion event (Wetherill's model or Grand Tack) left a population of asteroids in the belt that was about 4× the current one.

With the depletion of unstable resonances, the asteroid belt would have become an extraordinarily boring place from a dynamical point of view. Fortunately, collisional breakup events keep refreshing the asteroid population, generating dynamical families very rich in small objects, while non-gravitational forces, mostly the Yarkovsky effect (Bottke *et al.*, 2006), cause small asteroids to drift in semimajor axis, eventually supplying new bodies to the unstable resonances. This combination of collisional activity and nongravitational forces allow the main asteroid belt to resupply and sustain in a quasi-steady state the intrinsically unstable population of near Earth objects. But this is the subject of another chapter.

## 4. CONCLUSIONS AND IMPLICATIONS

In this chapter, we have reviewed our current understanding of the evolution of the asteroid belt, from a massive and dynamically quiet disk of planetesimals to its current state, which is so complex and rich from the points of view of both its dynamical and physical structures.

According to this understanding, the asteroid population mainly evolved in two steps. There was an early event of strong dynamical excitation and asteroid removal, which left about 4× the current asteroid population on orbits with a wide range of eccentricities and inclinations. This event may have been due to the self-stirring of a population of planetary embryos resident in the asteroid belt (Wetherill, 1992), or to the migration of Jupiter through the asteroid belt [the Grand Tack scenario (Walsh *et al.*, 2011)]. The second step occurred later, possibly as late as 4.1 G.y. ago or ~400 m.y. after the removal of gas from the protoplanetary disk. At that time, the asteroid belt underwent a second dynamical excitation and depletion when the giant planets became temporarily unstable and their orbits evolved from an initial resonant and compact configuration to the current configuration. During this second event, the asteroid belt lost about 50% of its members. After this second event, the asteroid belt structure settled down with the progressive depletion at unstable resonances with the giant and terrestrial planets. Another 50% of the asteroid population was lost in this process, mostly during the subsequent 100 m.y.

If the first evolutionary step was due to the Grand Tack migration of Jupiter, we expect that S-type asteroids formed more or less *in situ* (2–3 AU region); the C-type asteroids formed in the giant-planet region (roughly 3–15 AU), and the P- and D-type asteroids formed beyond the initial location of Neptune (roughly 15–30 AU). The hot population of the Kuiper belt, the scattered disk, and the Oort cloud would also derive from the same transneptunian disk (Levison *et al.*, 2008; Brasser and Morbidelli, 2013). There is a growing consensus that the cold Kuiper belt (42–45 AU) is primordial and born *in situ* (Petit *et al.*, 2011; Parker *et al.*, 2011; Batygin *et al.*, 2011; Fraser *et al.*, 2014). Thus, the cold Kuiper belt objects should not have any correspondent in the asteroid belt.

If instead the first step was due to the self-stirring of resident embryos as in Wetherill's model, we expect that S-type asteroids formed in the inner part of the belt, C-type asteroids in the outer part, and no asteroids sample the planetesimal population in the giant-planet region. The origin of P- and D-type asteroids would be the same as above. Thus, deciding which of these two models is preferable requires a better understanding of the nature of C-type asteroids and their water content, the similarities and differences between them and comets, and among comets themselves. This may not be an easy task. The population of main-belt comets (asteroids showing cometary activity such as 133P/Elst-Pizarro or 238P/Read) and their relationship with the parent bodies of carbonaceous chondrites is key in this respect. If it turns out that main-belt comets are consistent with carbonaceous chondrites in terms of isotope composition (mostly for H, N, and O), then this will argue that carbonaceous chondrites are just the rocky counterpart of bodies much richer in water/ice than meteorites themselves. This would imply that C-type asteroids formed beyond the snowline, thus presumably in the vicinity of the giant planets. If instead the main-belt comets

are not related to carbonaceous chondrites, but are more similar to comets from their isotope composition (it should be noted that even though Comet Hartley 2 has a chondritic water D/H ratio, it has a nonchondritic  $^{14}\text{N}/^{15}\text{N}$  ratio), then this would argue for their injection in the belt from the cometary disk and would suggest that the parent bodies of carbonaceous chondrites are not so water-rich, and therefore formed somewhat closer to the Sun than the snowline.

Whatever the preferred scenario for the first depletion and excitation of the asteroid belt, it is clear that the asteroid population must have suffered in the first hundreds of millions of years as much collisional evolution as over the last 4 G.y. However, all asteroid families formed during the early times are not identifiable today because the dynamical excitation events dispersed them (and possibly depleted them) too severely. The presence of metallic asteroids not associated with a family of objects of basaltic or dunitic nature, as well as the existence of rogue basaltic asteroids such as 1459 Magnya, should therefore not come as a surprise. The only families that are preserved are those that formed after the last giant-planet-instability event and have not been made unrecognizable by subsequent collisional evolution and Yarkovsky drift; thus they are either relatively young or large.

In this chapter, we have also examined several other asteroid excitation and depletion scenarios, most of which have serious difficulties in reconciling their predicted outcomes with observations. We have done this not just for historical completeness, but also to illustrate the critical constraints on putative alternative scenarios of solar system evolution. For instance, numerous studies on the possible *in situ* formation of extrasolar super-Earths close to their host stars assume a large pileup of drifting material of various sizes, from grains to small-mass embryos, in the inner part of the protoplanetary disks (Hansen, 2014; Chatterjee and Tan, 2014; Boley et al., 2014). By analogy, these models could be used to suggest that the outer edge of the planetesimal disk at 1 AU, required to form a small Mars, was due to the same phenomenon rather than to the Grand Tack migration of Jupiter. However, from what we reported in this chapter, we think that the asteroid belt rules out this possibility. In fact, the inward migration of small planetesimals (due to gas drag) and large embryos (due to disk tides) could explain the pileup of solid mass inside 1 AU and the mass deficit of the asteroid belt, but not the asteroids' orbital distribution (Izidoro et al., 2015). In the absence of the Grand Tack migration of Jupiter, we showed in section 3 that the only mechanism that could give the belt an orbital structure similar to that observed is Wetherill's model of mutual scattering of resident embryos. But if this was the case, then the mass distribution could not be concentrated within 1 AU because a massive population of embryos is required in the main-belt region. Thus, at the current state of knowledge (which may change in the future), only the Grand Tack scenario seems able to explain the required mass concentration to make a small Mars.

In summary, the asteroid belt remains the population of choice to test old, current, and future models of solar system evolution.

The Yarkovsky effect describes a small but significant force that affects the orbital motion of meteoroids and asteroids smaller than 30–40 km in diameter. It is caused by sunlight; when these bodies heat up in the Sun, they eventually reradiate the energy away in the thermal waveband, which in turn creates a tiny thrust. This recoil acceleration is much weaker than solar and planetary gravitational forces, but it can produce measurable orbital changes over decades and substantial orbital effects over millions to billions of years. The same physical phenomenon also creates a thermal torque that, complemented by a torque produced by scattered sunlight, can modify the rotation rates and obliquities of small bodies as well. This rotational variant has been coined the Yarkovsky-O’Keefe-Radzievskii-Paddack (YORP) effect. During the past decade or so, the Yarkovsky and YORP effects have been used to explore and potentially resolve a number of unsolved mysteries in planetary science dealing with small bodies. Here we review the main results to date, and preview the goals for future work.

## 1. INTRODUCTION

Interesting problems in science usually have a long and complex history. It is rare, though, that they have a prehistory or perhaps even mythology. Yet, until recently this was the case for the Yarkovsky effect. Ivan O. Yarkovsky, a Russian civil engineer born in a family of Polish descent, noted in a privately published pamphlet (Yarkovsky, 1901; Beekman, 2006) that heating a prograde-rotating planet should produce a transverse acceleration in its motion and thus help to counterbalance the assumed drag from the then-popular ether hypothesis. While this context of Yarkovsky’s work was mistaken and he was only roughly able to estimate the magnitude of the effect, he succeeded in planting the seed of an idea that a century later blossomed into a full-fledged theory of how the orbits of small objects revolving about the Sun are modified by the absorption and reemission of solar energy.

It is mainly Ernst J. Öpik who is to be credited for keeping Yarkovsky’s work alive and introducing it to western literature, long after the original pamphlet had been lost

(Öpik, 1951). Curiously, at about the same time, similar ideas also started to appear in Russian regular scientific literature through the works of Vladimir V. Radzievskii and his collaborators (Radzievskii, 1952). While Radzievskii was also the first to consider the effects of systematic photon thrust on a body’s rotation, his concept was based on a variable albedo coefficient across the surface (Radzievskii, 1954). However, there is no strong evidence of large enough albedo variations over surfaces of asteroids or meteoroids. Stephen J. Paddack and John O’Keefe pushed the idea forward by realizing that irregular shape, and thermal radiation rather than just reflected sunlight, will more efficiently change the meteoroid’s spin rate. Thence, the Yarkovsky-O’Keefe-Radzievskii-Paddack (YORP) effect was born as an alter ego of the Yarkovsky effect little more than half a century after Yarkovsky’s work (see Paddack (1969), Paddack and Rhee (1975), and Rubincam (2000) for a summation of the history and coining of the terminology). Radzievskii’s school also briefly touched upon a concept of a radiation-induced acceleration of synchronous planetary satellites (Vinogradova

and Radzievskii, 1965), an idea that reappeared much later in a slightly different form as a binary YORP (BYORP) effect (Ćuk and Burns, 2005).

The three decades from the 1950s to the 1970s resulted in today's understanding of Yarkovsky and YORP effects. The works that led to a major resurgence in these studies, however, occurred in the second half of the 1990s through the work of David P. Rubincam and Paolo Farinella. Interestingly, both were studying thermal perturbations of artificial satellite motion. With that expertise, they realized a direct link between the orbital effects acting on the artificial satellites such as the Laser Geodynamics Satellites (LAGEOS) and the orbital effects on small meteoroids (e.g., Afonso *et al.*, 1995; Rubincam, 1995, 1998; Farinella *et al.*, 1998).

From there, a momentum was gained and a wealth of new results appeared, with applications extending to dynamics of small asteroids and their populations (e.g., Bottke *et al.*, 2002a, 2006). Studies of the Yarkovsky effect were soon followed by those of the YORP effect (Rubincam, 2000). Today, both effects belong to a core culture in planetary sciences, as well as beyond (e.g., <http://www.youtube.com/watch?v=kzlgxqTtxYs>), and have become an important part of the agenda of space missions (e.g., Lauretta *et al.*, 2015). Especially after the spectacular discovery of the “once lost” Yarkovsky pamphlet in Russian archives by Dutch amateur astronomer George Beekman (see Beekman, 2006), it seems timely to review the current knowledge of the Yarkovsky and YORP effects. This effort could start with a translation, and perhaps a commented edition, of the Yarkovsky work (presently available in its original form as an Appendix to Miroslav Brož's thesis, <http://sirrah.troja.mff.cuni.cz/mira/mp/phdth>). We look forward to future historians editing the more than a century long story of the Yarkovsky and YORP effects, with all the known and possibly hidden roots, into a consolidated picture.

Leaving historical issues to their own time, we now turn to current scientific issues related to the Yarkovsky and YORP effects. There are several good technical reviews already existing in the literature (e.g., Bottke *et al.*, 2002a, 2006). While not always possible, we try to avoid discussing the same topics as presented in these previous texts. For instance, we do not review the elementary concepts of the Yarkovsky and YORP effects, assuming the reader is familiar with them. Rather, we try to focus on new results and ideas that emerged during the past decade and that will lead to research efforts in the next several years.

## 2. THEORY OF THE YARKOVSKY AND YORP EFFECTS

We start with the simplest analytical models of the Yarkovsky and YORP effects (section 2.1). This is because they provide useful insights, such as scalings with several key parameters, and their results are correct to leading order. They also allow us to understand why modeling of the YORP effect is inevitably more complicated than modeling of the Yarkovsky effect. And yet, the quality of the Yarkovsky

and YORP effects detections, as well as other applications, have reached a level that requires more accurate models to be used. The first steps toward these new models have been taken recently and these are briefly reviewed in section 2.2.

### 2.1. Classical Models

**2.1.1. The Yarkovsky effect.** Absorbed and directly reflected sunlight does not tend to produce long-term dynamical effects as far as orbital motion is concerned (e.g., Vokrouhlický and Milani, 2000; Žížka and Vokrouhlický, 2011). The Yarkovsky effect thus fundamentally depends on emitted thermal radiation and requires a body to have a nonzero thermal inertia. Any meaningful evaluation of the Yarkovsky effect, therefore, requires a thermophysical model of that body. Fortunately, an evaluation of the Yarkovsky effect imposes a minimum of requirements on the shape of the body; even a simple spherical model provides us with a fair approximation of how the body will orbitally evolve.

While the Yarkovsky effect results in variations to all the orbital elements, what is distinct from most other perturbations is the secular effect in the semimajor axis  $a$ , and therefore we only discuss this contribution. Assuming (1) a linearization of the surface boundary condition, (2) a rotation about a spin axis fixed in the inertial space (at least on a timescale comparable with the revolution about the Sun), and (3) a circular orbit about the Sun, one easily finds that the total, orbit-averaged change in  $a$  is composed of two contributions (e.g., Rubincam, 1995, 1998; Farinella *et al.*, 1998; Vokrouhlický, 1998a, 1999), the diurnal effect

$$\left( \frac{da}{dt} \right)_{\text{diurnal}} = -\frac{8}{9} \frac{\alpha \Phi}{n} W(R_\omega, \Theta_\omega) \cos \gamma \quad (1)$$

and the seasonal effect

$$\left( \frac{da}{dt} \right)_{\text{seasonal}} = \frac{4}{9} \frac{\alpha \Phi}{n} W(R_n, \Theta_n) \sin^2 \gamma \quad (2)$$

Here,  $\Phi = \pi R^2 F / (mc)$ , where  $R$  is the radius of the body,  $F$  the solar radiation flux at the orbital distance  $a$  from the Sun,  $m$  the mass of the body,  $c$  the light velocity,  $n$  the orbital mean motion, and  $\alpha = 1-A$ , with  $A$  denoting the Bond albedo (e.g., Vokrouhlický and Bottke, 2001). The  $\Phi$  factor is characteristic to any physical effect related to sunlight absorbed or scattered by the surface of the body. Since  $m \propto R^3$ , one obtains a typical scaling  $\Phi \propto 1/R$ .

More importantly, the diurnal and seasonal components of the Yarkovsky effect have a different dependence on the spin axis obliquity  $\gamma$ : (1) the diurnal part is  $\propto \cos \gamma$ , and consequently can make a positive or negative change in the semimajor axis, being maximum at  $0^\circ$  and  $180^\circ$  obliquity values; and (2) the seasonal part is  $\propto \sin^2 \gamma$ , and consequently always results in a decrease in semimajor axis, being

maximum at 90° obliquity. Their magnitude is proportional to the function

$$W(R_v, \Theta_v) = -\frac{\kappa_1(R_v)\Theta_v}{1 + 2\kappa_2(R_v)\Theta_v + \kappa_3(R_v)\Theta_v^2} \quad (3)$$

determined by the thermal parameters of the body and a frequency  $v$ . The latter is equal either to the rotation frequency  $\omega$  for the diurnal component, or the orbital mean motion  $n$  for the seasonal component. The thermal parameters required by the model are (1) the surface thermal conductivity  $K$ , (2) the surface heat capacity  $C$ , and (3) the surface density  $\rho$ . These parameters, together with the frequency  $v$ , do not appear in equation (3) individually. Rather, in the process of solving the heat diffusion problem and determination of the orbital perturbations, they combine in two relevant parameters. First, they provide a scale length  $\ell_v = \sqrt{K/(\rho Cv)}$ , which indicates a characteristic penetration depth of temperature changes assuming the surface irradiation is periodic with the frequency  $v$ . The nondimensional radius of the body  $R_v$  in equation (3) is defined by  $R_v = R/\ell_v$ . Second, the surface thermal inertia  $\Gamma = \sqrt{K\rho C}$  enters the nondimensional thermal parameter  $\Theta_v$  in equation (3) using a definition  $\Theta_v = \Gamma\sqrt{v}/(\epsilon\sigma T_\star^3)$ , with  $\epsilon$  the thermal emissivity of the surface,  $\sigma$  the Stefan-Boltzmann constant, and  $T_\star$  the subsolar temperature ( $\epsilon\sigma T_\star^4 = \alpha F$ ). When the characteristic size  $R$  of the body is much larger than  $\ell_v$  (a large-body limit), a situation met in the typical applications so far, the three  $\kappa$  coefficients in equation (3) are simply equal to  $\frac{1}{2}$  [Rubincam (1995); see Vokrouhlický (1998a) for their behavior for an arbitrary value of  $R_v$ ]. Hence, for large bodies the  $W$  factors do not depend on the size  $R$  and read  $W \approx W(\Theta_v) = -0.5 \Theta_v / (1 + \Theta_v + 0.5 \Theta_v^2)$ . Consequently, the Yarkovsky effect is maximum when  $\Theta_v \approx 1$ ; for small or large values of  $\Theta_v$  the effect vanishes. In this case, the semimajor axis secular change  $da/dt$  due to the Yarkovsky effect scales as  $\propto 1/R$  with the characteristic radius  $R$ . For small asteroids, either in near-Earth space or in the main belt,  $\Theta_\omega$  is typically on the order of unity (see also the chapter by Delbò et al. in this volume), while  $\Theta_n$  is much smaller, which implies that the diurnal Yarkovsky component usually dominates the seasonal component.

A handful of models were subsequently developed to probe the role of each of the simplifying assumptions mentioned above using analytical, semianalytical, or fully numerical methods. These include (1) an inhomogeneity of the thermal parameters (e.g., Vokrouhlický and Brož, 1999), (2) a coupling of the diurnal and seasonal components of the Yarkovsky effect (e.g., Vokrouhlický, 1999; Sekiya and Shimoda, 2013, 2014), (3) effects of a nonspherical shape for simple (e.g., Vokrouhlický, 1998b) or general geometries (including nonconvex shapes and the role of small-scale surface features; section 2.2), (4) a nonlinearity of the surface boundary condition of the thermal model (e.g., Sekiya and Shimoda, 2013, 2014), (5) the role of very high orbital eccentricity (e.g., Spitale and Greenberg, 2001, 2002; Sekiya

and Shimoda, 2014); (6) a nonprincipal-axis rotation state (e.g., Vokrouhlický et al., 2005a), or (7) the Yarkovsky effect for binary asteroids (e.g., Vokrouhlický et al., 2005b). Each of them was found to modify results from the zero approximation model by as much as several tens of percent without modifying the fundamental dependence of the Yarkovsky effect on obliquity, size, or thermal parameters [except perhaps for the special case of very high eccentricity orbits, where the sign of the Yarkovsky effect may be changed (see Spitale and Greenberg, 2001)].

**2.1.2. The YORP effect.** The YORP effect, the rotational counterpart of the Yarkovsky effect, broadly denotes the torque arising from interaction with the impinging solar radiation. As in the orbital effect, the absorbed sunlight does not result in secular effects (e.g. Breiter et al., 2007; Nesvorný and Vokrouhlický, 2008b; Rubincam and Paddack, 2010). Both directly scattered sunlight in the optical band and the recoil due to thermally reprocessed radiation, however, produce dynamical effects that accumulate over long timescales. In principle, one would need to treat the two components of the YORP effect independently, since the bidirectional characteristics of the scattered and thermally emitted radiation are not the same and would produce different torques. Additionally, the thermal component has a time lag due to the finite value of the surface thermal inertia and its bidirectional function should formally depend on the time history of the particular surface element.

While these issues are at the forefront of current research (section 2.2), we start with a zero-order approximation initially introduced by Rubincam (2000): (1) the surface thermal inertia is neglected, such that thermal radiation is reemitted with no time lag; and (2) the reflected and thermally radiated components are simply assumed to be Lambertian (isotropic). This approximation avoids precise thermal modeling and the results are relatively insensitive to the body's surface albedo value. At face value, this looks simple, but layers of complexity unfold with the geometrical description of the surface. This is because the YORP effect vanishes for simple shape models [such as ellipsoids of rotation (Breiter et al., 2007)] and stems from the irregular shape of the body (see Paddack, 1969). Obviously, its quantitative description involves a near infinity of degrees of freedom if middle- to small-scale irregularities are included. This may actually be the case for real asteroids because these irregularities may present a large collective cross-section and thus could dominate the overall strength of the YORP effect. This is now recognized as a major obstacle to our ability to model the YORP effect (section 2.2).

The importance of fine details of geometry, somewhat unnoticed earlier, were unraveled by the first analytical and semianalytical models of the YORP effect. There were two approaches developed in parallel. Scheeres (2007) and Scheeres and Mirrahimi (2008) used the polyhedral shape description as a starting point for their study, while Nesvorný and Vokrouhlický (2007, 2008a) and Breiter and Michalska (2008) used shape modeling described by a series expansion in spherical harmonics. To keep things simple,

these initial models assumed principal axis rotation and disregarded mutual shadowing of the surface facets. Both models predicted, after averaging the results over the rotation and revolution cycles, a long-term change of the rotational rate  $\omega$  and obliquity  $\gamma$  (the precession rate effect is usually much smaller than the corresponding gravitational effect due to the Sun), which could be expressed as

$$\frac{d\omega}{dt} = \frac{\Lambda}{C} \sum_{n \geq 1} A_n P_{2n}(\cos \gamma) \quad (4)$$

and

$$\frac{d\gamma}{dt} = \frac{\Lambda}{C\omega} \sum_{n \geq 1} B_n P_{2n}^1(\cos \gamma) \quad (5)$$

Here,  $\Lambda = 2 FR^3/(3c)$  with  $C$  being the moment of inertia corresponding to the rotation axis (shortest axis of the inertia tensor),  $P_{2n}(\cos \gamma)$  are the Legendre polynomials of even degrees, and  $P_{2n}^1(\cos \gamma)$  are the corresponding associated Legendre functions. The particular characteristics of the even-degree Legendre polynomials and Legendre functions on the order of 1 in equations (4) and (5) under prograde to retrograde reflection  $\gamma \leftrightarrow \pi - \gamma$  indicate the behavior of  $d\omega/dt$  and  $d\gamma/dt$ : (1) the rotation-rate change is symmetric, while (2) the obliquity change is antisymmetric under this transformation. Earlier numerical studies (e.g., Rubincam, 2000; Vokrouhlický and Čapek, 2002; Čapek and Vokrouhlický, 2004) had suggested that the net effect of YORP on rotation-rate often vanishes near  $\gamma \sim 55^\circ$  and  $\gamma \sim 125^\circ$ . This feature was finally understood using equation (4) because these obliquity values correspond to the roots of the second-degree Legendre polynomial. The previous works that numerically treated smoothed surfaces thus mostly described situations when the first term in the series played a dominant role. When the effects of the surface finite thermal inertia are heuristically added to these models, one finds that only the coefficients  $B_n$  change (e.g., Nesvorný and Vokrouhlický, 2007, 2008a; Breiter and Michalska, 2008). This confirms an earlier numerical evidence of Čapek and Vokrouhlický (2004).

Since  $C \propto R^5$ , equations (4) and (5) imply that both rotation rate and obliquity effects scale with the characteristic radius as  $\propto 1/R^2$ . This is an important difference with respect to the “more shallow” size dependence of the Yarkovsky effect, and it implies that YORP’s ability to change the rotation state increases very rapidly moving to smaller objects. Additionally, we understand well that for very small bodies the Yarkovsky effect becomes eventually nil. When the characteristic radius  $R$  becomes comparable to the penetration depth  $\ell_\omega$  of the diurnal thermal wave the efficient heat conduction across the volume of the body makes temperature differences on the surface very small. However, Breiter et al. (2010a) suggested that in the same limit the YORP strength becomes  $\propto 1/R$ , still increasing for small objects. Additionally, their result was only concerned with the thermal component of the YORP effect, while the part

related to the direct sunlight scattering in optical waveband continues to scale with  $\propto 1/R^2$ . Thus, the fate of the rotation of small meteoroids is still unknown at present.

The principal difference in complexity of the YORP effect results in equations (4) and (5), as compared to simple estimates in equations (1) and (2) for the Yarkovsky effect, is their infinite series nature. The nondimensional coefficients  $A_n$  and  $B_n$  in equations (4) and (5) are determined by the shape of the body, either analytically or semianalytically (e.g., Nesvorný and Vokrouhlický, 2007, 2008a; Scheeres and Mirrahimi, 2008; Breiter and Michalska, 2008; Kaasalainen and Nortunen, 2013). Interestingly, analytical methods help us to understand the torque component that changes the spin rate and the components that change the axis orientation couple, at leading order, to different attributes of the surface. The spin torque couples to chirality — the difference between eastward and westward facing slopes — while the other components couple merely to asphericity. Mathematically, this concerns the symmetric and antisymmetric terms in the Fourier expansion of the topography. If mutual shadowing of the surface facets is to be taken into account, one may use the semianalytic approach mentioned by Breiter et al. (2011) (see also Scheeres and Mirrahimi, 2008). Depending on details of the shape, the series in equations (4) and (5) may either converge quickly, with the first few terms dominating the overall behavior, or may slowly converge, with high-degree terms continuing to contribute (e.g., Nesvorný and Vokrouhlický, 2007, 2008a; Kaasalainen and Nortunen, 2013).

While this behavior had been noticed in analytical modeling, a detailed numerical study of YORP sensitivity on astronomically motivated, small-scale surface features such as craters and/or boulders was performed by Statler (2009). This also allowed Statler to suggest a new direction to YORP studies. He noted that the sensitivity of YORP on such small-scale features may affect its variability on short enough timescales to significantly modify the long-term evolution of the rotation rate, with the evolution changing from a smooth flow toward asymptotic state to a random walk (section 2.2).

The quadrupole ( $2n = 2$ ), being the highest multipole participating in the series expansion in equations (4) and (5), is related to the assumption of coincidence between the reference frame origin and the geometric center of the body (i.e., its center of mass for homogeneous density distribution). If instead the rotation axis is displaced from this point, additional terms in the series become activated and the coefficients ( $A_n, B_n$ ) become modified, and thus the predicted YORP torque will change (e.g., Nesvorný and Vokrouhlický, 2007, 2008a). This theoretical possibility has found an interesting geophysics interpretation for (25143) Itokawa’s anomalously small YORP value by Scheeres and Gaskell (2008) [see section 3.2, Breiter et al. (2009), and eventually Lowry et al. (2014)].

## 2.2. Frontiers in Modeling Efforts

### 2.2.1. Resolved and unresolved surface irregularities.

While the models discussed above suffice to describe broad-

scale features of the Yarkovsky and YORP effects, there are important aspects that are intrinsically *nonlinear*. Current models need to explicitly treat these nonlinearities in order to capture the physical essence of radiation recoil mechanisms and to provide precise predictions. Here we discuss some recent efforts along these lines.

The simplest of such nonlinear effects is shadowing of some parts of the surface by other parts, which can occur on surfaces that are not convex. By blocking the Sun, shadowing lowers the incident flux, and increases the temperature contrast, compared to the clear-horizon case. Computationally, shadowing requires testing whether the sunward-pointing ray from each surface element intersects another surface element (e.g., Vokrouhlický and Čapek, 2002). This “who blocks whom” problem is of  $O(N^2)$  complexity (where  $N$  is the number of surface elements); but there are strategies for storing an initial  $O(N^2)$  calculation so that all subsequent calculations are only  $O(N)$  (e.g., Statler, 2009).

Closely related to shadowing are the processes of *self-heating* (e.g., Rozitis and Green, 2013); these can be split conceptually into *self-illumination*, in which a surface element absorbs reflected solar flux from other parts of the surface, and *self-irradiation*, where it absorbs reradiated thermal infrared. Self-heating has the tendency to reduce the temperature contrast, by illuminating regions in shadow. Computing these effects requires prescriptions for the angular distribution of reflected and reradiated power from an arbitrary surface element, as well as the solution to the “who sees whom” problem — similar to the “who blocks whom” problem from shadowing. But since energy is traded between pairs of surface elements, self-heating, unlike shadowing, is unavoidably  $O(N^2)$  if full accuracy is required.

As mentioned in section 2.1, a periodic driving at a frequency  $v$  introduces a length scale, the thermal skin depth  $\ell_v$ . Asteroid surfaces are driven quasiperiodically, with the fundamental modes at the diurnal and seasonal frequencies. For typical materials,  $\ell_v$  is on the order of meters for the seasonal cycle and millimeters to centimeters for the diurnal cycle. If the surface’s radius of curvature  $s$  satisfies the condition  $s \gg \ell_v$ , one can consider surface elements to be independent (facilitating parallelization) and solve the heat conduction problem as a function of the depth only. The radiated flux then depends on the material parameters only through the thermal inertia  $\Gamma$ . Most models that treat conduction explicitly do so in such one-dimensional approximation. Standard finite-difference methods are typically used to find a solution over a rotation or around a full orbit; but numerical convergence can be slow [although acceleration schemes were also considered (Breiter et al., 2010b)]. Whether the condition  $s \gg \ell_v$  is truly satisfied depends on the scale on which topography is resolved. A surface boulder can give an object a locally small radius of curvature and three-dimensional effects may become important. Full three-dimensional conduction is computationally expensive (e.g., Golubov et al., 2014; Ševeček et al., 2015), but the potential consequences are significant. In this case, a general finite-element method is used to solve the heat diffusion problem.

Surface roughness concerns the effects of unresolved texture on reflection, absorption, and reradiation. Parametric models for a rough-surface reflectance are well developed [e.g., see Hapke (1993), and references therein; and see Breiter and Vokrouhlický (2011) for an application to the YORP effect], although the functional forms and parameter values are matters of current research. Models for the thermal emission are at present purely numerical. In the most complete implementation (Rozitis and Green, 2012, 2013), a high-resolution model of a crater field is embedded inside a coarse-resolution model of a full object. The primary effects of roughness in this model are to enhance the directionality (“beaming”) of the radiated intensity (relative to Lambertian emission), and to direct the radiated momentum slightly away from the surface normal, toward the Sun. Roughness models for emission and for reflection are not automatically mutually consistent, and the emission models employ the one-dimensional approximation for heat conduction despite the likelihood that  $s$  may not be much larger than  $\ell_\omega$  at the roughness scale.

Finally, nonlinear *dynamical coupling* affects both spin evolution and the orbital drift modulated by the spin state. Yarkovsky evolution models have generally incorporated heuristic prescriptions based on the YORP cycle (e.g., Rubincam, 2000; Vokrouhlický and Čapek, 2002), with possibly important effects of spin-induced material motion or reshaping included only in rudimentary ways. These processes may be modeled with particle-based discrete-element numerical codes (e.g., Richardson et al., 2005; Schwartz et al., 2012) and seminumerical granular dynamics in predefined potential fields (e.g., Scheeres, 2015). Simulated rubble piles artificially fed with angular momentum are seen to reshape and shed mass (e.g., Walsh et al., 2008; Scheeres, 2015). Linking a particle code with a thermophysical YORP model would then allow the coupled spin and shape evolution to be followed self-consistently.

Statler (2009) argued that topographic sensitivity would make rubble piles, or any objects with loose regolith, susceptible to possibly large changes in torque triggered by small, centrifugally driven changes in shape. Repeated interruptions of the YORP cycle might then render the overall spin evolution stochastic and significantly extend the timescale of the YORP cycles (self-limitation property of YORP). Cotto-Figueroa et al. (2015) have tested this prediction by simulating self-consistently the coupled spin and shape evolution (toggling between configurations in a limit cycle), and stagnating behaviors that result in YORP *self-limitation*. Bottke et al. (2015) implemented a heuristic form of such stochastic YORP in a Yarkovsky drift model to find an agreement with the structure of the Eulalia asteroid family.

Accurate Yarkovsky measurements allow constraining mass and bulk density (section 4.1), but rely on precise models, with an important component due to the surface features discussed above. Rozitis and Green (2012) show that surface roughness can increase the Yarkovsky force by tens of percent, owing mainly to the beaming. Including the seasonal effect caused by the deeper-penetrating thermal wave can

have a comparable influence. Self-heating, in contrast, has a minimal influence on Yarkovsky forces (e.g., *Rozitis and Green*, 2013). On the other hand, the same works indicate that the YORP effect is in general damped by beaming because it equalizes torques on opposite sides of the body.

*Golubov and Krugly* (2012) highlight another small-scale aspect of the YORP effect: an asymmetric heat conduction across surface features for which  $s \leq \ell_\omega$ . A rock conducts heat from its sunlit east side to its shadowed west side in the morning, and from its west side back to its east side in the afternoon. Owing to nighttime cooling, the morning temperature gradient is steeper, and hence more heat is conducted to, and radiated from, the west side, resulting in an eastward recoil. Clearly, if the collective cross section of such surface features is large, details of conduction across them may have significant consequences. Ideally, the situation calls for a complete three-dimensional heat transfer model (e.g., *Golubov et al.*, 2014; *Ševeček et al.*, 2015). Importantly, these studies indicate an overall tendency for YORP to spin objects up. However, a better understanding of small-scale surface effects is essential to understand YORP's long-term dynamics.

**2.2.2. Time domain issues (tumbling).** A particular problem in the modeling of the thermal effects occurs for tumbling bodies. This is because solving the heat diffusion in the body also involves the time domain. While the spatial dimensions are naturally bound, the time coordinate in general is not. However, both analytical and numerical methods involve finite time domains: The analytical approaches use a development in the Fourier series, while the effective numerical methods use iterations that require one to identify configurations at some moments in time. For bodies rotating about the principal axis of the inertia tensor, thus having a fixed direction in the inertial space, it is usually easy to modify the rotation period within its uncertainty limits such that it represents an integer fraction of the orbital period. The orbital period is then the fundamental time interval for the solution. This picture becomes more complicated for tumbling objects whose rotation is not characterized by a single time period. Rather, it is fully described with two periods, the proper rotation period and precession period, which may not be commensurable.

This situation has been numerically studied by *Vokrouhlický et al.* (2005a) in the case of (4179) Toutatis, and more recently in the case of (99942) Apophis by *Vokrouhlický et al.* (2015). Both studies suggest the tumbling may not necessarily “shut down the Yarkovsky effect,” at least in the large-bodies regime. Rather, it has been found that the Yarkovsky acceleration for these tumbling objects is well represented by a simple estimate valid for bodies rotating about the shortest axis of the inertia tensor in a direction of the rotational angular momentum and with the fundamental period of tumbling, generally the precession period.

**2.2.3. More than one body (binarity).** Another particular case is the Yarkovsky effect for binaries (see *Vokrouhlický et al.*, 2005b). Unless the satellite has nearly the same size as the primary component, the rule of thumb is that the heliocentric

motion of the system's center of mass is affected primarily by the Yarkovsky acceleration of the primary component, while the motion of the satellite feels the Yarkovsky acceleration of the satellite itself. Nevertheless, a secular change in the orbit of the satellite is actually caused by an interplay of the thermal effects and the shadow geometry in the system dubbed the Yarkovsky-Schach effect [and introduced years ago in space geodesy (*Rubincam*, 1982)]. However, it turns out that the BYORP effect, discussed in section 2.3, is more important and dominates the orbital evolution of the satellite.

### 2.3. Binary YORP

The binary YORP (BYORP) effect was first proposed in a paper by *Ćuk and Burns* (2005). They noted that an asymmetrically shaped synchronous secondary asteroid in a binary system should be subject to a net force differential that acts on average in a direction tangent to the orbit. Thus, as the secondary orbits about the primary body and maintains synchronicity, this would lead to either an acceleration or deceleration of the secondary, which would cause the mutual orbit of the system to spiral out or in, respectively. This seminal paper presented a basic conceptual model for the BYORP effect and provided a broad survey of many of the possible implications and observable outcomes of this effect. It also numerically studied the evolution of randomly shaped secondary bodies over a year to establish the physical validity of their model. It is key to note that a necessary condition for the BYORP effect is that at least one of the bodies be synchronous with the orbit, and it can be shut off if both bodies are nonsynchronous. *Ćuk and Burns* concluded that the BYORP effect should be quite strong and lead binary asteroids to either spiral in toward each other or cause them to escape in relatively short periods of time. This was further expanded in a second paper by *Ćuk* (2007) that outlined significant implications for the rate of creation and destruction of binary asteroid systems in both the near-Earth asteroid (NEA) and main-belt population, leading to the initial estimate of binary asteroid lifetimes due to BYORP on the order of only 100 k.y.

*McMahon and Scheeres* (2010a,b) then developed a detailed analytical model of the BYORP effect that utilized the existing shape model of the (66391) 1999 KW<sub>4</sub> binary asteroid satellite (*Ostro et al.*, 2006). In their approach the solar radiation force was mapped into the secondary-fixed frame and expanded as a Fourier series, following a similar approach to the YORP model development of *Scheeres* (2007). This enables any given shape model to be expressed with a series of coefficients that can be directly computed, and allows for time averaging. Using this approach they showed that the primary outcome of the BYORP effect could be reduced to a single parameter — the so-called “BYORP coefficient,”  $B$  — uniquely computed from a given shape model. Henceforth, if the secondary is in a near-circular orbit, the entire BYORP effect results in simple evolutionary equations for semimajor axis  $a$  and eccentricity  $e$  ( $\ll 1$ ) of the binary orbit

$$\frac{da}{dt} = \frac{FB}{c\eta'} \frac{a^{3/2}}{m_2 \sqrt{\mu}} \quad (6)$$

$$\frac{de}{dt} = -\frac{FB}{4c\eta'} \frac{ea^{3/2}}{m_2 \sqrt{\mu}} \quad (7)$$

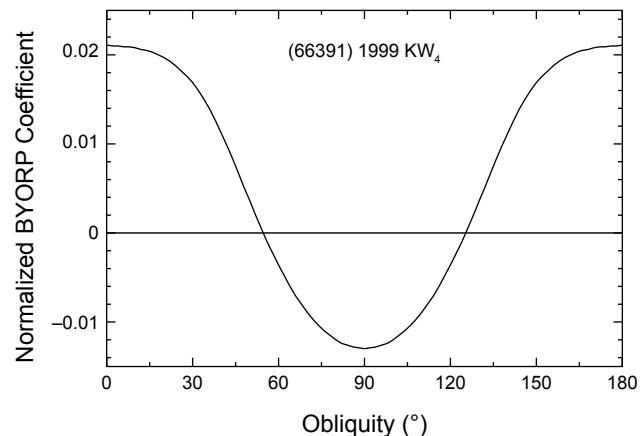

where again  $F$  is the solar radiation flux at the heliocentric distance  $a'$  (equal to the semimajor axis of the heliocentric orbit),  $\eta' = \sqrt{1 - e'^2}$  with  $e'$  being the eccentricity of the heliocentric orbit,  $c$  the light velocity,  $m_2$  the mass of the secondary, and  $\mu = G(m_1 + m_2)$  the gravitational parameter of the binary system. If the orbit is expansive ( $B > 0$ ), the eccentricity will be stabilized, and vice-versa (see Čuk and Burns, 2005). In the case where the binary orbit is highly elliptic, the evolutionary equations become much more complex, and require additional Fourier coefficients to be included into the secular equations, as discussed in detail in McMahon and Scheeres (2010a).

The BYORP coefficient  $B$  is computed as a function of the shape of the body and the obliquity of the binary's orbit relative to the heliocentric orbit of the system. Assume a model for the instantaneous solar radiation force acting on the secondary has been formulated by some means, denoted as  $\mathbf{F}_{SRP}(M, M')$ , where  $M$  and  $M'$  are the mean anomalies of the binary mutual orbit and heliocentric orbit, respectively. Then the computation of the BYORP coefficient requires double averaging of the radiation force over the binary and heliocentric revolution cycles, and projection in the direction of binary orbital motion (denoted here in abstract as  $\hat{\mathbf{t}}$ )

$$B = \hat{\mathbf{t}} \cdot \frac{1}{(2\pi)^2} \int_0^{2\pi} \int_0^{2\pi} \frac{\mathbf{F}_{SRP}}{P(r_s)} dM dM' \quad (8)$$

where  $P(r_s) = (F/c)(a'/r_s)^2$  is the solar radiation pressure acting on the unit surface area of the body at the heliocentric distance  $r_s$ . The normalization by  $P$  implies that units of the BYORP coefficient are measured in area; thus  $B$  can be further normalized by dividing it by the effective radius squared of the secondary body. The BYORP coefficient is a function of several physical quantities such as albedo, surface topography, and potentially thermophysical effects. However, the strongest variation of the BYORP coefficient is seen to vary with the binary obliquity with respect to the heliocentric orbit (Fig. 1). If the synchronous body is rotated by  $180^\circ$  relative to the orbit, then the sign of the BYORP coefficient will be uniformly reversed. Due to this, when a body initially enters into a synchronous state it is supposed that the probability of it being either positive or negative is 50%.

A more recent analysis of the BYORP effect was published by Steinberg and Sari (2011), who found a positive correlation between the strength of the BYORP and YORP effects for bodies, and provided predictions related to the BYORP-driven evolution of the obliquity of a binary asteroid. In addition, they probed the possible effects of thermophysical models on the evolution of a binary system.

**Fig. 1.** BYORP coefficient  $B$ , normalized by the square of the effective radius, computed for the secondary of the (66391) 1999 KW<sub>4</sub> binary asteroid system, as a function of the binary orbital obliquity (abscissa).

The above discussions focus on the effect of BYORP in isolation, and not in conjunction with other evolutionary effects. However, recent work has found that the BYORP effect can mix with other evolutionary effects in surprising ways that require additional verification and study. These are primarily discussed later in section 5.3, where the long-term evolution of binary systems subject to BYORP is briefly considered. However, one of these combined effects has significant implications and is discussed here.

In particular, Jacobson and Scheeres (2011b) proposed the existence of an equilibrium between the BYORP effect and tides. For this equilibrium to exist, the BYORP coefficient must be negative, leading to a contractive system, and the primary asteroid must be spinning faster than the orbit rate. This creates a tidal dissipation torque that acts to expand the secondary orbit. Based on current theories of energy dissipation within rubble-pile asteroids (e.g., Goldreich and Sari, 2009), Jacobson and Scheeres (2011b) noted that all singly-synchronous rubble-pile binary asteroids with a negative BYORP coefficient for the secondary should approach a stable equilibrium that balances these two effects. This is significant, as it provides a mechanism for the persistent effect of BYORP to become stalled, leaving binary asteroids that should remain stable over long time spans. This, in turn, means that rapid formation of binary asteroids is not needed to explain the current population.

### 3. DIRECT DETECTIONS

Accurate observations have now allowed direct detections of both the Yarkovsky and YORP effects. This is an important validation of their underlying concepts, but also it motivates further development of the theory. These direct detections have two aspects of usefulness or application. First, the Yarkovsky effect is being currently implemented as a routine part of the orbit determination of small NEAs whose orbits are accurately constrained in the forefront software packages.

Additionally, the Yarkovsky effect is already known to be an essential part of the Earth impact hazard computations in selected cases (section 4.2 and the chapter by Farnocchia et al. in this volume). Second, many applications of the Yarkovsky and YORP effects involve statistical studies of small-body populations in the solar system rather than a detailed description of the dynamics of individual objects. Aside from a general validation, the known detections help in setting parameter intervals that could be used in these statistical studies.

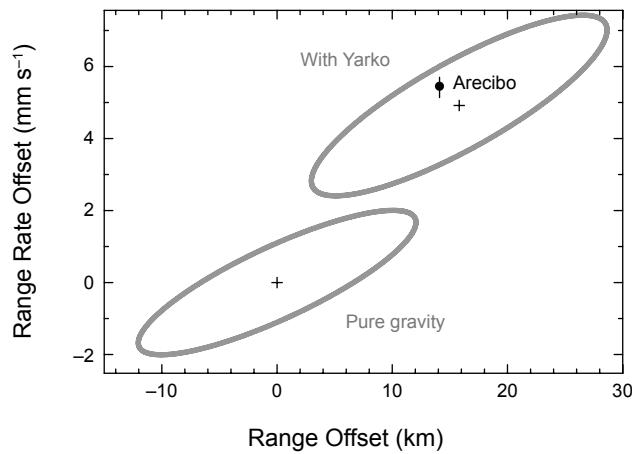

### 3.1. Yarkovsky Effect

The possibility of detecting the Yarkovsky effect as a measurable orbital deviation was first proposed by Vokrouhlický et al. (2000). The idea is at first astounding given that the transverse thermal recoil force on a half-kilometer NEA should be at most 0.1 N, causing an acceleration of only  $\sim 1 \text{ pm s}^{-2}$ . And yet such small perturbations can lead to tens of kilometers of orbital deviation for 0.5-km NEAs after only a decade. In principle, such a deviation is readily detectable during an Earth close approach, either by optical or radar observations, but the key challenge is that the precision of the position prediction must be significantly smaller than the Yarkovsky deviation that is to be measured. In practical terms, this means that detection of the Yarkovsky effect acting on a typical 0.5-km NEA requires at least three radar ranging apparitions spread over a decade, or several decades of optical astrometry in the absence of radar ranging. Of course, smaller objects could in principle reveal the Yarkovsky effect much more quickly, but the problem for small objects is that it is more difficult to build up suitable astrometric datasets. Because of this, only a few objects with diameters  $D < 100 \text{ m}$  have direct detections of the Yarkovsky effect.

It should be pointed out that observations do not allow measurement of the secular change in the orbital semimajor axis directly. Rather, they reveal an associated displacement in the asteroid position along the orbit, an effect that progresses  $\propto t^2$  in a given time  $t$  (see Vokrouhlický et al., 2000). This is similar to the way the YORP effect is observed as discussed in section 3.2.

As predicted by Vokrouhlický et al. (2000), (6489) Golevka was the first asteroid with an unambiguous detection of the signature of the Yarkovsky effect in its orbit (Chesley et al., 2003). In this case the detection was possible only due to the availability of three well-separated radar ranging apparitions, in 1991, 1995, and 2003. The first two radar apparitions constrain the semimajor axis, affording a precise position prediction in 2003, while the 2003 radar ranging revealed a deviation from a ballistic trajectory. Figure 2 depicts the predicted 2003 delay-Doppler observations with their uncertainty along with the associated uncertainties. The predictions were well separated with  $>90\%$  confidence, and the actual asteroid position fell close to the Yarkovsky prediction.

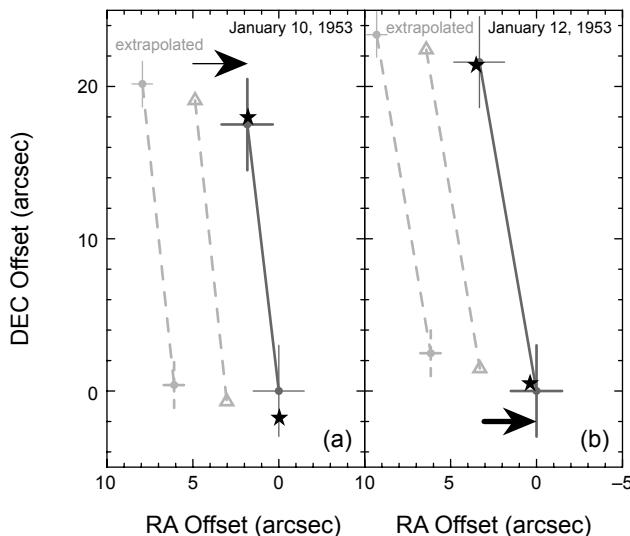

The second reported detection of the Yarkovsky effect was for (152563) 1992 BF, which was also the first detection that did not rely on radar astrometry (Vokrouhlický et

**Fig. 2.** Orbital solution of near-Earth asteroid (6489) Golevka from astrometric data before May 2003 projected into the plane of radar observables: (1) range at the abscissa, and (2) range-rate on the ordinate. The origin referred to the center of the nominal solution that only includes gravitational perturbations. The gray ellipse labeled “pure gravity” represents a 90% confidence level in the orbital solution due to uncertainties in astrometric observations as well as small body and planetary masses. The center of the gray ellipse labeled “with Yarko” is the predicted solution with the nominal Yarkovsky forces included (taken from Vokrouhlický et al., 2000); note the range offset of  $\sim 15 \text{ km}$  and the range rate offset of  $\sim 5 \text{ mm s}^{-1}$ . The actual Arecibo observations from May 24, 26, and 27, 2003, are shown by the black symbol (the measurement uncertainty in range is too small to be noted in this scale). The observations fall perfectly in the uncertainty region of the orbital solution containing the Yarkovsky forces. Adapted from Chesley et al. (2003).

al., 2008). This 0.5-km asteroid had a 13-yr optical arc (1992–2005) and four archival positions over two nights dating to 1953. These so-called precovery observations could not be fit to a purely gravitational orbit, but including the Yarkovsky effect in the orbit fitting enabled the observations to fit well and allowed a  $da/dt$  estimate with the signal-to-noise ratio  $\text{SNR} \simeq 15$  (Fig. 3). In these cases, where the detection relies heavily on isolated and archival data, caution is warranted to avoid the possibility that mismeasurement or astrometric time tag errors are corrupting the result. As depicted in Fig. 3, the 1953 position offsets could not be attributed to timing errors, and the trail positions were re-measured with modern catalogs.

In subsequent studies a progressively increasing number of Yarkovsky detections have been announced (Chesley et al., 2008; Nugent et al., 2012a; Farnocchia et al., 2013b). The most precise Yarkovsky measurement is that of (101955) Bennu, the target of the OSIRIS-REx asteroid sample return mission, which has a 0.5% precision Yarkovsky detection, by far the finest precision reported to date. At the extremes, asteroid 2009 BD is the smallest object ( $D \sim 4 \text{ m}$ ) with a verified Yarkovsky detection, which was achieved

**Fig. 3.** Measured and predicted positions of (152563) 1992 BF on (a) January 10 and (b) January 12, 1953. The dark gray solid line is the asteroid trail appearing on Palomar plates on the two nights. Coordinate origin, right ascension at the abscissa, and declination at the ordinate are arbitrarily set to the end of the respective trail. The leftmost dashed trail labeled “extrapolated” represent pure extrapolation of the modern orbit without the thermal forces included. The mismatch in right ascension slightly improves if the 1953 data are included in the orbital solution as shown by the middle dashed trail. Still, the solution is more than  $3\sigma$  away from the measured trail. Only when the thermal accelerations are included in the orbital solution do the predicted orbital positions match the observations: Stars show fitted position at the beginning and the end of the trail. Adapted from Vokrouhlický et al. (2008).

because of its Earth-like orbit and the 2-yr arc of observations that the orbit enabled (Mommert et al., 2014). On the large end, there are two detections of 2- to 3-km-diameter asteroids, namely (2100) Ra-Shalom and (4179) Toutatis (Nugent et al., 2012a; Farnocchia et al., 2013b), which are both exceptionally well observed, having four and five radar apparitions, respectively.

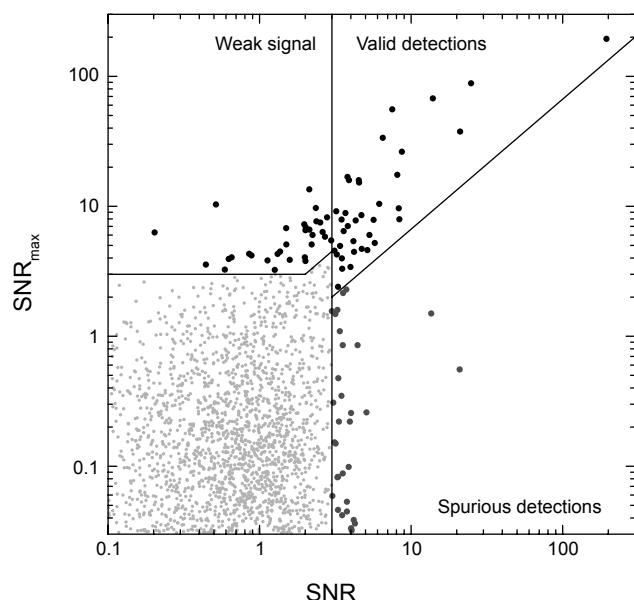

To initially test for a signal from the Yarkovsky effect in the astrometric data of a given object, one can fit the orbit with a transverse nongravitational acceleration  $a_T = A_2/r^2$ , with  $A_2$  being an estimated parameter, in addition to the orbital elements. This simple model yields a mean semimajor axis drift rate proportional to  $A_2$ , thus capturing the salient orbital deviation due to the Yarkovsky effect. The approach of using a one-parameter ( $A_2$ ) Yarkovsky model is particularly convenient because it completely bypasses the thermophysical processes that are otherwise fundamental to the Yarkovsky effect. Instead, by focusing only on the level of perturbation visible in the orbit, one is able to discern the Yarkovsky effect in the absence of any knowledge of physical properties. And yet, as we shall see in section 4.1,

the detection of a Yarkovsky drift can be used to estimate or infer a number of the physical and dynamical characteristics of the body. Obviously, in the case of bodies with particular interest, one can use a detailed thermophysical model of the Yarkovsky acceleration for the orbit determination in a subsequent analysis.

A population-wise, head-on approach to Yarkovsky detection thus starts with the list of asteroids with relatively secure orbits, e.g., at least 100 d of observational arc, among the NEAs. For each considered object the statistical significance of the Yarkovsky effect is obtained from the estimated value of  $A_2$  and its *a posteriori* uncertainty  $\sigma_{A_2}$  according to  $\text{SNR} = |A_2|/\sigma_{A_2}$ , where  $\text{SNR} > 3$  is generally considered to be a significant detection. Another parameter that is helpful in interpreting the results for a given object is the ratio between the estimated value of  $A_2$  and the expected value for extreme obliquity and the known or inferred asteroid size, which we call  $A_{2\max}$ . The value of  $A_{2\max}$  can be obtained by, for instance, a simple diameter scaling from the Bennu result (Farnocchia et al., 2013b; Chesley et al., 2014). The ratio  $S = A_2/A_{2\max} = \text{SNR}/\text{SNR}_{\max}$  provides an indication of how the estimated value of  $A_2$  compares to what could be theoretically expected. A value of  $S \gg 1$  indicates that the transverse nongravitational acceleration may be too strong to be related to the Yarkovsky effect. This could imply that the body has a far smaller density or size than assumed, or that nongravitational accelerations other than Yarkovsky are at play. A large value of  $S$  could also imply a spurious  $A_2$  estimate due to corrupt astrometry in the orbital fit. On the other hand,  $S \ll 1$  would suggest the possibility of higher density, size, or surface thermal inertia than assumed, but is often more readily explained by mid-range obliquity, which tends to null the diurnal component of the Yarkovsky drift.

Figure 4 depicts the distribution of NEAs in the  $\text{SNR}$  and  $\text{SNR}_{\max}$  space that we divide into four regions:

- We consider cases with  $\text{SNR} > 3$  and  $S < 1.5$  to be *valid detections* because the estimated value is no more than 50% larger than expected, perhaps as a result of unusually low density or a size far smaller than assumed. Table 1 lists the 36 objects with valid Yarkovsky detections given currently available astrometry.
- *Spurious detections* are those with  $\text{SNR} > 3$  and  $S > 1.5$ . Many of these are due to astrometric errors in isolated observation sets, such as precoveries, and can be moved to the left in Fig. 4 by deweighting the questionable data. We find 56 cases in this category, but only 12 with  $\text{SNR} > 4$ . There are two spurious cases with  $\text{SNR} > 10$  and  $S \gtrsim 10$  that cannot be due to astrometric errors and are yet unlikely to be attributed to the Yarkovsky effect.
- There are a number of objects with relatively low values for  $\sigma_{A_2}$  and yet the orbit does not reveal an  $\text{SNR} > 3$  detection (denoted as *weak signal* zone on Fig. 4). Specifically, these cases have  $\text{SNR}_{\max} > 3$  and  $\text{SNR} < 3$ , with  $S < 2/3$ . These cases are potentially interesting because they generally

**Fig. 4.**  $\text{SNR} = A_2/\sigma_{A_2}$ , with  $A_2$  being the parameter of an empirical transverse acceleration and  $\sigma_{A_2}$  its formal uncertainty, for reliable orbits of NEAs at the abscissa. The ordinate shows  $\text{SNR}_{\max}$ , the maximum expected value of SNR for the body (from an estimate of its size and given an extremal obliquity, optimizing the Yarkovsky effect). Various classes of solutions, organized into four sectors by the straight lines, are discussed in the text. Situation as of December 2014.

indicate a mid-range obliquity and, despite the lack of significance in the  $A_2$  estimate, useful bounds can be still placed on the Yarkovsky mobility of the object. We find 35 such cases in the current NEA catalog, six of which have  $S < 0.05$  (Table 2). In fact, this class warrants further dedicated analysis, similar to the search of new detections.

- The vast majority of NEAs are currently uninteresting due to  $\text{SNR} < 3$  and  $\text{SNR}_{\max} < 3$ , meaning that no detection was found nor was one reasonably expected.

It is worth noting that objects with nonprincipal-axis rotation states can reveal the Yarkovsky effect (e.g., Vokrouhlický *et al.*, 2005a); (4179) Toutatis is a large, slowly tumbling asteroid (e.g., Hudson and Ostro, 1995) with Yarkovsky SNR  $\approx 8$  (and  $S \approx 1$ ) due to an extensive set of radar ranging data. Also, the much smaller asteroid (99942) Apophis, which has been reported to have a measurable polar precession (Pravec *et al.*, 2014), presently has a solid Yarkovsky signal with  $\text{SNR} \approx 1.8$  (and  $S < 1$ ), although not high enough to be listed in Table 1, but still significant in light of the abundant radar astrometry available for Apophis (Vokrouhlický *et al.*, 2015). Similarly, binary asteroid systems may also reveal Yarkovsky drift in their heliocentric orbits (e.g., Vokrouhlický *et al.*, 2005b), although none presently appears in Table 1. We note that (363599) 2004 FG<sub>11</sub> has a satellite (Taylor *et al.*, 2012) and currently has a Yarkovsky SNR  $\approx 2.8$  (and  $S \approx 1$ ).

### 3.2. YORP Effect

Analyses of small-asteroid populations indicate clear traits of their evolution due to the YORP effect, both in rotation rate and obliquity (sections 4.5, 5.1, and 5.2). Accurate observations of individual objects, however, do not presently permit detection of the secular change in obliquity and reveal only the secular effect in rotation rate. Even that is a challenging task, because the YORP torque has a weak effect on kilometer-sized asteroids at roughly 1 AU heliocentric distance. Similar to the case of the Yarkovsky effect, the YORP detection is enabled via accurate measurement of a phase  $\phi$  associated with the rotation rate. This is because when the rotation frequency  $\omega$  changes linearly with time,  $\omega(t) = \omega_0 + (d\omega/dt)t$  (adopting the simplest possible assumption, since  $d\omega/dt$  may have its own time variability), the related phase  $\phi$  grows quadratically in time,  $\phi(t) = \phi_0 + \omega_0 t + \frac{1}{2}(d\omega/dt)t^2$ . Additionally, other perturbations (such as an unresolved weak tumbling) do not produce an aliasing signal that would disqualify YORP detection. So the determination of the YORP-induced change in the rotation rate  $d\omega/dt$  may basically alias with the rotation rate frequency  $\omega_0$  itself in the  $d\omega/dt = 0$  model. This is because small variations in  $\omega_0$  propagate linearly in time in the rotation phase. The YORP detection stems from the ability to discern this linear trend due to the  $\omega_0$  optimization and the quadratic signal due to a nonzero  $d\omega/dt$  value. In an ideal situation of observations sufficiently densely and evenly distributed over a given time interval  $T$ , one avoids the  $\omega_0$  and  $d\omega/dt$  correlation setting time origin at the center of the interval. At the interval limits the YORP effect manifests via phase change  $\approx \frac{1}{8}(d\omega/dt)T^2$ . Therefore, a useful approximate rule is that the YORP effect is detected when this value is larger than the phase uncertainty  $\delta\phi$  in the observations. Assuming optimistically  $\delta\phi \approx 5^\circ$  and  $T$  about a decade, the limiting detectable  $d\omega/dt$  value is  $\approx 5 \times 10^{-8}$  rad d<sup>-2</sup>. Obviously, detection favors a longer time-base  $T$  if accuracy of the early observations permits. In practice, the late 1960s or early 1970s was the time during which photoelectric photometry was introduced and allowed sufficiently reliable light curve observations. This sets a maximum  $T$  of about 40 yr today for bright-enough objects [e.g., (1620) Geographos (Durech *et al.*, 2008a); see, for completeness, an interesting YORP study for asteroid (433) Eros by Durech (2005)]. We should also mention that  $\omega$  and  $\phi$  above denote sidereal rotation rate and phase, respectively. Hence to convert asteroid photometry to  $\phi$  one needs to know the orientation of its spin axis in the inertial space and the shape model. Their solution may increase the realistic uncertainty in  $d\omega/dt$  if compared to the simple estimate discussed above.

Figure 5 shows an example of detected quadratic advance in sidereal rotation phase  $\phi$  in the case of the small coorbital asteroid (54509) YORP (see Lowry *et al.*, 2007; Taylor *et al.*, 2007). The expected YORP value of rotation-rate change matched the observed value, thus allowing interpretation of the signal as a YORP effect detection, although an accurate comparison is prohibited by lack of knowledge of

TABLE 1. List of the Yarkovsky effect detections as of December 2014.

Reliable detections with SNR larger than 3 are listed:  $\bar{r} = a\sqrt{1 - e^2}$  is the solar flux-weighted mean heliocentric distance, H is the absolute magnitude, D is the diameter derived from the literature when available [and obtained here from the European Asteroid Research Node (EARN) Near-Earth Asteroids Database, <http://earn.dlr.de/nea>] or from absolute magnitude with 15.4% albedo, the da/dt and formal uncertainty  $\sigma_{da/dt}$  are derived from the orbital fit (via  $A_2$  and  $\sigma_{A_2}$  values as described in Farnocchia et al., 2013b). SNR = (da/dt)/ $\sigma_{da/dt}$  is the quality of the semimajor axis drift determination, and S = SNR/SNR<sub>max</sub>, where SNR<sub>max</sub> is the maximum estimated SNR for the Yarkovsky effect. Data arc indicates the time interval over which the astrometric information is available, and N<sub>rad</sub> denotes the number of radar apparitions in the fit.

TABLE 2. List of the most notable Yarkovsky effect nondetections as of December 2014.

Notable nondetections of the Yarkovsky effect with 1/S > 10 are listed. Columns as in Table 1.

**Fig. 5.** Advance of the sidereal rotation phase  $\Delta\phi$  (ordinate in degrees) vs. time (in days) for the small Earth-coorbital asteroid (54509) YORP. Symbols are measurements with their estimated uncertainty, as follow from assembling the radar observations at different apparitions. The gray line is a quadratic progression  $\Delta\phi = \frac{1}{2}(\mathrm{d}\omega/\mathrm{d}t)t^2$ , with  $\mathrm{d}\omega/\mathrm{d}t = 350 \times 10^{-8} \text{ rad d}^{-2}$ . Time origin set arbitrarily to July 27, 2001, corresponding to the first measurement. Adapted from *Taylor et al.* (2007).

the full shape of this body (due to repeated similar viewing geometry from Earth). A complete list of the YORP detections, as of September 2014, is given in Table 3. To appreciate their accuracy, we note that they correspond to a tiny change in sidereal rotation period by a few milliseconds per year: 1.25 ms  $\text{y}^{-1}$  for (54509) YORP to a maximum value of 45 ms  $\text{y}^{-1}$  for (25143) Itokawa. While not numerous at the moment, we expect the list will more than double during the next decade. There are presently two asteroids, (1620) Geographos and (1862) Apollo, for which both Yarkovsky and YORP effects have been detected. These cases are of special value, provided a sufficiently accurate physical model of the body is available (see *Rozitis et al.*, 2013; *Rozitis and Green*, 2014).

(25143) Itokawa holds a special place among the asteroids for which the YORP effect has been detected. Not

only was this the first asteroid for which YORP detection was predicted (*Vokrouhlický et al.*, 2004), but the shape of this body is known very accurately thanks to the visit of the Hayabusa spacecraft. This has led researchers to push the attempts for an accurate YORP prediction to an extreme level (e.g., *Scheeres et al.*, 2007; *Breiter et al.*, 2009; *Lowry et al.*, 2014), realizing that the results depend in this case very sensitively on the small-scale irregularities of the shape (see *Statler*, 2009, for a general concept). However, in spite of an uncertainty in the YORP prediction, the most detailed computation consistently predicted deceleration of the rotation rate by YORP, as opposed to the detected value (Table 3). A solution to this conundrum has been suggested by *Scheeres et al.* (2007), who proposed that the difference in density between the “head” and “body” of this asteroid may significantly shift the center of mass. This effect introduces an extra torque component that could overrun the YORP torque, canonically computed for homogeneous bodies, and make the predicted deceleration become acceleration of the rotation rate. *Lowry et al.* (2014) adopted this solution, predicting that the two parts of Itokawa have a very different densities of  $\approx 1.75 \text{ g cm}^{-3}$  and  $\approx 2.85 \text{ g cm}^{-3}$ . Nevertheless, the situation may be even more complicated: *Golubov and Krugly* (2012) have shown that transverse heat communication across boulder-scale features on the surface of asteroids may cause a systematic trend toward acceleration of the rotation rate. Indeed, in the most complete works so far, *Golubov et al.* (2014) and *Ševeček et al.* (2015) show that the detected acceleration of Itokawa’s rotation rate may be in large part due to detailed modeling of the effects described by *Golubov and Krugly* (2012) without invoking a large density difference in the asteroid. The complicated case of Itokawa thus keeps motivating detailed modeling efforts of the YORP effect. Luckily, not all asteroidal shapes show such an extreme sensitivity on the small-scale surface features (e.g., *Kaasalainen and Nortunen*, 2013), thus allowing an easier comparison between the detected and predicted YORP signals.

On a more general level, we note that in spite of rotation periods ranging from a fraction of an hour to more than 12 h, all five asteroids for which the YORP effect was detected reveal acceleration of the rotation rate. It is not yet known

TABLE 3. List of the YORP effect detections as of September 2014.

Object	$\mathrm{d}\omega/\mathrm{d}t$ ( $\times 10^{-8} \text{ rad/d}^2$ )	H (mag)	P (h)	$\gamma$ (deg)	$\bar{r}$ (AU)	Reference
(54509) YORP	$350 \pm 35$	22.6	0.203	173	0.98	<i>Lowry et al.</i> (2007); <i>Taylor et al.</i> (2007)
(25143) Itokawa	$3.5 \pm 0.4$	18.9	12.132	178	1.27	<i>Lowry et al.</i> (2014)
(1620) Geographos	$1.2 \pm 0.2$	15.6	5.223	152	1.18	<i>Ďurech et al.</i> (2008a)
(1862) Apollo	$5.5 \pm 1.2$	16.3	3.065	162	1.22	<i>Kaasalainen et al.</i> (2007); <i>Ďurech et al.</i> (2008b)
(3103) Eger	$1.4 \pm 0.6$	15.3	5.710	176	1.32	<i>Ďurech et al.</i> (2012)
(1865) Cerberus	$<0.8$	16.8	6.803	178	0.96	<i>Ďurech et al.</i> (2012)

For each of the asteroids with the YORP effect detected we give (1) rotation rate change  $\mathrm{d}\omega/\mathrm{d}t$  derived from the photometric data, (2) absolute magnitude H, (3) rotation period P, (4) obliquity  $\gamma$ , and (5) the solar flux weighted mean heliocentric distance  $\bar{r} = a\sqrt{1 - e^2}$ , with semimajor axis a and eccentricity e. In the case of (1865) Cerberus, the observational limit  $|\mathrm{d}\omega/\mathrm{d}t| < 0.8 \times 10^{-8} \text{ rad/d}^2$  is nontrivial for a body of its size, orbit, and rotation state. Less severe limits on  $|\mathrm{d}\omega/\mathrm{d}t|$  were also derived for (2100) Ra-Shalom (*Ďurech et al.*, 2012) and (433) Eros (*Ďurech*, 2005).

whether this expresses observational bias against detection of the YORP-induced deceleration of the rotation rate, or whether it points toward the true asymmetry in YORP's ability to accelerate vs. decelerate rotation rate. Note that one would statistically expect to detect YORP deceleration of the rotation rate principally among asteroids rotating slowly, but this is exactly where accurate photometric observations are especially difficult. Efforts with the goal of detecting the YORP effect for asteroids with rotation periods in the 20–40-h range are underway, with the results expected in the next couple of years. Hopefully, they will help in settling the issue of possible asymmetry in the YORP effect on  $\omega$ .

### 3.3. Binary YORP Effect

The BYORP effect has not been directly observed as of yet, although some predictions stemming from this effect have been confirmed. There are currently significant campaigns observing binary asteroids to search for predicted outcomes of the BYORP effect, both in isolation or mixing with other evolutionary effects. The basic technique for detecting the BYORP effect as it acts in solitude was proposed by *McMahon and Scheeres* (2010b) and suggests that computing the drift in a binary system's mean anomaly due to changes in the semimajor axis is the most effective approach, as this drift will increase quadratically in time as compared to purely Keplerian motion. The relative change  $\Delta M$  in the mean anomaly  $M$  of a binary asteroid due to the BYORP effect in time  $t$  is  $a\Delta M = -\frac{3}{4}n(da/dt)t^2$ , where  $n$  is the binary mean motion and  $(da/dt)$  should be substituted from equation (6). The corresponding delay, or advance, in occultation timing of the binary is  $\approx -\frac{3}{4}[(da/dt)/a]t^2$ .

*McMahon and Scheeres* (2010b) provide a table of known and possibly synchronous binary asteroids along with an estimate of mean anomaly drift, based on scaling the computed (66391) 1999 KW<sub>4</sub> BYORP coefficient to the different asteroid systems, accounting for secondary size, system mass, and heliocentric orbit. As these stated drifts make a strong assumption in applying the KW<sub>4</sub> BYORP coefficient, they are not true predictions, but rather provide a prediction of relative strength of the BYORP effect for different bodies. Petr Pravec has expanded this list of predicted drift rates, making them accessible in the Binary Asteroid Database (<http://www.asu.cas.cz/~asteroid/binasdata.htm>) and indicating which should have the largest, and hence easiest to detect, drifts along with other information of use to observers.

This list represents an active longer-term campaign by Pravec and colleagues to observe binary asteroid systems during predicted occultation events. The most significant result of this effort to date has been focused on the binary asteroid (175706) 1996 FG<sub>3</sub> (*Scheirich et al.*, 2015). For this body, observations over a 17-yr time span provided a strong “zero” constraint on the BYORP drift rate. While not a direct detection of the BYORP effect, this is fully consistent with a current prediction that involves the BYORP-tide equilibrium state. The confirmation of a binary system in this state has scientific implications as it means that the tidal dissipation

that occurs within a rapidly spinning primary body can be determined once the BYORP coefficient for a secondary asteroid is determined. Although it cannot be directly measured when this will occur in such an equilibrium, it is possible to estimate the BYORP coefficient based on detailed models of the secondary and its albedo, such as could be obtained by an *in situ* spacecraft. Thus, a space mission to a binary in such a state could provide an unprecedented view into the internal geophysics of a rubble pile.

Other bodies of current interest include any binary systems with a synchronous secondary. A direct detection of BYORP is feasible if the body is in an expansive state, although the relatively short lifetime predicted for such binaries would imply that finding such a binary may be difficult. Similarly, this is also true of a contractive state, as this should be heading toward a BYORP-tide equilibrium. Additional measurements are important, however, as the number of binaries found to be in the equilibrium state relative to the number found in expansive or contractive states will be an important measurement with implications beyond the BYORP effect in isolation. Specifically, such observations could provide insights into the internal tidal dissipation of energy that occurs for rubble-pile binary asteroid primaries (e.g., *Jacobson and Scheeres*, 2011b).

## 4. APPLICATIONS OF THE YARKOVSKY EFFECT

### 4.1. Physical Properties of Asteroids

The Yarkovsky effect can be used as a tool to probe the nature of individual asteroids. This is possible because an asteroid's Yarkovsky drift is a manifestation of several of its physical properties, and so a direct measurement of  $da/dt$  allows insight into the characteristics of the body. Of primary importance are the obliquity, size, and mass of the asteroid, although the thermal and reflective properties and the rotation rate are also important.

Not surprisingly, the more that is known about the asteroid, the more that can be divined from a Yarkovsky detection. In the weakest situation, which is not so unusual, we have only  $da/dt$  and the absolute magnitude  $H$ . Even in this case we can already put meaningful constraints on the obliquity of the body through the  $\cos \gamma$  dependence. For instance, the sign of  $da/dt$  reveals immediately whether the rotation is retrograde or direct. Moreover, the value of  $S$  from Table 1 can serve as a proxy for  $|\cos \gamma|$ , while variations in  $pD$  and  $\Theta_\omega$  add uncertainty to this estimate. *Vokrouhlický et al.* (2008) used this principle to infer that (152563) 1992 BF must have obliquity  $\gamma > 120^\circ$ , after accounting for reasonable variations in other unknowns.

If the spin state of the body is known, generally from some combination of radar imaging and optical light curves, we have a much clearer insight into the nature of the body because  $\cos \gamma$  is removed as an unknown and the thermal parameter  $\Theta_\omega$  is better constrained. Indeed, in such cases we are left with a simple relationship between  $pD$  and the

thermal inertia  $\Gamma$ . But the diameter  $D$  can be measured directly by radar, or inferred from taxonomic type or measured albedo, or can just be derived from an assumed distribution of asteroid albedo, allowing the constraint to be cast in terms of the bulk density  $\rho$  and thermal inertia  $\Gamma$ . The gray region of Fig. 6 depicts this type of constraint for the case of (101955) Bennu. The peak in  $\rho$  seen in Fig. 6 is associated with  $\Theta_{\omega} \approx 1$ , where the Yarkovsky effect obtains its maximum effectiveness. This characteristic peak in the  $\rho$  vs.  $\Gamma$  relationship often allows strict upper bounds on  $\rho$  (e.g., Chesley et al., 2003).

We note that the degeneracy between  $\rho$  and  $\Gamma$  could in principle be broken by an independent estimate of  $\rho$  that would allow a direct estimate of  $\Gamma$ , albeit with the possibility of two solutions. While this approach has so far not been possible, we anticipate it here as a natural outcome of the first detection of the Yarkovsky effect on a well-observed binary system.

Another approach to breaking the correlation between  $\rho$  and  $\Gamma$  makes use of measurable solar radiation pressure deviations on the orbit, which yields an area-to-mass ratio. With a size estimate, an independent mass estimate can lead to a double solution for the thermal inertia of the body (e.g., Mommert et al., 2014).

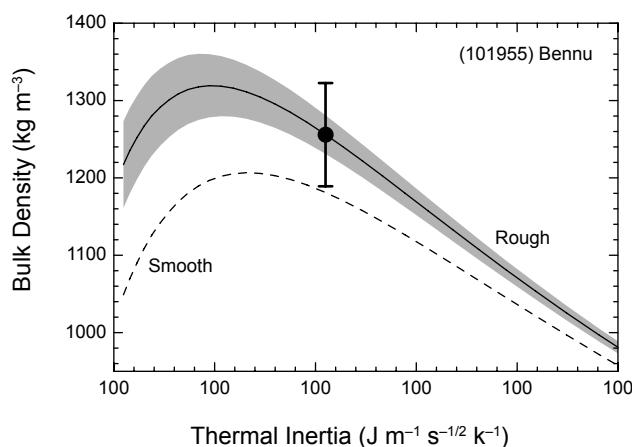

The alternative approach has been applied successfully in a few special cases to date. Specifically, observations of an asteroid's thermal emissions can afford independent constraints on the thermal inertia, breaking the degeneracy between  $\rho$  and  $\Gamma$ , allowing a direct estimate of the asteroid's bulk density. Perhaps the most striking example here is the

case of (101955) Bennu, which has a well-constrained shape, spin state, and thermal inertia. When these are linked with the high precision  $da/dt$  estimate (Table 1), the result is a bulk density of  $1260 \pm 70 \text{ kg m}^{-3}$  (Fig. 6), where the formal precision is better than 6% (Chesley et al., 2014). Other similar cases include (1862) Apollo, (1620) Geographos, and (29075) 1950 DA (respectively, Rozitis et al., 2013, 2014; Rozitis and Green, 2014). In each of these cases the authors combine  $da/dt$ , radar imaging, and thermal measurements to derive the bulk density of the asteroid.

In the best cases of Yarkovsky detection, where we also have a shape model, spin state, and thermophysical characterization, one can infer the local gravity of the body. This can be of profound engineering interest for the asteroid targets of space missions, e.g., (101955) Bennu. The mission design challenges for the OSIRIS-REx mission are significantly eased due to the Yarkovsky constraint on Bennu's mass and bulk density. Another such case is (29075) 1950 DA, which is not a space mission target, and yet the estimates of local surface gravity derived from Yarkovsky have profound implications. Rozitis et al. (2014) found that their thermal measurements, when combined with the Yarkovsky drift reported for 1950 DA by Farnocchia and Chesley (2014), required a low asteroid mass. The estimated mass was so low, in fact, that it implied that the equatorial surface material on 1950 DA is in tension due to centrifugal forces. And yet the estimated thermal inertia was low enough that it required a loose, fine-grained regolith on the surface. This seeming contradiction is most readily resolved by the action of cohesive forces due to van der Waals attraction between regolith grains, and represents the first confirmation of such forces acting on an asteroid, which had already been anticipated by Scheeres et al. (2010). And so, through a curious interdisciplinary pathway, the measurement of the Yarkovsky drift on 1950 DA reveals the nature of minute attractive forces at work in the asteroid's regolith.

**Population implications** — The discussion above treats Yarkovsky detections in a case-by-case manner, deriving additional information for the specific asteroid at hand. However, the wealth of Yarkovsky detections listed in Table 1 allows an insight into the NEA population as a whole. Of particular interest is the distribution of obliquities implied by the tabulated detections, of which 28 out of 36 detections reveal  $da/dt < 0$  and thus about 78% of the sample requires retrograde rotation (see also Fig. 9).

This excess of retrograde rotators represents an independent confirmation of a result first reported by La Spina et al. (2004). The mechanism for an excess of retrograde rotators in the NEA population is a result of the Yarkovsky driven transport mechanism (e.g., Morbidelli and Vokrouhlický, 2003). The location of the  $v_6$  resonance at the inner edge of the main belt implies that main-belt asteroids entering the inner solar system through this pathway must have  $da/dt < 0$  and thus retrograde rotation. Direct rotators will tend to drift away from the resonance. Asteroids entering the inner solar system through other resonance pathways, principally the 3:1 mean-motion resonance with Jupiter, may drift either in or out into the resonance, and so will have parity between retrograde

**Fig. 6.** Bulk density  $\rho$  solution for (101955) Bennu from detected value of the Yarkovsky orbital effect as a function of the surface thermal inertia  $\Gamma$ . The dashed line corresponds to the  $da/dt = \text{const.}$  solution for a smooth-surface model, taking into account a detailed shape model and a nonlinear boundary condition. The solid line accounts for 50% small-scale roughness in each of the surface facets of the shape model, while the gray zone takes into account the estimated ~17% uncertainty in the roughness value. The nonlinearity of the  $da/dt$  isoline in the  $\rho$  vs.  $\Gamma$  plane follows from equations (1) and (3). Adapted from Chesley et al. (2014).

and direct rotators. *Farnocchia et al.* (2013b) analyze this retrograde prevalence, including selection effects among the Yarkovsky detections, and find that it is fully consistent with the Yarkovsky-driven transport, and point out that this can be used to derive a distribution of the obliquities of NEAs.

#### 4.2. Impact Hazard Assessment

Most reported potential impacts are associated with newly discovered objects for which the uncertainty at the threatening Earth encounter is dominated by the uncertainties in the available astrometric observations. However, as the astrometric dataset grows, the fidelity of the force model used to propagate the asteroid from discovery to potential impact becomes more and more important. For a few asteroids with extraordinarily precise orbits, the Yarkovsky effect is a crucial aspect of an analysis of the risk posed by potential impacts on Earth. When the Yarkovsky effect is directly revealed by the astrometric data, the analysis approach is straightforward, as is the case for (101955) Bennu and (29075) 1950 DA (e.g., *Milani et al.*, 2009; *Chesley et al.*, 2014; *Farnocchia and Chesley*, 2014).

However, there are some cases in which the astrometry provides little or no constraint on the Yarkovsky effect, and yet Yarkovsky drift is a major contributor to uncertainties at a potentially threatening Earth encounter. In these situations we are forced to assume distributions on albedo, obliquity, thermal inertia, etc., and from these we can derive a distribution of  $A_2$  or  $da/dt$ . A Monte Carlo approach with these distributions allows us to better represent uncertainties at the threatening Earth encounter, and thereby compute more realistic impact probabilities. This technique has been necessary for (99942) Apophis and has been applied by *Farnocchia et al.* (2013a) before *Vokrouhlický et al.* (2015) made use of rotation-state determination of this asteroid. See the chapter by Farnocchia et al. in this volume) for a more complete discussion of Yarkovsky-driven impact hazard analyses.

#### 4.3. Meteorite Transport Issues

The Yarkovsky effect, with its ability to secularly change the semimajor axes of meteoroids (precursors of meteorites, which are believed to be fragments of larger asteroids located in the main belt between the orbits of Mars and Jupiter), was originally proposed to be the main element driving meteorites to Earth (see *Öpik*, 1951; *Peterson*, 1976). However, direct transport from the main belt, say as a small body slowly spiraling inward toward the Sun by the Yarkovsky effect, required very long timescales and unrealistic values of the thermal parameters and/or rotation rates for meter-sized bodies. Moreover, a.m./p.m. fall statistics and measured preatmospheric trajectories in rare cases (like the Příbram meteorite) indicated many meteorites had orbits with the semimajor axis still close to the main-belt values.

The problem was overcome in the late 1970s and early 1980s by advances in our understanding of asteroid dynamics. Numerous works have shown that the transport routes

that connect main-belt objects to planet-crossing orbits are in fact secular and mean-motion resonances with giant planets, such as the  $v_6$  secular resonance at the lower border of the main asteroid belt and/or the 3:1 mean-motion resonance with Jupiter. Putting this information together with the Yarkovsky effect, *Vokrouhlický and Farinella* (2000) were able to construct a model in which meteoroids or their immediate precursor objects are collisionally born in the inner and/or central parts of the main belt, from where they are transported to the resonances by the Yarkovsky effect. En route, some of the precursors may fragment, which can produce new swarms of daughter meteoroids that eventually reach the escape routes to planet-crossing orbits. With this model, Vokrouhlický and Farinella could explain the distribution of the cosmic-ray exposure ages of stony meteorites as a combination of several timescales: (1) the time it takes for a meteoroid to collisionally break, (2) the time it takes a meteoroid to travel to a resonance, (3) the time it takes for that resonance to deliver the meteoroid to an Earth-crossing orbit, and (4) the time it takes the meteoroid on a planet-crossing orbit to hit Earth.

While successful to the first order, this model certainly contains a number of assumptions and potentially weak elements, especially in the light of subsequent rapid development of the YORP effect theory, that warrant further work. For instance, one of the difficulties in refining the meteorite delivery models is the uncertainty in identification of the ultimate parent asteroid (or asteroids) for a given meteorite class (e.g., see the chapter by Vernazza et al. in this volume). Thus, among the ordinary chondrites we have a reasonable guess that LL-chondrites originate from the Flora region [or the asteroid (8) Flora itself] and the L-chondrites originate from disruption of the Gefion family. There were numerous guesses for the H-chondrite source region [such as the asteroid (6) Hebe], but none of them has been unambiguously confirmed. The model presented by *Nesvorný et al.* (2009), while more educated in the choice of the L-chondrite source region than the previous work of *Vokrouhlický and Farinella* (2000), requires immediate parent bodies of these meteorites, 5–50 m in size, to reach the powerful 3:1 mean-motion resonance with Jupiter. This means they should have migrated by the Yarkovsky effect some 0.25–0.3 AU from their source location in less than 0.5 b.y. While this is not a problem in a scenario where the bodies rotate about the body-fixed axis whose direction is preserved in the inertial space, it is not clear if this holds when the bodies would start to tumble or their axes started to evolve rapidly due to the YORP effect. Clearly, more work is needed to understand the Yarkovsky effect in the small-size limit for bodies whose spin axis may undergo fast evolution.

#### 4.4. Orbital Convergence in Asteroid Families and Pairs

Over the past decade the Yarkovsky and YORP effects have helped to significantly boost our knowledge of the asteroid families (e.g., see the chapter by Nesvorný et al. in

this volume). This is because they represent a unique time-dependent process in modeling their structure, thus allowing us to constrain their ages for the first time.

The most accurate results are obtained for young-enough families (ages  $< 10$  m.y., say), for which effects of the deterministic chaos are weak. As shown in the pioneering works of Nesvorný *et al.* (2002, 2003), the basic tool to determine the origin of the family is provided by the convergence of orbital secular angles (the nodal and pericenter longitudes  $\Omega$  and  $\varpi$ ) at some moment in the past. Because the rate at which these angles precess in space depends sensitively on the semimajor axis value, the past values of  $\Omega$  and  $\varpi$  of the family members depend on their Yarkovsky drift-rates  $da/dt$ . This contribution may not be negligible, because the changes in precession rates produce effects that grow quadratically in time (the same way as described in sections 3.1 and 3.2 for longitude in orbit or sidereal rotation phase). Thus Nesvorný and Bottke (2004) were able to significantly improve the uncertainty in the age of the Karin family by including the Yarkovsky effect in their model. At the same time, this work provided an effective detection of the Yarkovsky effect for the main-belt asteroids. This technique has been later used for age constraints of several other young families (e.g., Novaković, 2010; Novaković *et al.*, 2012, 2014), including sub-million-year-old clusters (e.g., Nesvorný *et al.*, 2006, 2008; Nesvorný and Vokrouhlický, 2006; Vokrouhlický *et al.*, 2009).

While the methods of dating young asteroid families involve convergence of the orbital angles only, the determination of ages of the asteroid pairs (e.g., Vokrouhlický and Nesvorný, 2008; Pravec *et al.*, 2010) represents an even more ambitious task. In this case, one seeks to achieve a full convergence of two asteroidal orbits into a single location in the Cartesian space (within the distance of about a radius of the Hill sphere of the parent body) and with a small relative velocity (comparable to the escape velocity from the parent body). It is not surprising that the Yarkovsky effect again plays important role in this effort. The best cases, such as the pair (6070) Rheinland and (54827) 2001 NQ<sub>8</sub>, allow one to also infer constraints on the obliquities of the individual components, consequently providing predictions directly testable by further observations (e.g., Vokrouhlický and Nesvorný, 2009; Vokrouhlický *et al.*, 2011).

#### 4.5. Spreading of Asteroid Families

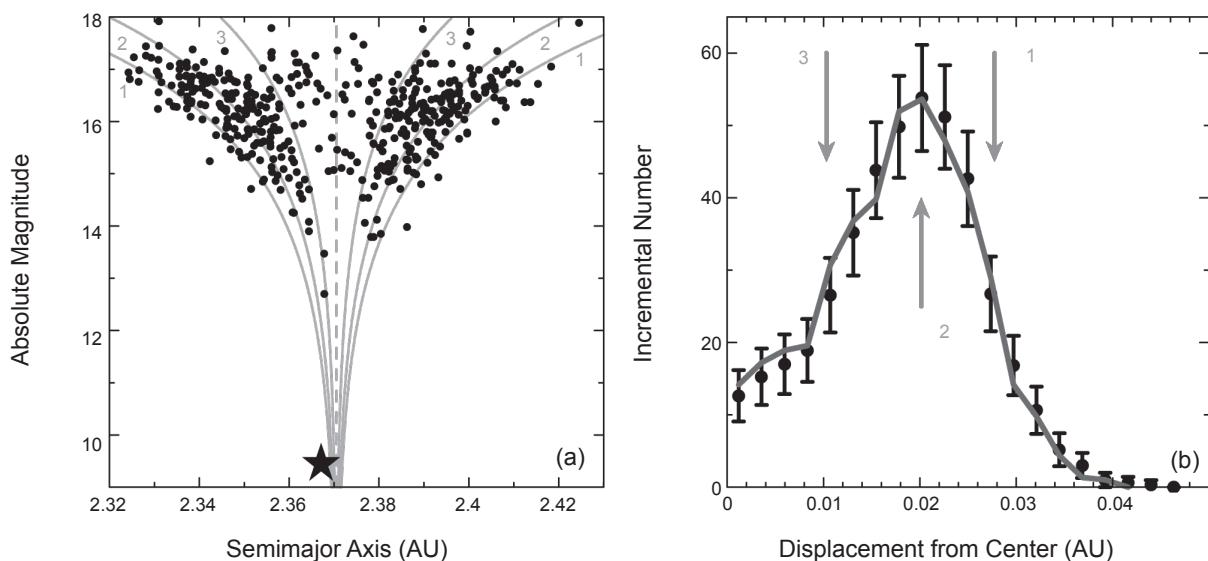

Older asteroid families (ages  $> 10$  m.y., say) do not permit application of the fine age-determination methods described in section 4.4. This is because orbits in the main asteroid belt are affected by deterministic chaos over long timescales. Hence it is not possible to reliably reconstruct past values of the orbital secular angles, with the proper values of semimajor axis  $a_p$ , eccentricity  $e_p$ , and inclination  $i_p$  being the only well-defined parameters at hand. Still, these proper elements are constructed using approximate dynamical models, spanning time intervals quite shorter than the typical ages of large asteroid families. While the deterministic chaos is still in action over long timescales and produces a

slow diffusion of the proper  $e_p$  and  $i_p$  values, the Yarkovsky effect is the principal phenomenon that changes the proper  $a_p$  values of multi-kilometer-sized asteroids. Bottke *et al.* (2001), studying an anomalous structure of the Koronis family, presented the first clear example of the Yarkovsky effect sculpting a large-scale shape of an asteroid family in  $a_p$  and  $e_p$ . It also approximately constrained its age to  $\sim 2.5\text{--}3$  b.y. [see also Vokrouhlický *et al.* (2010) for a similar study of the Sylvia family].

A novel method suitable for age determination of families a few hundred million years old has been presented by Vokrouhlický *et al.* (2006a). It stems from the observation that small asteroids in some families are pushed toward extreme values of the semimajor axis and, if plotted in the  $a_p$  vs.  $H$  (absolute magnitude) diagram, they acquire an “eared” structure (Fig. 7). Since this peculiar structure is not compatible with a direct emplacement by any reasonable ejection field, Vokrouhlický *et al.* (2006a) argued it must result from a long-term dynamical evolution of the family. In particular, postulating that the initial dispersal in  $a_p$  of the family members was actually small, they showed that Yarkovsky drift itself accounted for most of the family’s extension in semimajor axis. Assisted by the YORP effect, which over a YORP-cycle timescale tilts obliquities toward extreme values, the Yarkovsky effect (dominated by its diurnal component) is maximized, and pushes small family members toward the extreme values in  $a_p$ . If properly modeled, this method allows us to approximately constrain the interval of time needed since the family-forming event to reach the observed extension (Fig. 7). Several applications of this method can be found in Vokrouhlický *et al.* (2006a,b,c), Bottke *et al.* (2007), Carruba (2009), or Carruba and Morbidelli (2011). Recently Bottke *et al.* (2015) noticed that the classical setting of this method does not permit a satisfactory solution for the low-albedo, inner-belt Eulalia family. Their proposed modification requires an extended time spent by small asteroids in the extreme obliquity state, which in turn requires a simultaneous slowdown in the evolution of their rotation rates by the YORP effect. In fact, this may be readily obtained by postulating that the YORP strength changes on a timescale shorter than the YORP cycle, an assumption that may follow from the extreme sensitivity of the YORP effect to asteroid shape [the self-limitation effect discussed in section 2.1; see also Cotto-Figueroa *et al.* (2015)]. It is not clear, however, why this phenomenon should manifest itself primarily in this particular family, or whether it generally concerns all families  $\sim 1$  b.y. old.

The model of Vokrouhlický *et al.* inherently contains a prediction that the small members in the “eared” families have preferred obliquity values (such that prograde-rotating objects occupy regions in the family with largest  $a$  values, and vice versa). Interestingly, recent works of Hanuš *et al.* (2013b) and Kryszczyńska (2013) confirm this trend in the cases of several families, and more detailed studies are underway.

A peculiar situation arises for families embedded in the first-order mean-motion resonances with Jupiter. In these cases, the resonant lock prohibits large changes in the

**Fig. 7.** (a) The Ergone family members projected on the plane of the proper semimajor axis  $a_p$  and the absolute magnitude  $H$ ; 432 numbered family members, including (163) Ergone (star), are shown as black symbols. The gray lines show  $0.2 H = \log(|a_p - a_0|/C)$ , with  $a_0 = 2.3705$  AU and three different values of the  $C$  parameter labeled 1, 2, and 3. (b) Fixing the  $H$  level (16 mag in our case) results in a one-to-one link between the  $C$  value and a displacement from the center  $a_0$ , shown here at the abscissa. The symbols represent the Ergone family using a statistical distribution in the  $C$ -bins (assuming a symmetry  $C \rightarrow -C$  in this case); uncertainty is simply  $\sqrt{N}$ , where  $N$  is the number of asteroids in the bin. A numerical model (dark gray line) seeks to match the distribution by adjusting several free parameters such as the family age and initial dispersal of fragments from the largest fragment. The gray arrows point to the corresponding  $C = \text{const.}$  lines on (a). Adapted from Vokrouhlický et al. (2006a), with the family update as of April 2014.

semimajor axis, but the Yarkovsky effect manifests itself by a secular increase or decrease of the eccentricity. Modeling of this evolution allowed Brož and Vokrouhlický (2008) and Brož et al. (2011) to estimate the age of the Schubart and Hilda families located in the 3:2 mean-motion resonance with Jupiter.

## 5. APPLICATIONS OF THE YORP AND BINARY YORP EFFECTS

### 5.1. Distribution of Rotation Rate and Obliquity for Small Asteroids

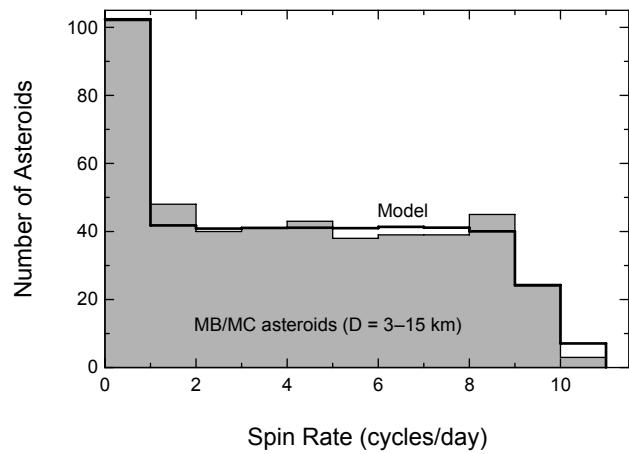

As explained in section 2.1, a secular change in rotation rate and obliquity are the two main dynamical implications of the YORP effect. Therefore, it is has been natural to seek traits of these trends among the populations of small asteroids. Luckily, the amount of data and their quality have significantly increased over the last decade and allowed such analyses.

**5.1.1. Rotation-rate distribution.** The distribution of rotation frequencies of large asteroids in the main belt matches a Maxwellian function quite well with a mean rotation period of  $\sim 8\text{--}12$  h, depending on the size of the bin used. However, data for asteroids smaller than  $\sim 20$  km show significant deviations from this law, with many asteroids either having very slow or very fast rotation rates. Note that similar data are also available for NEAs, but the main-belt sample is more

suitable because its interpretation is not complicated by possible effects of planetary close approaches. After eliminating known or suspected binary systems, solitary kilometer-sized asteroids in the main asteroid belt were shown to have a roughly uniform distribution of rotation frequencies (Pravec et al., 2008) (Fig. 8). The only statistically significant deviation was an excess of slow rotators (periods less than a day or so). Note that the sample described by Pravec et al. (2008) is superior to other existing datasets so far in elimination of all possible survey biases [which may prevent recognition of slow rotators (P. Pravec, personal communication)].

These results are well explained with a simple model of a relaxed YORP evolution. In this view asteroid spin rates are driven by the YORP effect toward extreme (large or small) values on a characteristic (YORP) timescale dependent on the size. Asteroids evolving toward a state of rapid rotation shed mass and thus put a brake on their rotation rate, while those who slow their rotation too much enter into a tumbling phase. They may later emerge from this state naturally, with a new spin vector, or may gain rotation angular momentum by subcatastrophic impacts. After a few cycles the spin rates settle to an approximately uniform distribution and the memory of its initial value is erased. In fact, the observations similar to those shown in Fig. 8 may help to quantitatively calibrate the processes that allow bodies to reemerge from the slow-rotating state.

Statler et al. (2013) presented a first attempt to obtain unbiased rotation properties of very small NEAs. They found

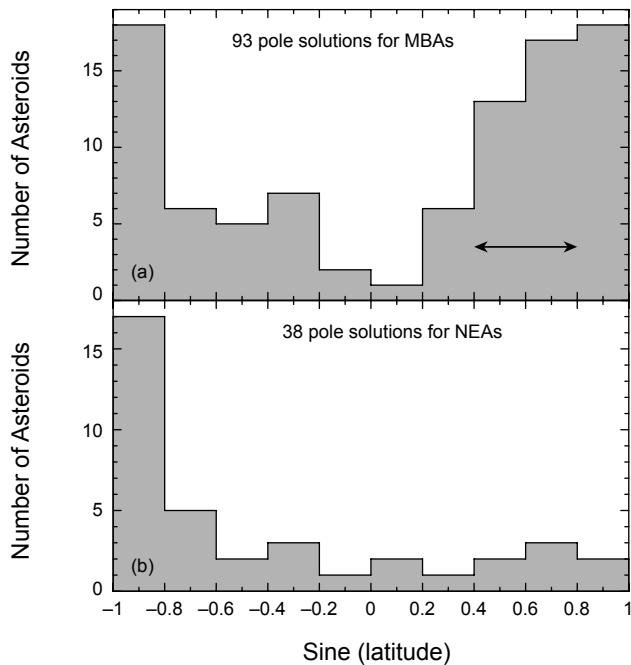

**Fig. 8.** Spin rate distribution of 462 small main-belt and Mars-crossing asteroids (sizes in the 3–15-km range, with a median value of 6.5 km). The distribution is flat with only two features: (1) an excess of slow rotators with periods longer than 1 d (the first bin), and (2) a linear decrease on the 8–10 cycles d<sup>-1</sup> interval. The latter is simply due to rotational fission limit dependence on the actual shape of the body, while the former holds information how the spin reemerges from the slow-rotation limit. Results from a simple model of a YORP-relaxed population of objects is shown in black (model). Adapted from Pravec *et al.* (2008), with an update from P. Pravec as of April 2014.

an anomalously large fraction of very fast rotating bodies in the <60-m group, which may witness a preferential ability of YORP to accelerate the rotation rate of small asteroids. A larger sample, less vulnerable to potential errors and biases, will be needed to verify this potentially important result.

**5.1.2. Obliquity distribution.** Similarly, the distribution of pole orientation of large asteroids in the main belt is roughly isotropic, with only a moderate excess of prograde rotating bodies. On the other hand, rotation poles of small asteroids (sizes  $\leq$ 30 km) are strongly concentrated toward ecliptic south and north poles (Hanuš *et al.*, 2013a) (Fig. 9). Note that this trend is better exhibited in the retrograde-rotating group (obliquities  $>90^\circ$ ), because the prograde-rotating asteroids are perturbed by secular spin-orbit resonances (e.g., Vokrouhlický *et al.*, 2006d). As a result, there is more mixing among the obliquities  $<90^\circ$ , which causes their flatter distribution in Fig. 9. Overall, this result can again be matched with the above-mentioned simple model of YORP evolution, because YORP torques drive obliquity toward its extreme values (e.g., Čapek and Vokrouhlický, 2004).

The pole distribution of NEAs, in spite of a still limited sample, indicates a strong preference of directions near the south ecliptic pole (La Spina *et al.*, 2004) (Fig. 9). The ratio between the number of retrograde- vs. prograde-rotating bodies is nearly 3:1. This is in a very good agreement with prediction from a model, where most NEAs are delivered from the main belt via principal resonant routes, secular v<sub>6</sub> resonance, and 3:1 mean-motion resonance with Jupiter

**Fig. 9.** (a) Distribution of ecliptic pole latitude for 93 small main-belt asteroids (MBAs; sizes less than 30 km). The arrow indicates the zone of prograde-rotating objects potentially affected by the spin-orbit resonances (e.g., Vokrouhlický *et al.*, 2006d). This effect is nonexistent for retrograde-rotating objects and the poles are let to drift closer to the extreme value. (b) Distribution of ecliptic pole latitude for 38 near-Earth asteroids (NEAs). This is dominated by retrograde-rotating objects ( $\approx$ 73% cases), because this sense of rotation offers a better chance to migrate to the planet-crossing space. In both cases, the tendency to extreme latitude values is due to the YORP effect. MBA data adapted from Hanuš *et al.* (2013a), NEA data from the Asteroid Lightcurve Database (LCDB) compilation as of February 2014.

(Bottke *et al.*, 2002b), resupplied by the Yarkovsky effect (Morbidelli and Vokrouhlický, 2003). This is because while the 3:1 resonance may be reached from heliocentric orbits with both larger and smaller value of the semimajor axis, asteroids can enter the v<sub>6</sub> resonance only by decreasing their semimajor axis. Taking into account the proportion by which these resonances contribute to the NEA population (Bottke *et al.*, 2002b), one obtains the observed 3:1 ratio between spin retrograde vs. prograde rotators. This obviously assumes that the rotation pole directions do not become significantly modified after the asteroids enter the planet-crossing zone.

Another interesting piece of information comes from a study of orbital pole distribution of small binary systems in the main belt. Pravec *et al.* (2012) show that poles of these systems are non-isotropic with strong concentration toward the ecliptic poles, thus mimicking the spin distribution of solitary asteroids in the same class. This picture is consistent with a model in which these small binaries are formed by fission of the parent body, whose rotation has been brought to the rotational limit by the YORP effect.

## 5.2. Asteroids with Rotation Axes Caught in Spin-Orbit Resonances

In an attempt to generalize Cassini's second and third laws, Giuseppe Colombo developed a mathematical model in the 1960s that describes the evolution of a body's spin axis rotating about a principal axis of its inertia tensor (Colombo, 1966). Colombo included two fundamental elements in his approach: (1) gravitational torques due to a massive center (e.g., the Sun), and (2) regular precession of the orbital plane of the body by exterior perturbers (e.g., planets). Because approach (1) produces a regular precession of the spin axis, a secular spin-orbit resonance (with a stable fixed point called Cassini state 2) may occur between its frequency and the frequency by which the orbital plane precesses in the inertial space. Such a resonance may occur only for a certain range of obliquity and rotation period values, and thus there is only a small probability that the spin state of any given asteroid is located in the Cassini state 2 associated with one of the frequencies by which its orbital plane precesses in space.

With this as background, the discovery of five prograde-rotating Koronis member asteroids with similar spin vectors (i.e., spin axes nearly parallel in inertial space and similar rotation periods) was a surprise. Additionally, the sample of retrograde-rotating asteroids in the same observation campaign showed obliquities anomalously large ( $\geq 154^\circ$ ) and either short or long rotation periods (Slivan, 2002; Slivan et al., 2009). This puzzling situation, however, was solved with a model where the gravitational spin dynamics were complemented with the long-term effects of YORP torques (Vokrouhlický et al., 2003). The YORP effect was shown to bring, on a  $\sim 2\text{--}3\text{-G.y.}$  timescale, prograde states close to Cassini state 2 associated with the prominent  $s_6$  frequency in the orbital precession, thus providing a natural explanation for the alignment in inertial space. Note that while the capture is fundamentally unstable, the evolution becomes slowed down near the observed obliquities where the YORP effect changes rotation period only slowly (section 2.1). No resonant trapping zone exists for retrograde-rotating bodies, whose evolution is thus simpler and, driven solely by the YORP effect, evolve toward extreme values in both their obliquities and rotation periods.

The possibility exists for asteroid spin states to be trapped in similar spin-orbit resonant states, dubbed "Slivan states," for bodies residing on low-inclination orbits, especially in the central and outer parts of the main asteroid belt. Recently reported Slivan states in the inner part of the belt, namely in the Flora region (Kryszczyńska, 2013), are questionable because of their instability. Yet model refinement would be clearly needed if more bodies are observed near these states in the Flora region (Vraštil and Vokrouhlický, 2015).

## 5.3. Formation and Long-Term Evolution of Binary Systems

The BYORP effect is predicted to play a fundamental role in the evolution of asteroid binaries. As noted earlier, it has

been hypothesized that nearly all observed small, rubble-pile binary asteroid systems lie in an equilibrium state where BYORP and tidal torques are balanced.

The BYORP effect plays many other roles in controlling the evolution of a binary asteroid. Jacobson and Scheeres (2011a) studied the evolution of asteroid systems arising from the rotational fission of a primary body (due to YORP torques). While the initial creation of a stable binary system is a complex process (see the chapter by Walsh and Jacobson in this volume), once a stable binary forms with at least one of the bodies being synchronous, the BYORP effect can take control of its subsequent evolution. There are several different pathways, which we briefly review here.

First, if the ratio between the secondary and primary is greater than  $\sim 0.2$ , the system is expected to eventually settle into a double-synchronous binary asteroid such as (69230) Hermes. In this configuration both of the synchronous bodies can contribute to the BYORP effect, either working together to contract or expand the system, or working against each other. In none of these cases is it expected that the system will settle into a stable equilibrium, as migration would only stop if the two BYORP effects counteract each other exactly. Similarly, there are no significant tidal dissipation effects once a system is doubly synchronous, and thus the case of contraction will lead directly to collapse (e.g., Taylor and Margot, 2014). The expansion phase of a doubly synchronous binary asteroid has not been investigated in detail as of yet in terms of physical evolution. However, as the system becomes larger, it should be more susceptible to other exogenous perturbations (e.g., Fang and Margot, 2012).

For stable binaries that have a mass ratio  $< 0.2$  between the secondary and primary, the evolutionary path is seen to be quite different (see also the chapter by Walsh and Jacobson in this volume). If a stable binary is formed, it is generally a singly synchronous system with the secondary in a synchronous state and the primary rotating faster than the spin rate. If the secondary's BYORP coefficient is negative and the system contracts, then it should migrate into a BYORP-tide equilibrium. Once in this state it may persist for long periods of time, as the system has been hardened against exogenous perturbations due to its more compact state (e.g., Fang and Margot, 2012). A noticeable outcome is that the primary body should lose spin rate, due to the tidal transfer of torque. However, the primary may still be subject to the YORP effect and thus may not exhibit a clear slowing of its spin rate.

If the secondary's BYORP coefficient is positive, the system expands, with tides now working in the same direction. In this case there is also an interesting interplay between the libration of the secondary about its synchronous state and tidal dissipation that acts to damp out such librations. In the expansive case without librational damping, the amplitude of libration is expected to increase as the orbit increases, due to an adiabatic integral involving the libration state (e.g., Jacobson et al., 2014). How these two effects combine can control when the secondary can lose synchronous lock, causing the BYORP effect to shut down. The model and

simulations developed in *Jacobson et al.* (2014) indicate that synchronicity is lost at a far enough distance so that further tidal evolution of the system does not occur, and the system can be described as a wide-asynchronous binary. This paper makes favorable comparisons between predictions of the theory and such observed binary systems. An alternate, earlier theory was proposed by *Ćuk and Nesvorný* (2010) in which the expanding system can become trapped in a resonance with the eccentricity of the orbit growing secularly. They hypothesized that such a system would then lose synchronicity, but subsequently relax back into synchronous rotation several times until the system enters a contractive phase. The very different predictions from these models indicate that the full interaction of such expanding binary systems is not yet fully understood.

In addition to expansion and contraction effects, there may also be out-of-plane BYORP effects that cause migration of the binary system's orbit pole, similar to the YORP effect (see *Ćuk and Burns*, 2005). *Steinberg and Sari* (2011) further studied these situations and proposed that, similar to YORP, the obliquity states should preferentially migrate toward some asymptotic values (either 0°, 90°, or 180° in their model). *Ćuk* (2007) noted that this effect, when combined with the characteristic zero-crossing of the BYORP coefficient as a function of obliquity, could create an accumulation of binaries at obliquities between these limits. It should also be mentioned that *McMahon and Scheeres* (2010b) did not predict an inclination evolution due to the BYORP effect, owing to the effects of the primary oblateness. Thus, it is apparent that the obliquity migration of a binary orbit due to BYORP is not fully understood or settled, and remains a ripe topic for further investigation.

## 6. CONCLUSION AND FUTURE WORK

As with many mature disciplines in science, studies of the Yarkovsky and YORP effects have their own agenda of development in the future years. What makes them even more appealing is that some of these future results have interesting implications for other domains in planetary astronomy. Here we try to summarize at least a few examples.

While it seems nearly certain that numerous detections of the Yarkovsky effect will emerge from current and upcoming astrometric surveys in the next decade (e.g., *Delbò et al.*, 2008; *Mouret and Mignard*, 2011; *Nugent et al.*, 2012b; *Desmars*, 2015), more work is needed to secure YORP detections, especially across the whole range of possible rotation periods. This should help us understand in what proportion the YORP effect results in acceleration or deceleration of the rotation rate.

The binary YORP detections are in their infancy but will become an important topic of future research. This is because the BYORP effect is an essential element, as far as we understand it today, in orbital evolution of binary asteroids. Detections, or continuing nondetections, of the expected BYORP signal will have implications not only for the orbital

evolution pathways of binaries and their physical parameters, but also for estimates of their lifetime and formation rate.

As the rotations of asteroids become slower by the YORP effect, they naturally enter the tumbling state. The available models so far, whether analytical or numerical in nature (*Vokrouhlický et al.*, 2007; *Cicalò and Scheeres*, 2010; *Breiter et al.*, 2011), indicate that the YORP effect keeps navigating the rotation through the tumbling phase space without an easy return to the rotation about the shortest axis of the inertia tensor. Yet, more than 90% of asteroids do rotate in the shortest-axis mode. A solution for this conundrum is not yet clear and warrants further work. The above-mentioned models of the YORP effect in the tumbling regime neglect thermal inertia, which may be an important factor. Additionally, no detailed model combining the YORP effect and the effects of inelastic energy dissipation inside the body has been presented [although the initial work does not seem to remedy the problem (*Breiter and Murawiecka*, 2015)].

While it is generally accepted that the YORP effect is the driving dynamical process that brings small asteroids to their fission, more work is needed to understand how the fission mechanics really work. Along the path to the fission limit, the body may undergo structural and shape changes that could either help the fission process, or potentially invert the YORP acceleration to effectively prevent fission. It is not known which of these alternatives typically dominates and in what proportion. This, again, could have important implications for the formation rate of both small binaries and asteroid pairs. Additionally, this would help us to better understand the YORP self-limitation processes and the way in which they potentially modify classical YORP results.

**Acknowledgments.** The authors are grateful to D. Farnocchia for assistance in the compilation of Table 1 and P. Pravec for providing data shown in Fig. 8. We also thank reviewers D. P. Rubincam and B. Rozitis for their suggestions, which helped to improve the original form of the chapter. The work of D.V. was partially supported by the Czech Grant Agency (grant P209-13-01308S). The participation of W.F.B. was supported by NASA's Solar System Evolution Research Virtual Institute (SSERVI) program through a grant to the Institute for the Science of Exploration Targets at the Southwest Research Institute in Boulder, Colorado. The work of S.R.C. was conducted at the Jet Propulsion Laboratory, California Institute of Technology, under a contract with NASA. T.S.S. acknowledges support from NASA Planetary Geology and Geophysics grant NNX11AP15G.

The diversity of mineralogies and textures in the asteroidal meteorite collection promises a similarly diverse array of parent bodies and relatives as we continue exploring the asteroid belt. The presence of metamorphosed and igneous meteorites demonstrates that even some small bodies were heated significantly, permitting a variety of complexly interacting processes and heterogeneities within an individual planetesimal. In particular, chondritic meteorites could even originate from the same parent body as some highly differentiated meteorites. The histories and present-day features of the asteroids depend on their initial composition and the timing and duration of the accretion process. We first discuss the energy sources driving thermal modification of planetesimals and summarize the processes involved in differentiation as hydrous, metal, and silicate melting occurs. Then we outline the aftermath of differentiation as the body cools, and close with a discussion of magnetic, geophysical, and meteoritic evidence for differentiation in planetesimals.

## 1. ENERGY SOURCES FOR METAMORPHISM AND MELTING

Chondrites consist of material that never heated sufficiently to melt, while primitive achondrites only underwent partial melting. Such samples can be explained as fragments of relatively homogeneous small bodies without invoking differentiation processes. However, iron meteorites analogous to planetary cores and stony achondrites analogous to differentiated planetary crusts demonstrate that metal-silicate differentiation occurred in planetesimals during the first few million years after the formation of calcium-aluminum-rich inclusions (CAIs) (e.g., Kleine et al., 2012; Markowski et al., 2006; Baker et al., 2005).

Differentiation requires heating above the melting temperature of iron-nickel alloys, and may require melting beyond the silicate solidus as well. First melting of bulk chondritic meteoritic material occurs at the Fe,Ni-FeS eutectic at 950°C (Kullerud, 1963). Even higher temperatures are probably necessary to facilitate large-scale differentiation (see further discussion in section 2.2).

Two potential heat sources contributed largely to melting in a planetesimal: radiogenic heating from short-lived radioisotopes  $^{26}\text{Al}$  and  $^{60}\text{Fe}$  (Fish et al., 1960; Huss et al., 2006; LaTourette and Wasserburg, 1998; Lee et al., 1976; Urey, 1955) and the gravitational energy of accretion. A

third potential source, electromagnetic induction heating (Sonnett and Colburn, 1968; Sonnett et al., 1968; Herbert et al., 1991), has received little attention recently, and relies on relatively unconstrained parameters. A better understanding of T Tauri star mass loss has rendered it less plausible as a dominant heat source (Ghosh et al., 2006) and it has not been included in recent thermal models.

### 1.1. Distribution and Effects of Initial Solar System Aluminum-26

Radioactive decay of the aluminum isotope  $^{26}\text{Al}$  into  $^{26}\text{Mg}$  is thought to be the primary heat source for planetesimals in the early history of the solar system. The idea was first postulated by Urey (1955), who suggested that short-lived radionuclides (SLRs) such as  $^{26}\text{Al}$  could have contributed more energy than the primary modern-day contributors to radiogenic heating,  $^{238}\text{U}$ ,  $^{232}\text{Th}$ , and  $^{40}\text{K}$ . Heating of a parent body is significantly affected by the initial isotopic abundance of  $^{26}\text{Al}$ . Much effort has therefore been expended in measuring meteoritic materials in an attempt to determine the distribution of  $^{26}\text{Al}$  in the planetary nebula and in planetesimals.

Most CAIs contained an initial  $^{26}\text{Al}/^{27}\text{Al}$  ratio near what has been called the “canonical” value,  $5.23 \pm 0.13 \times 10^{-5}$  (Jacobsen et al., 2008), derived from bulk CAI measurements in CV chondrites. However, the initial ratio of  $^{26}\text{Al}/^{27}\text{Al}$  in

individual CAIs is known to have varied from  $<2 \times 10^{-6}$  to  $5 \times 10^{-5}$  (Krot et al., 2012). For example, CH chondrites, which are among the most primitive identified, had an initial  $^{26}\text{Al}/^{27}\text{Al} < 5 \times 10^{-6}$  (Makide et al., 2009; Sahijpal and Goswami, 1998; Liu et al., 2009; Krot et al., 2008). Krot et al. (2012) comprehensively summarized variations in initial  $^{26}\text{Al}$  concentrations of CAIs between and within chondrite groups. Rather than a homogenous distribution of initial  $^{26}\text{Al}$  at the canonical ratio, meteoritic evidence implies that  $^{26}\text{Al}$  was unevenly distributed through the planetary disk.

Primitive materials with very low radiogenic content may have formed before injection of  $^{26}\text{Al}$  into the solar system (e.g., Makide et al., 2009; Liu et al., 2009; Krot et al., 2008), or they may have formed after  $^{26}\text{Al}$  mostly decayed (Krot et al., 2005; MacPherson et al., 1995). The isotopic ratio is too high to be explained by solar irradiation (Duprat and Tatischeff, 2007) and thus must have been exogenous to the solar system. The nature of the stellar source of SLRs is still unsettled, although massive star wind is a good candidate (Gounelle and Meynet, 2012). See further discussion in the chapter by Johansen et al. in this volume.

The radiogenic component may have been mixed into the nebula before the formation of a planetary disk, and the planetary disk may have partially homogenized the aluminum composition (Krot et al., 2012). Further homogenization of  $^{26}\text{Al}$  distribution may have occurred with radial mixing and accretion, effectively damping the range of compositions from the CAIs samples as they accreted into larger bodies. If this homogenization was not complete, then planetesimals would not be expected to have had identical  $^{26}\text{Al}$  compositions. Instead, the  $^{26}\text{Al}$  content of a given planetesimal would have depended upon both time and radial domain within the planetary disk of its accretion.

The range of  $^{26}\text{Al}$  content within CAIs is large enough to influence whether significant melting will occur. Kunihiro et al. (2004) found that there is insufficient radiogenic aluminum in CO and CV chondrites to cause more than minimal melting even with the help of radiogenic  $^{60}\text{Fe}$ . However, they assumed that these bodies accreted instantaneously after the age of the youngest chondrules (estimated to be  $\sim 2\text{--}3$  m.y. after CAI formation). In contrast, Elkins-Tanton et al. (2011) and Weiss and Elkins-Tanton (2013) found that the potentially older age of CV chondrules (the oldest being essentially as old as CAIs) means the CV body could have melted if it started to accrete before the age of the youngest chondrules (i.e., before  $\sim 1.5$  m.y. after CAI formation).

The canonical  $^{26}\text{Al}$  concentration yields an integrated energy output of around  $\epsilon_i = 6.7 \times 10^6 \text{ J kg}^{-1}$  (Moskovitz and Gaidos, 2011). If this energy were converted to heat all at once, it would suffice to raise temperatures by several thousand degrees and completely melt the host material. The energy output is derived by integrating over time the power from radiogenic decay

$$\epsilon_i = \int_0^\infty W \frac{m_{\text{Al}}}{m} \frac{^{26}\text{Al}}{^{27}\text{Al}} e^{-\lambda t} dt \quad (1)$$

where  $w$  is heat production for pure  $^{26}\text{Al}$  [ $\text{W kg}^{-1}$ ], given by  $w = \lambda E_0/m_0$ , where  $\lambda$  is the decay constant of  $^{26}\text{Al}$ ,  $m_0$  is the mass of a single isotope, and  $E_0$  is the energy produced by its decay;  $(m_{\text{Al}}/m)$  is the bulk elemental mass fraction of Al (approximately the same as solely for the isotope  $^{27}\text{Al}$ ); and  $(^{26}\text{Al}/^{27}\text{Al})$  is the isotopic ratio at CAI formation ( $t = 0$ ).

To obtain the energy output available for heating for accretion times after the time of first formation of solids in the solar system, the initial power is multiplied by  $e^{-\lambda t}$ , where  $t$  is the time from CAI formation to instantaneous accretion. By definition, half the integrated energy output is produced within the first half-life. Therefore, due to its short half-life [0.71 m.y. (Norris et al., 1983)], the effect of  $^{26}\text{Al}$  on planetary bodies strongly depends on the timeline of accretion. Radiogenic heating depends on the quantity of material, and therefore is proportional to the radius cubed of a body, while radiative heat loss depends on area, which grows as radius squared. Thus if the bulk of accretion occurred within a million years, the majority of radiogenic heat would have remained in the body; otherwise, it would have readily dissipated.

Given the chondritic abundance of  $^{26}\text{Al}$  shown in Table 1,  $^{26}\text{Al}$  decay provides sufficiently large amounts of heating that models agree that bodies that accreted to more than  $\sim 7\text{--}10$  km radius before  $\sim 1.5$  m.y. after the formation of CAIs likely contained sufficient  $^{26}\text{Al}$  to melt internally from radiogenic heating (Hevey and Sanders, 2006; Merk et al., 2002; Sahijpal et al., 2007; Urey, 1955). A summary of papers modeling the internal heating, melting, and differentiation of planetesimals is given in Table 2.

Another potentially important radiogenic element is  $^{60}\text{Fe}$ , but it has been difficult to constrain the initial  $^{60}\text{Fe}/^{56}\text{Fe}$  ratio because of the isotope's low abundance in CAIs. Until recently, it was estimated at initial  $^{60}\text{Fe}/^{56}\text{Fe} \sim 1 \times 10^{-6}$  (Tachibana et al., 2006; Dauphas et al., 2008; Mishra et al., 2010). However, recent studies have revised the value downward to  $\sim 1 \times 10^{-8}$  (Tang and Dauphas, 2012; Chen et al., 2013). With this reduced value, the integrated energy output from  $^{60}\text{Fe}$  would have been only  $1.2 \times 10^4 \text{ J kg}^{-1}$ , insignificant in comparison with  $^{26}\text{Al}$  output, although its half-life [2.4 m.y. (Rugel et al., 2009)] is several times longer.

Aluminum-26 and  $^{60}\text{Fe}$  behave differently in differentiating bodies. Because aluminum is lithophilic, the formation of a core results in an increased concentration of  $^{26}\text{Al}$  in the remainder of a planetesimal. While this does subject the mantle to slightly more heating and higher temperatures than would occur in an undifferentiated body, the concentration of radiogenic heating nearer the surface means that that energy reaches the surface more easily, cooling the planetesimal faster. Moskovitz and Gaidos (2011) also point out that silicate melt could form a crust that would be especially enriched in  $^{26}\text{Al}$ , further enhancing heat flow (see section 2.3 for further discussion). On the other hand, most  $^{60}\text{Fe}$  would proceed to the core and would be the only potentially significant radiogenic heat source of a metal planetesimal shard or stripped core (Moskovitz and Walker, 2011).

In summary,  $^{26}\text{Al}$ , with its relatively high concentration and short half life, would have been the main driving heat

TABLE 1. Primary short-lived radionuclides and their properties.

Variable	Isotope/Element	Value(s)	Units	Reference
Heat production from decay	$^{26}\text{Al}$	0.355	$\text{W kg}^{26}\text{Al}^{-1}$	<i>Castillo-Rogez et al. (2009)</i>
	$^{60}\text{Fe}$	0.044*		
Bulk content of CV chondrites	Al	1.8	wt. %	<i>Lodders and Fegley (1998)</i>
	Fe	24		
Initial isotopic ratio	$^{26}\text{Al}/^{27}\text{Al}$	$5.23 \times 10^{-5}$	—	<i>Jacobsen et al. (2008)</i> <i>Chen et al. (2013); Dauphas et al. (2008)</i>
	$^{60}\text{Fe}/^{50}\text{Fe}$	$1 \times 10^{-8}-1 \times 10^{-6}$		
Decay constant	$^{26}\text{Al}$	$3.0124 \times 10^{-14}$	$\text{s}^{-1}$	<i>Castillo-Rogez et al. (2009)</i> <i>Rugel et al. (2009)</i>
	$^{60}\text{Fe}$	$9.08 \times 10^{-15}$		

\*Derived given  $w = \lambda E/m$ , where  $w$  is heat production from decay,  $\lambda$  is the decay constant,  $m$  is the mass of a single isotope, and  $E$  is the energy produced by its decay.

source for melting prior to  $\sim 2$  m.y. after CAIs (e.g., *Merk et al., 2002*), while  $^{60}\text{Fe}$ , with a longer half-life, might have supplied some critical late heating within the core if the first concentration estimates are accurate.

## 1.2. Effects of Accretion Characteristics and Body Size

Accretionary energy is the potential gravitational energy input released by assembling a body from materials initially at infinite distance

$$E = \int_0^R \frac{G M(r) dm}{r} \quad (2)$$

where  $E$  is accretionary gravitational potential energy [J],  $G$  is the gravitational constant,  $M(r)$  is the mass of the planet as a function of radius  $r$ , expressed as  $4/3\pi r^3 \rho$  [kg] where  $\rho$  is density, and  $dm$  can be expressed as  $4\pi r^2 \rho dr$ . This integration yields  $E = 16/15\pi^2 \rho^2 G R^5$ . For a planetesimal with a 10-km radius, total accretionary gravitational potential energy  $E$  is  $\sim 10^{17}$  J, and for a 300-km-radius body,  $\sim 10^{25}$  J (in comparison, for Earth  $E$  is  $\sim 2 \times 10^{32}$  J; for Mars,  $\sim 5 \times 10^{30}$  J; and for Mercury,  $\sim 2 \times 10^{30}$  J).

The addition of energy can be roughly translated to temperature increase using the expression  $\Delta T = E/MC_p$ , where  $C_p$ , the heat capacity, is  $\sim 800 \text{ J kg}^{-1} \text{ K}^{-1}$  for silicates (*Fabrichnaya, 1999*) and is only slightly higher for metallic core material (*Bartels and Grove, 1991*). The hypothetical

10-km-radius planetesimal would have been heated only a fraction of a degree if all accretionary energy were instantaneously applied homogeneously to the whole body, and the hypothetical body with 300-km radius would have been heated by only 10° to 20°C.

Due to radiogenic heating, these early accreting bodies would have melted from the interior outward, resulting in an interior magma ocean under a solid, conductive, undifferentiated shell (Ghosh and McSween, 1998; Hevey and Sanders, 2006; McCoy et al., 2006; Merk et al., 2002; Sahijpal et al., 2007; Schölling and Breuer, 2009). The size of the body therefore strongly impacted thermal evolution, since heat was being produced in the bulk interior and being radiated from the surface. Other critical controlling parameters are the rate of accretion, the initial  $^{26}\text{Al}$  ratio, the initial Al bulk composition, the material density and composition (which control both radiogenic content and heat transfer), and the rate of accretion.

The rate and timing of accretion are highly dependent on the assumed model of planetesimal accretion. In one scenario, sticking collisions between solid particles in the nebula may lead to steady incremental growth of the first planetesimals (Windmark et al., 2012). Alternatively, centimeter- to meter-sized objects may be concentrated by streaming instabilities or by turbulent eddies into 10- to >100-km-sized solid bodies on timescales of just tens to hundreds of years in the asteroid belt region (Cuzzi et al., 2008; Johansen et al., 2007; Morbidelli et al., 2009). For many bodies, this early collapse phase may have been followed by a subsequent period of incremental growth. Turbulent concentration is an inefficient process, owing to disruption of clumps by rotational breakup and ram pressure from the surrounding gas, such that bodies were likely produced sporadically over millions of years (Chambers, 2010). Each body would have collapsed quickly, but may have had further coatings added to their surfaces over the tail of accretion as the disk cleared out.

Despite this complexity, most models consider instantaneous accretion over a range of times starting with the age of CAIs. Recent numerical modeling incorporating the effects of prolonged accretion suggests that molten planetesimals can build up substantial (kilometers to tens of kilometers thick) crusts if they accrete to radii of at least a few tens of kilometers by 1.5 m.y. after CAI formation and continue to accrete over a minimum period of perhaps one to several million years (Sahijpal and Gupta, 2011; Elkins-Tanton et al., 2011; Šrámek et al., 2012; Neumann et al., 2012; Weiss and Elkins-Tanton, 2013).

### 1.3. Impact-Induced Metamorphism and Melting

Aside from their bulk contribution of accretionary energy, impacts also played a more direct role in metamorphism and melting on planetesimals, although current consensus assigns an uncertain but likely volumetrically minor effect (Keil et al., 1997; Šrámek et al., 2012).

The abundance of metamorphosed ordinary chondrites suggests global-scale metamorphism (e.g., Wood, 1962;

Van Schmus and Wood, 1967; Dodd, 1969). Wasson et al. (1987), Cameron et al. (1990), and Rubin (1995) argued for impact-induced heating as the most likely heat source. Keil et al. (1997) disfavored this hypothesis after determining, based on laboratory shock wave and cratering experiments and numerical models, that the cumulative global temperature increase due to impacts would be at most a few tens of degrees. However, Rubin and Jones (2003) and Rubin (2004) presented further evidence of impact heating in meteorites and argued for a major effect of porosity, which although mentioned, was not accounted for in numerical heating models. Most asteroids are believed to have porosities near 30%, although estimates for some range up to 70% (Britt et al., 2002); this would have been even higher in the early solar system before compaction processes (impacts included). Davison et al. (2010) accounted for porosity and found that collision of highly porous bodies could in some cases result in nearly global melting. However, they conclude that the cumulative effects of nondisruptive impacts for a typical planetesimal would be minor, with no more than 3% heated by more than 100°C. A final disruptive impact, on the other hand, would melt one-tenth of the parent body.

Ciesla et al. (2013) numerically modeled impacts on porous bodies that were already being heated by  $^{26}\text{Al}$ . They concluded that while local heating and metamorphism would occur near the site of the impact, impacts would actually accelerate global cooling of the planetesimal in two ways. First, hot material (primarily heated by  $^{26}\text{Al}$ ) from deep in the body would be drawn up toward the surface by the impact, leading to a faster cooling rate for this hot material and thus a larger net heat flow rate out of the body. Second, newly compacted material would have a higher thermal conductivity, further enabling heat flow from the body.

Evidence of shock events in meteorites (e.g., Scott et al., 1992; Sharp and de Carli, 2006) probably records impact events in the early solar system. However, the contribution of impacts to metamorphism and melting was probably low on a global scale. Subcatastrophic impacts may have even reduced the likelihood of melting by allowing internally heated material to cool more quickly.

## 2. PLANETESIMAL DIFFERENTIATION PROCESSES DURING HEATING

Based on our current knowledge of their physics and chemistry, planetesimals may have a range of internal structures and material states following peak heating, including an unmelted onion-skin structure, a partially differentiated body with some magma within and a primitive crust, a partially differentiated body with magma that erupted and flooded a primitive crust, and a body that melted entirely (Fig. 1).

Internal radiogenic heating coupled with radiation from the planetary surface means that a planetesimal would initially form an “onion shell” structure, with the highest temperatures reached in its center, surrounded by concentric zones of materials exposed to progressively lower peak temperatures (see McSween et al., 2002, and references therein).

Such a body, should it never reach a melting temperature, is considered primitive, but still could be highly altered from its original, unheated material. Its interior may be variably heated and metasomatized by mobile fluids, and these fluids may be unevenly redistributed within the body, or lost to space, or both. Furthermore, the bulk density of the body may change due to sintering and fluid migration.

Should the interior be heated to the point of melting, a further spectrum of potential planetesimal structures is possible. As temperature rises in a young planetesimal interior, the silicates will pass through the stability zones for several possible hydrated silicate minerals, but then a free hydrous fluid will be released. The first melting to occur will be eutectic melting of iron-nickel sulfide. This metal liquid may or may not be able to migrate downward and form a core without silicate melting.

If accretion is rapid and aluminum remains in the matrix [i.e., it is not all pulled away through buoyant melt migration, as in Moskovitz and Gaidos (2011)], then the planetesimal may be rapidly and completely melted and differentiated (e.g., Hevey and Sanders, 2006). Vesta itself may be such a body.

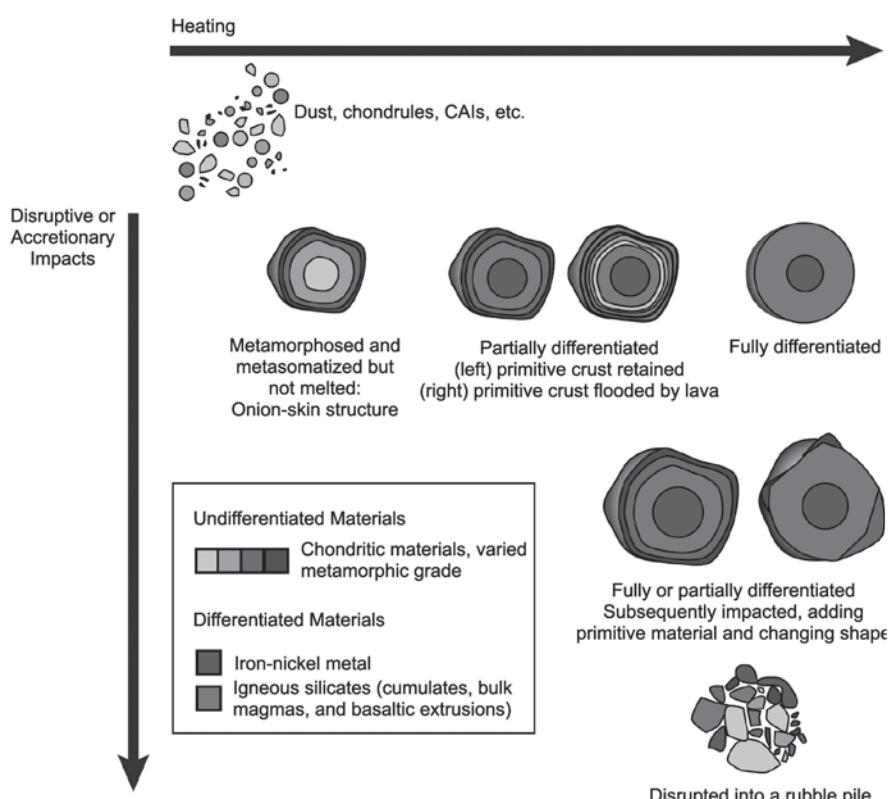

Other planetesimals may only undergo *partial differentiation*. In this scenario, the body differentiates internally

into a primarily metallic core and a bulk silicate mantle. A chondritic lid would either be retained from original material that never melted, or accreted onto the surface during and after the primary melting phase. Models indicate that in some cases this chondritic lid would be flooded with magma from the interior, while in other cases it would remain at the surface (Fu and Elkins-Tanton, 2014; Wilson and Keil, 2012). In either case, a partially differentiated planetesimal would be differentiated internally but retain chondritic material at or near the surface. Multiple meteorite types could therefore be sourced from the same parent body (Elkins-Tanton et al., 2011; Weiss and Elkins-Tanton, 2013; Golabek et al., 2014).

In the next three sections, we consider the behavior of volatile, metal, and silicate material, respectively, as they successively melt during the progressive heating of a planetesimal.

## 2.1. Flow and Escape of Volatile Compounds

For planetesimals accreting with a water ice component, progressive internal heating due to radiogenic decay results in ice melting once temperature surpasses approximately 0°C (Fig. 2). In such a scenario, the formation of liquid water may lead to mineralogical changes that are reflected in the observed

**Fig. 1.** See Plate 17 for color version. Three possible end-states of asteroid differentiation. *Left:* Unmelted but variably metamorphosed and aqueously altered body composed of chondritic materials. *Middle:* Partially differentiated body with melted interior and unmelted surface layer. *Right:* Fully differentiated body with metallic core and igneous silicate mantle. *Bottom:* Partially or fully differentiated bodies disrupted and coated by later impacts, disrupted even to the point of internal disorganization into a rubble pile.

elemental, isotopic, and modal compositions of meteorites and asteroids. Flow of interstitial water, if it occurred, may have also resulted in the transport of labile elements, altering the local bulk composition in affected regions of the planetesimal. Finally, the presence of water and other volatiles during the melting of the metallic and silicate components of the planetesimal may alter the migration patterns of the resulting melt.

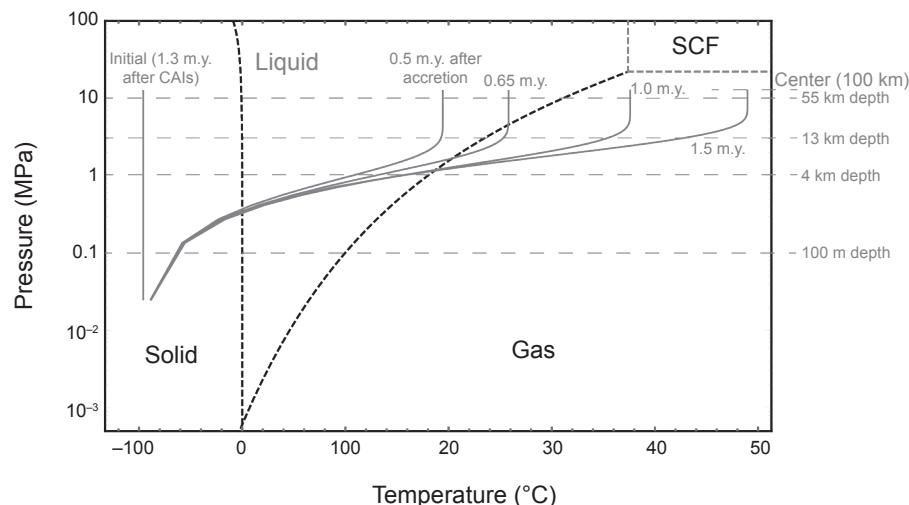

Meteoritic observations indicate that most chondritic parent bodies indeed accreted with significant quantities of water (Brearley, 2006). Carbonaceous chondrites include abundant hydrated minerals in addition to free water. The total mass fraction of  $H_2O$  measured in highly altered CM and CI chondrites ranges between 0.09 and 0.17 (Jarosewich, 1990). Ordinary chondrites typically display lower  $H_2O$  abundances of <0.02. However, metamorphism above 200°–300°C leads to the dehydration of silicate phases and removal of  $H_2O$  in chondritic material (Akai, 1992; Meunow *et al.*, 1995). The high metamorphic grade of most ordinary chondrites, coupled with observations that mildly metamorphosed ordinary chondrites contain hydrated phases (Alexander *et al.*, 1989; Hutchison *et al.*, 1987), suggests that ordinary chondrite parent bodies accreted with significantly higher water content than presently observed, likely greater than 0.02 mass fraction. Metamorphism may also be responsible for the low water contents of dry carbonaceous chondrites. In a well-studied case, the Allende CV chondrite contains no water at the present time while displaying mineral assemblages that strongly imply the past presence of hydrated minerals during a period of fluid-assisted metamorphism (Brearley and Krot, 2012; Krot *et al.*, 1997, 1998). Spectroscopic observations of main-belt asteroids confirm the prevalence of hydrated mineralogies (Jones *et al.*, 1990; Rivkin *et al.*, 2002).

The hydration of originally anhydrous phases in chondritic planetesimals commenced shortly after internal heat-

ing led to the formation of liquid water. The oxygen and carbon isotopic composition of material from several CM chondrites shows that aqueous alteration occurred between 0° and 70°C (Clayton and Mayeda, 1984; Guo and Eiler, 2007; Lerner, 1995). Meanwhile, altered minerals in CR and CI chondrites likely formed in conditions of <130°C and 50°–150°C, respectively (Lee *et al.*, 1992; Zolensky *et al.*, 1989). Continued heating leads to the decomposition of alteration phases between 200° and 900°C (Akai, 1992; Meunow *et al.*, 1992, 1995). Even in the largest, Vesta-sized planetesimals, pressures in the deep interior are unable to stabilize hydrated minerals above ~950°C (Niida and Green, 1999). Therefore, progressive interior heating of differentiating planetesimals implies both a hydration and a dehydration phase — free water becomes bonded to secondary, hydrous silicates in the 0°–200°C range and are released again as a free fluid between 200° and 900°C.

The presence of free fluids inside internally heated planetesimals over a wide range of temperatures permits the redistribution of labile elements during fluid flow. For differentiating bodies undergoing progressive heating due to  $^{26}Al$ , the rapid rise in temperature implies that free fluids in most of the interior persist for a timescale of only 0.1–1 m.y. before the onset of metallic and silicate melting (Fu and Elkins-Tanton, 2014). The length scale of elemental redistribution during this time period depends on the velocity of fluid advection.

Fluid flow velocities in planetesimals may be modeled by balancing driving forces arising from gravitational and thermal sources with resistive forces arising from the low permeability of chondritic material. The density of liquid and supercritical water at the relevant pressures ranges between 900 kg m<sup>-3</sup> at 200°C and only 4.5 kg m<sup>-3</sup> at 900°C (Smits *et al.*, 1994). The large difference between these

**Fig. 2.** The evolving temperature profile of an early forming, 200-km-diameter planetesimal internally heated by the decay of  $^{26}Al$ . Temperatures in the body interior are compared to the phase diagram of pure  $H_2O$ . Note the formation of gas phase at ~10 km depth during progressive heating. SCF = supercritical fluid.

densities and those of the surrounding chondrite matrix [2100–3700 kg m<sup>-3</sup> (*Britt and Consolmagno*, 2003)] is one potentially significant driving force, especially after heating above the 374°C critical point of water. The velocity ( $v_D$ ) of such density-induced Darcy flow is given by (*Bear*, 1972)

$$v_D = \frac{kg\Delta\rho}{\eta\phi} \quad (3)$$

where  $k$  is the rock permeability,  $g$  is the gravitational acceleration,  $\Delta\rho$  is the difference in density between the fluid and rock,  $\eta$  is the dynamic viscosity, and  $\phi$  is the dimensionless volumetric porosity. For a permeability of 10<sup>-15</sup> m<sup>2</sup> corresponding to permeable carbonaceous and ordinary chondrites [see discussion below and *Corrigan et al.* (1997) and *Sugiura et al.* (1984)], a dynamic viscosity of 5 × 10<sup>-5</sup> Pa s (*Sengers and Kamgar-Parsi*, 1984), and a dimensionless porosity of 0.1, fluid is expected to migrate at rates of ~1 m yr<sup>-1</sup> (*Fu and Elkins-Tanton*, 2014), implying that whole-body fluid flow can occur within the time span of radiogenic heating. Assuming a body radius on the order of 100 km, permeabilities as low as 10<sup>-16</sup> m<sup>2</sup> would permit the migration of fluids from the deep interior to the surface on 1-m.y. timescales. Migration driven by this mechanism is expected to result in a single pass of fluids from the deep interior to the surface, which has been termed *exhalation flow*. The buoyant fluid may freeze in any conductive lid, after metasomatizing some regions, or it may be lost to space (*Young et al.*, 2003).

In contrast, multiple pass flow of pore fluid due to thermal convection may result from the large vertical temperature gradient in early forming planetesimals. After deriving the convective stability criterion for fluids in an internally heated, radially symmetric body with an equilibrium conductive temperature gradient, *Young et al.* (2003) concluded that, assuming permeabilities of 10<sup>-13</sup> m<sup>2</sup> (*Grimm and McSween*, 1989), fluids in bodies larger than 120 km diameter would undergo convection.

A major uncertainty in the above fluid transport models is the permeability of chondritic material. Direct measurements on unfractured chondrites have yielded a wide range of permeabilities between 10<sup>-15</sup> and <10<sup>-21</sup> m<sup>2</sup>, with most measured carbonaceous and ordinary chondrites falling in a range between 0.01 and 2 × 10<sup>-15</sup> (*Corrigan et al.*, 1997; *Sugiura et al.*, 1984). The extreme value of <10<sup>-21</sup> m<sup>2</sup> was obtained from an enstatite chondrite, suggesting that systematic variations in permeability exist between chondrite groups. Models and arguments based on terrestrial analogs have estimated chondritic permeabilities between 10<sup>-11</sup> m<sup>2</sup> (*Grimm and McSween*, 1989) and 10<sup>-19</sup> m<sup>2</sup> (*Bland et al.*, 2009). These estimates represent lower bounds on the permeability of bulk material, as fractures may increase the effective permeability by 2 to 9 orders of magnitude (*Brace*, 1980; *Trimmer et al.*, 1980). Furthermore, increasing the relevant length scale from hand sample to kilometers may augment permeability by another factor of 10<sup>3</sup> (*Clauser*, 1992). Observations of chondrite samples reveal a high degree of fracturing and brecciation while the production of gas and supercritical

fluids can overcome the tensile strength of chondritic material and lead to fracturing in the deep interior (Fig. 2) (*Grimm and McSween*, 1989; *Young et al.*, 2003). Fractures therefore likely had a significant effect on the permeability of strongly heated planetesimals. Integrating these constraints, for fractured carbonaceous and ordinary chondrite material at the global scale, most permeabilities were likely greater than 10<sup>-14</sup> m<sup>2</sup>, while enstatite chondrite materials may have had permeabilities <10<sup>-16</sup> m<sup>2</sup>, depending on the effect of fractures. The permeabilities for carbonaceous and ordinary chondrites were likely sufficient to permit the planetesimal-scale ascent of fluids (*Fu and Elkins-Tanton*, 2014). In contrast, in the case of parent bodies with low permeabilities of <10<sup>-16</sup> m<sup>2</sup>, fluid-facilitated elemental redistribution may have occurred on only the <100-μm scale (*Bland et al.*, 2009).

The large observed spread in oxygen isotopic composition in the altered components of carbonaceous chondrites provide meteoritic evidence in favor of large-scale fluid migration (*Young*, 2001; *Young et al.*, 1999). The expected heterogeneity in a small volume of water trapped in pore space appears insufficient to explain the isotopic variation, while open-system fluid flow down a temperature gradient is capable of reproducing the measured oxygen isotopes. On the other hand, the essentially solar abundance of elements in CI chondrites (*Lodders*, 2003) and the depletions of volatile elements in other chondrites (*Kallemeyn and Wasson*, 1981) have been cited as evidence against open-system behavior of planetesimal fluids (*Bland et al.*, 2009). However, because most volatile elements are also the most labile, the depletion patterns in carbonaceous chondrites have also been interpreted to be a consequence of open-system fluid flow (*Matza and Lipschutz*, 1977; *Young et al.*, 2003).

To summarize, abundant meteoritic and spectroscopic evidence shows that early forming planetesimals accreted with a significant budget of H<sub>2</sub>O and other volatiles. Progressive heating of differentiating planetesimals above ~200°C generated free fluids in the liquid, gas, and supercritical phases. For probable values of permeability in fractured carbonaceous and ordinary chondrite parent bodies, heated fluids were likely able to participate in single-pass exhalation flow and multiple-pass thermal convection in regions with a high temperature gradient. Depending on the degree of fracturing, enstatite chondrite parent bodies may have insufficient permeability to permit large-scale fluid flow.

## 2.2. Metal Fluid Flow and Core Formation

In order to form a core, the dense melted metal must be able to drain to the body's center and displace the lighter silicate material present there. Although melting of core-forming material likely began when temperatures reached the Fe,Ni-FeS eutectic at 950°C (*Kullerud*, 1963), the core-formation process was complicated by the necessity of pore connectivity, slow adjustment of the silicate matrix, and the presence of volatiles.

The threshold for connectivity of molten Fe-S in an olivine matrix has been estimated as low as 3–6% melt (*Yoshino*

*et al.*, 2003, 2004) but as high as 17.5% (*Bagdassarov et al.*, 2009). An even smaller percent melt is needed when the dihedral angle between the molten metal and solid silicate is less than a critical value of 60°. *Terasaki et al.* (2008) found dihedral angles below 60° for pressures of 2–3 GPa, depending on the liquid's oxygen content. The volume fraction of metal in primitive chondrites typically varies from a few percent to <20% (*Scott et al.*, 1996a), while Earth's metal core is about 15% of its volume. Silicate melting was thus probably unnecessary to reach the connectivity threshold for most planetesimals.

Additionally, the silicate material must have a sufficiently low viscosity that it can be deformed and displaced. If this process is inefficient, then significant differentiation could occur only after partial or complete melting of the silicate, which would occur between the solidus and liquidus temperatures, around 1100°C and 1500°C respectively for planetary silicates (*McKenzie and Bickle*, 1988; *Agee*, 1997). An experimental study by *McCoy et al.* (1999) concluded that significant (~50%) silicate melting, reached at ~1450°C, is necessary to initiate migration of metallic melt in an enstatite chondrite.

However, *Šrámek et al.* (2012) noted that percolation through a solid silicate matrix would proceed on a timescale inversely proportional to length scale and thus would not be observable in a laboratory setting, where length scale is on the order of 1 cm rather than 100 km. The timescale is also inversely proportional to gravity, which scales with radius in a homogenous body. The larger the body, the more quickly this process could occur. This would only be one factor that makes a larger body differentiate faster; more directly, a larger body would reach higher interior temperatures and thus partially melt more readily.

Finally, as discussed in the previous section, volatile elements were likely still present at this stage of heating either as free fluids or as hydrous silicate phases (*Fu and Elkins-Tanton*, 2014). The resulting oxygen fugacity may result in oxidized iron, which could then only be reduced to a metal and flow to form a core after further heating and removal of oxidizing agents through fluid migration. Thus the presence of volatiles may delay metal melting and lead to an overall reduction in melt available for core formation.

*Ghosh and McSween* (1998) modeled differentiation of the asteroid (4) Vesta (mean radius 263 km) and determined core formation was not possible if accretion (assumed instantaneous) occurred later than 3 m.y. after CAI formation, and that core formation would occur effectively instantaneously at around 4.6 m.y.

*Šrámek et al.* (2012) modeled the liquid percolation and silicate compaction process for a body heated by  $^{26}\text{Al}$  decay and impacts and assumed accretion occurred gradually rather than instantaneously. They considered a multi-phase model tracking metal and silicate material in both solid and liquid form and found that partial melting of silicate is necessary for compaction of the remaining silicate to occur on the planetesimal timescale. They conclude that due to the similar timescales of accretion and radiogenic heating, diverse outcomes are possible depending on size and accretion rate.

Bodies with radii of 500–1000 km, if accreted steadily over the first 3 m.y. of solar system history, could have retained enough heat to segregate about half of its metal component, although only half of that (about a quarter of the total metal content) would have formed a core. On the other hand, accretion within 1 m.y. of a 1500-km body would have easily produced a large core. Even a body of this size would not have been able to form a core if accretion were extended over 5 m.y. (about seven  $^{26}\text{Al}$  half-lives).

*Neumann et al.* (2012) considered differentiation of planetesimals with radii smaller than 120 km. Their model included heat loss due to transport toward the surface by silicate melt and found this process would diminish planetesimal heating by tens to 100 K. They found that the core-formation process would have lasted for 2–10 m.y., but that core formation would only be likely if the bulk of accretion occurred within 3.5 m.y. of CAI formation. Porosity played a large role, with the maximum reachable temperature much higher for porous bodies than for comparable consolidated ones. This was especially true for small bodies.

Another scenario for core formation involves the accretion of already differentiated iron-nickel. This would occur when a separate differentiated body or a fragment of one impacted the planetesimal. In this case, the metal could descend as a diapir due to its gravitational instability (e.g., *Stevenson*, 1981; *King and Olson*, 2011). Of course, this can only occur if diffusion through silicate melting or metal melt percolation, as described as above, occurred to differentiate the earlier body. Since the magnitude of the gravitational instability is proportional to gravity and thus radius, it is more likely to occur on larger, planet-sized bodies than on small, early bodies.

### 2.3. Silicate Transport Effects on Core Formation

An important recent direction in planetesimal modeling involves the role of silicate melt transport in the time evolution of a planetesimal's thermal profile. As the silicate portion begins to melt, this melt may rise buoyantly and depart its source region. *Moskovitz and Gaidos* (2011) argue that because aluminum is preferentially partitioned into the melt phase, the melting source will immediately be depleted in the  $^{26}\text{Al}$  heat source, and melting will cease. The rising, ponding melt, however, will heat up even more vigorously due to its concentrated aluminum content. Migration and concentration of  $^{26}\text{Al}$  into a crust results in remelting of that crust for accretion times less than 2 m.y. and for bodies >100 km in size.

They also find that subsequent heating from the decay of  $^{60}\text{Fe}$  generates melt fractions in excess of 50%, thus completing differentiation for bodies that accreted within 2 m.y. of CAI formation. However, as discussed in section 1.1, these results are based on the larger  $^{60}\text{Fe}$  abundance estimates available in the literature at that time but later revised downward by nearly 2 orders of magnitude: This component of heating is probably overestimated.

The *Moskovitz and Gaidos* (2011) result differs slightly from one-dimensional models, in that they find differentiation would be most likely for planetesimals with radii larger

than 10 km that accreted within approximately 2.7 m.y. of CAI formation; the inclusion of  $^{60}\text{Fe}$  lengthens the possible time of differentiation from its former  $\sim 1.7\text{--}2$  m.y. after CAIs (Hevey and Sanders, 2006; Elkins-Tanton et al., 2011). Neumann et al. (2014) pursued a similar scheme in which  $^{26}\text{Al}$  is partitioned heavily into the melt phase. In a model for Vesta, a magma ocean 1 km to a few tens of kilometers in thickness forms in the near subsurface, as long as accretion occurred before 1.5 m.y. after CAIs. The magma ocean lasts 10,000–1,000,000 yr, and a basaltic crust is extruded onto the surface. Core formation is complete within  $\sim 0.3$  m.y., and silicate melt is present in the mantle for up to 150 m.y.

Both aluminum sequestration, as investigated by Moskovitz and Gaidos (2011) and Neumann et al. (2014), and the formation of an early basaltic crust rely on relatively efficient melt migration within these small bodies. Moskovitz and Gaidos (2011) point out that melt-migration rates are independent of planetesimal size, since the lower gravity of smaller planetesimals is offset by the shorter distances the melt needs to migrate. Migration on any planetesimal, however, requires that the melt be buoyant with respect to its country rock. In the following section we discuss the buoyancy of melt in putative parent bodies.

#### 2.4. Silicate Melting and Magma Migration

As temperatures continue to climb after the first eutectic melting of Fe,Ni-FeS-rich fluids at 950°C, the first silicate melts appear at 1050°–1150°C while complete melting occurs by 1500°C (Agee, 1997; Agee et al., 1995; McCoy et al., 2006). The potential upward migration of these silicate melts may strongly influence the observable surface composition of the body, the style and rate of heat loss (Neumann et al., 2012), the distribution of heat-producing isotopes (Moskovitz and Gaidos, 2011; Neumann et al., 2014), the loss of silicate material to space, and the preservation of the primitive chondritic crust.

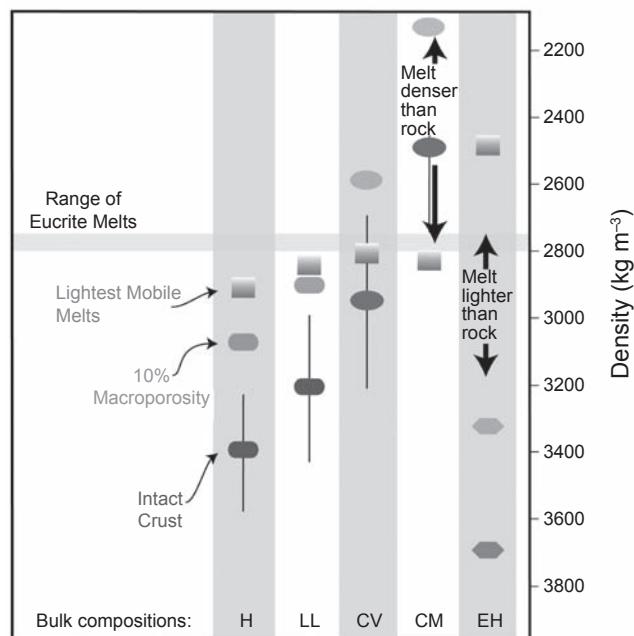

The direction and rate of silicate melt migration depends on the buoyancy of the magma relative to the overlying unmolten chondritic lid. The abundance of volatiles is an important control on buoyancy as their presence during silicate melting may lead to exsolution, which would dramatically lower the bulk density of the resulting magma. As discussed in section 2.1, high-temperature fluids on both carbonaceous and ordinary chondrite parent bodies were likely able to ascend efficiently from the deep interior before the onset of silicate melting.

In addition to water, other volatiles, principally CO, CO<sub>2</sub>, N<sub>2</sub>, and Cl, may have been present in sufficient quantities in chondritic protoliths to potentially affect the density of silicate melts. However, among these volatiles, only CO and Cl are retained in the protolith up to  $\sim 1250^\circ\text{C}$ , which is the temperature necessary for efficient silicate melt migration (McCoy et al., 1997; Meunow et al., 1992, 1995). Carbon monoxide is likely present in insufficient quantities (<100 ppm) during silicate melt migration to affect melt densities, except in cases where it is produced by the C-FeO smelting reaction (McCoy et al., 1997; Wilson et al., 2008).

Meanwhile, the residual Cl content of chondrites at 1250°C is likely soluble in silicate magmas at low pressures and would therefore not strongly decrease the magma density via exsolution (Fu and Elkins-Tanton, 2014; Webster, 1997).

Volatile-depleted (dry) melts of ordinary chondrites have model densities similar to those of an overlying fractured lid built from ordinary chondrites. Dry partial melts of carbonaceous and enstatite chondrites are likely denser and lighter, respectively, than a fractured lid with the corresponding composition (Fig. 3) (Fu and Elkins-Tanton, 2014; Jurewicz et al., 1993, 1995; McCoy et al., 1999). For parent bodies of CV chondrite composition, which are relevant to the paleomagnetic constraints discussed later in section 4.2, an unsintered, fractured crust would have a density between  $\sim 2600$  and  $2900 \text{ kg m}^{-3}$ , whereas the density of molten CV chondrite over a range of temperatures and pressures is between  $\sim 2800$  and  $2900 \text{ kg m}^{-3}$ . Therefore, if melts remain volatile poor, silicate magma produced at depth in planetesimals with carbonaceous chondrite compositions are expected to remain in the interior while similar melts on enstatite chondrite parent bodies likely ascend to the surface. Ordinary chondrite parent bodies represent an intermediate case where the fate of silicate magmas depends on the macroporosity of the overlying lid.

Some chondritic parent bodies may retain sufficient volatiles to result in exsolution-driven melt ascent. In the case of enstatite chondrite parent bodies, low bulk permeability may lead to the retention of H<sub>2</sub>O at depth (see section 2.1).

**Fig. 3.** Comparison of the densities of mobile silicate melts and unmolten chondritic material for five meteorite groups. Intact crust densities and uncertainties represent the measured densities of chondrite hand samples, while the values with 10% macroporosity approximate the bulk densities of fractured chondritic lids. Reproduced from Fu and Elkins-Tanton (2014, *EPSL*) with permission of Elsevier.

Likewise, carbonaceous and ordinary chondrite parent bodies with low intrinsic permeability, low degree of fracturing, or high initial volatile contents may have generated sufficiently volatile-rich melts to undergo buoyant ascent.

In such scenarios, magmas forming inside planetesimals may be expected to erupt with force, driven by expanding volatiles (Muenow *et al.*, 1992, 1995; Wilson and Keil, 2012). Melt extraction from the partially molten interior likely occurred in two stages (Wilson *et al.*, 2008; Wilson and Keil, 2012). First, magma would have ascended in dikes, but flow rates were likely insufficient to sustain continuous eruption from the melting region directly to the surface. This was especially the case for parent bodies smaller than ~400 km in diameter. The ascending melt therefore collected in sills within the chondritic lid. Second, the melt in these magma chambers, especially if it was volatile rich, would have explosively erupted onto the surface, propelling silicate fragments up to 1 m in size beyond the escape velocity of small (<100-km-diameter) asteroids (Wilson and Keil, 1991; Wilson *et al.*, 2010). On larger bodies with stronger gravity, most erupting melt may have been retained on the surface in melt ponds that, with sufficient accumulation, led to the subsidence and destruction of the primitive chondritic lid (Wilson and Keil, 1997, 2012).

Ghosh and McSween (1998) describe an end-member model for Vesta in which all melt from the interior erupts onto the surface and another end-member model in which no melt extrudes; their efforts demonstrate the difficulty of arguing completely for one or another eruptive scenario.

In summary, the potential of silicate melts to ascend from the melting region depends critically on the persistence of volatiles at supersolidus temperatures and on the parent body's bulk composition. Volatile-rich melts, which may have formed on bodies with very low fluid permeabilities such as enstatite chondrite parent bodies, are expected to rise efficiently to the surface, potentially resulting in the inundation of the chondritic lid and ejection of mass from the parent body. The discovery of possible pyroclasts of aubritic composition such as Larkman Nunatak (LAR) 04316, which may be sourced from an enstatite-chondrite-like protolith, supports the hypothesis that enstatite chondrite parent bodies retained sufficient volatiles to drive magma ascent (Keil, 2010; Keil *et al.*, 2011). For differentiated planetesimals with carbonaceous and ordinary chondrite compositions, efficient release and upward transport of volatiles before the onset of silicate melt migration likely resulted in negatively buoyant melts that permitted the preservation of the primitive chondritic lid on these bodies.

### 3. COOLING AND SOLIDIFICATION OF PLANETESIMALS

#### 3.1. Solidification of a Partially Molten Silicate Mantle

The physical process of magma solidification influences the range of both composition and texture that will occur in

the mantle and possible crust of a planetesimal. The compositional process of solidification can be viewed as having two end members: fractional solidification and batch solidification (e.g., Solomatov, 2000). For fractional solidification to occur, mineral grains must settle from flow and be effectively removed from communication with the remaining magma ocean liquids. The residual liquid composition thus evolves with the progressive removal of solidified material. In batch solidification, liquid contact and equilibrium are maintained throughout solidification. A fractional solidification model of a magma ocean therefore predicts mineral assemblages, cumulate bulk composition, and cumulate trace-element compositions that are completely different from those occurring in equilibrium solidification.

Due to their relatively small masses, planetesimals have internal pressures so low that, once melted, the bottom of a planetesimal's magma ocean has effectively the same pressure as the top. The high-pressure gradient in planets the size of Earth likely encourages fractional solidification as cool downwellings from the surface develop crystallinity with depth and deposit crystals at the bottom boundary. Without significant pressure or gravity, magma oceans on planetesimals may not fractionally solidify. Over the ~0.5-kbar mantle pressure range of a planetesimal ~200 km in radius, the solidus will change by only about 10°C, and the adiabat by only ~2°C. As it cools, therefore, the entire depth of the magma ocean will contain some crystal fraction. The magma ocean will have a high effective viscosity, perhaps in the range of hundreds to thousands of Pascal seconds. Combined with the high heat flux of a small body cooling without an atmosphere, mineral grains would have to be large, perhaps several to 10 cm, to settle from the magma ocean. Thus, in the time before crystallinity rises, only the earliest-forming crystals will settle (Suckale *et al.*, 2012). Given almost any of the candidates for bulk-chondritic silicate compositions and the low pressures in planetesimals, olivine alone would be the first material to crystallize. The rest of the planetesimal's mantle will solidify in bulk and never produce an olivine cumulate. This may be why we have no such samples in our collections.

Despite the lack of meteoritic olivine cumulate samples, olivine is by far the predominant silicate represented in the stony-iron meteorite group known as pallasites. Apart from olivine and metal, main-group pallasites contain <1 vol.% each of chromite, pyroxene, and phosphates (Buseck, 1977; Ulff-Møller *et al.*, 1998). Pallasites are usually thought to be samples of a core-mantle boundary (e.g., Mittlefehldt *et al.*, 1998; Benedix *et al.*, 2014), although Tarduno *et al.* (2012) argue instead that pallasites are the result of an impact that injected iron from the impactor's core into a planetesimal mantle. Assuming they are samples of a core-mantle boundary, the simplicity of the mineral assemblages in pallasites and iron meteorites strongly supports successful crystal settling of olivine alone at the beginning of magma ocean solidification in an internally differentiated planetesimal. Later solidification would occur in bulk, and thus planetesimal magma oceans will not produce olivine + pyroxene cumulate,

as predicted for the Moon, but would produce melt extraction from mushes consistent with observations from Vesta.

The slowness of magma movement and the inefficiency of mixing on planetesimals not only makes the formation of olivine cumulates unlikely, it predicts that planetesimals' mantles and crusts may well be inhomogeneous. The accreting material is not likely to be compositionally homogeneous, and it may not efficiently melt and mix. This prediction is supported by the findings of Kleine et al. (2012), who find that four texturally and temporally resolved groups of angrites can be identified that were derived from at least two distinct mantle sources. These mantle sources are the result of separate events of core formation, both of which took place within ~2 m.y. of CAI formation. Thus, core formation in the angrite parent body did not occur as a single event of metal segregation from a global magma ocean, but rather took place under varying conditions by several more local events. The disparate Hf-W systematics of the two distinct angrite source regions indicate that convection in the magma ocean was inefficient in homogenizing the composition of the mantle, possibly as a result of a continuous bombardment with small planetesimals during ongoing core formation. Furthermore, they find that mantle differentiation occurred at ~3.6 m.y. after CAI formation, in line with cooling models following early  $^{26}\text{Al}$  melting in the parent body.

In summary, the taxonomy of possible internal structures is not limited to the processes of melting. Mantle heterogeneities caused by a small extent of olivine settling followed by batch solidification, as well as complications from melt percolation and mixing caused by continued accretion, probably also influenced planetesimal structure. The surface of the body may experience ongoing accretion of primitive material while the partially or wholly molten interior continues to cool and differentiate. Finally, later impacts may partially strip the body and then allow blocks of material to fall back onto the surface, or may even break the body into pieces and produce a rubble pile.

### 3.2. Solidification of a Planetesimal Core

Metallic cores would have initially been entirely molten. The temperature at which core crystallization began depends on its composition, in particular, its sulfur content. The liquidus in an Fe-FeS system decreases from 1538°C for pure Fe to 988°C at its eutectic composition (~31 wt.% S), at which point FeS begins to crystallize as well (Kullerud and Yoder, 1959). In some parent cores, sulfur content as high as 17 wt. % has been inferred (Chabot, 2004). Iron sulfide is far less abundant in the meteorite collection than predicted by models, although this may be explained by the mineral's low strength (Kracher and Wasson, 1982; Chabot and Drake, 2000).

Although batch solidification might be expected given the shallow pressure gradient and low gravity, concentration trends of various minor and trace elements (e.g., Ni, Au, Ga, Ge, O, P, Ir) in iron meteorite groups demonstrate that their initially molten parent cores underwent fractional crystal-

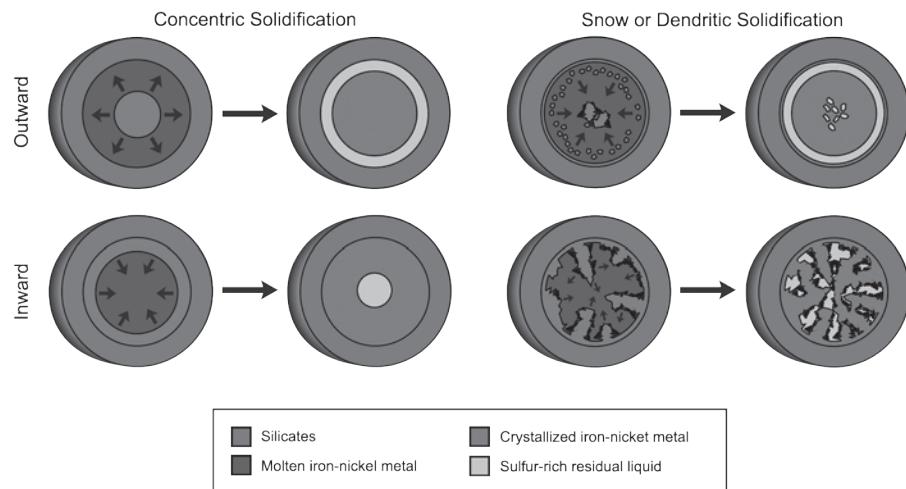

lization. However, scatter in these element trends indicate that at some point the assumption of a well-mixed liquid broke down (Haack and Scott, 1992, 1993; Pernicka and Wasson, 1987; Scott et al., 1996b; Wasson, 1999; Wasson and Richardson, 2001; Benedix et al., 2014).

On large planets, high-pressure gradients result in the adiabatic gradient intersecting the solidus at the body's center, causing solidification to first occur at the body's center and produce a solid, growing inner core. For pressures lower than ~4 GPa, the core-mantle boundary would be the first location to reach the liquidus during cooling (Williams, 2009). However, due to the low-pressure gradient in a planetesimal, both the adiabatic gradient and the pressure-induced solidus change in a well-mixed core were very small, with perhaps a ~1°C increase from the core-mantle boundary to the center for an asteroid with a 100-km radius. Because this variation in liquidus is so small, particularly compared to sulfur effects, it is difficult to predict how solidification would have proceeded. Chabot and Haack (2006) and Goldstein et al. (2009) provide recent reviews of the scenarios and supporting evidence.

Four possible core solidification scenarios are (1) outward concentric crystallization (similar to Earth), (2) inward concentric crystallization, (3) inward dendritic growth, and (4) cumulate solid inner-core formation (Fig. 4). None of these scenarios can be decisively confirmed or rejected on the basis of current observation and evidence.

Sulfur is almost fully excluded from crystallizing iron (Willis and Goldstein, 1982). Since increasing sulfur content lowers the melting temperature, a solidification front is inhibited as local sulfur content becomes too high to efficiently diffuse. This likely results in dendritic growth inward from the core-mantle boundary as cooling and solidification continue (Haack and Scott, 1992). Although kilometer-sized dendrites have been proposed (Narayan and Goldstein, 1982), the dendrites could be gravitationally unstable and descend to form a cumulate inner core. On the other hand, if sulfur accumulates near the core-mantle boundary due to its low density and effectively inhibits crystal growth there, solidification would then occur throughout the core in the form of iron snow. While this has not been discussed in a planetesimal context, iron snow has recently been discussed in the context of the small lunar (e.g., Laneuville et al., 2014) and Ganymede (e.g., Christensen, 2015) cores.

These different core scenarios would result in different configurations in modern-day asteroid cores (Fig. 4). An inward-crystallizing concentric solidification front would have the bulk of its late-stage solids (e.g., troilite), which would have formed upon eventually reaching a eutectic Fe-S composition, sequestered in the body's inner core. A dendritic inward-crystallization scenario would show a complicated network of dendrite growth interspersed with light-element-rich pockets. A core that crystallized from the inside out would have an outer core rich in late stage solids. Outward growth through snow or dendritic collapse would have a similar configuration, although inefficient compaction could result in pockets similar to the inward-dendritic-growth scenario.

**Fig. 4.** See Plate 18 for color version. Four possible core solidification scenarios and potentially resulting end-states. *Top left:* Outward (Earth-like) solidification. *Bottom left:* Concentric inward solidification. *Top right:* Outward solid core growth due to accumulated iron “snow” and/or destabilized dendrites. *Bottom right:* Dendritic inward solidification.

#### 4. ASTEROID AND METEORITE RECORDS OF THE DIFFERENTIATION PROCESSES

We have a diversity of geochemical and geophysical constraints on the compositions of asteroid surfaces and interiors. Collectively, these datasets provide evidence for surface compositions ranging from apparently chondritic bodies to fully differentiated bodies and possibly also including partially differentiated bodies. Here we review evidence for asteroidal cores from asteroidal shapes, and then discuss two relatively recently acquired datasets that constrain asteroidal differentiation and large-scale interior structures: studies of the remanent magnetization of meteorites, and *in situ* magnetic field observations of asteroids. These observations detect asteroid remanent magnetization, which in turn likely point to a convecting metal core capable of dynamo action in early solar system history.

##### 4.1. Asteroidal Shape and Core Detection

Absorption and emission spectra acquired in wavelengths from the ultraviolet to the far-infrared constrain the mineralogical and elemental composition of the surface layers of asteroids (see the chapters by DeMeo et al., Masiero et al., Reddy et al., and Vernazza et al. in this volume). Albedo and polarimetry data also provide indirect constraints on surface-layer mineralogy. Radar data constrain the bulk density of the surface layer (see the chapters by Benner et al., Delbo et al., Margot et al., and Scheeres et al. in this volume). Gravity data acquired either from spacecraft encounters, binary asteroid orbits, or perturbations to the orbits of more distant bodies constrain asteroid masses (see the chapter by

Scheeres et al. in this volume). When combined with shape data obtained from resolved images and/or joint infrared and optical photometry, the bulk asteroid density and sometimes the interior mass distribution can be constrained (see the chapter by Russell et al. in this volume). For example, the high surface density (ranging up to  $\sim 6 \text{ kg m}^{-3}$ ) of several M-type asteroids strongly suggests they are largely metallic bodies (Shepard et al., 2010), probably derived from early differentiated planetesimals whose silicate mantles were catastrophically removed by a collision (Asphaug, 2010).

Spacecraft-based geophysical observations of main-belt asteroids provides evidence for differentiated internal structure. One such example is the asteroid (21) Lutetia, whose high density strongly suggests that its deep interior underwent substantial heating and sintering. Because its surface spectral properties are most similar to those of carbonaceous or enstatite chondrites (Coradini et al., 2011; Vernazza et al., 2011), Lutetia may represent the first known partially differentiated asteroid (Weiss et al., 2012). Formisano et al. (2013) find that partial differentiation is likely in scenarios in which Lutetia completed its accretion in less than 0.7 m.y. from the injection of  $^{26}\text{Al}$  in the solar nebula and for post-sintering values of macroporosity not exceeding 30 vol.%.

There is indirect evidence for a metallic core in asteroid (4) Vesta from the oblateness of its gravity field and its bulk density (Russell et al., 2012). At the same time, observation of asteroid shape can offer further constraints on the degree of interior melting during the body’s early history. Finite-element models of Vesta indicate that, even in the low-gravity regime of such bodies, strong internal heating resulted in a thin early lithosphere that experienced pervasive fracturing, permitting efficient relaxation of the body to a

closely hydrostatic figure (*Fu et al.*, 2014a). Topography data provided by the Dawn spacecraft, combined with derived crustal thickness maps (*Ermakov et al.*, 2014), suggest that a large region in the northern hemisphere of Vesta has escaped significant reshaping due to late giant impacts and preserved an ancient figure closely consistent with an oblate ellipsoid of rotation, which is the shape expected for a body that nearly reached hydrostatic equilibrium. The presence of such a hydrostatic terrain confirms that the entire vestan interior, with the exception of a lithosphere of up to several tens of kilometers in thickness, underwent intense heating above approximately 800°C, which is necessary to permit viscous relaxation on the relevant timescale of asteroid thermal evolution. Future high-resolution observations of other large asteroids, including (2) Pallas, may reveal the presence of analogous hydrostatic terrain and thereby constrain the degree of early interior heating.

#### 4.2. Paleomagnetism of Meteorites

Remanent magnetization is the semipermanent alignments of electron spins in ferromagnetic minerals and provides a record of the intensity of past magnetic fields. It can be acquired by asteroid materials in the form of thermoremanent magnetization (produced during cooling) or as crystallization-remanent magnetization (produced during crystallization) when these processes occur in the presence of a magnetic field. Asteroidal materials could be remagnetized either on their parent body or, for chondrules and refractory inclusions, when they formed as free-floating objects in the nebula (*Weiss and Elkins-Tanton*, 2013). It is also possible that previously magnetized materials could be aligned by a background field as they accreted onto a planetesimal to produce accretional detrital-remanent magnetization (*Fu and Weiss*, 2012).

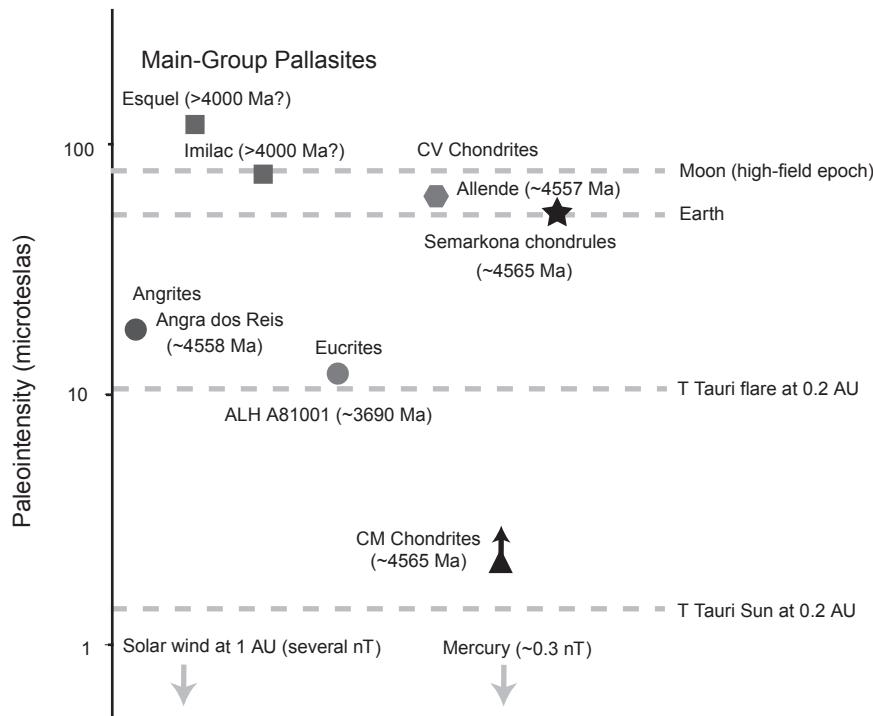

By constraining the existence and intensity of ancient magnetizing fields, remanent magnetization can be used to infer the existence and nature of putative magnetic field sources in the early solar system. Proposed field sources are magnetism in the solar nebula (dragged in from the parent molecular cloud and/or generated by *in situ* fluid motions), induction currents generated in advecting planetesimal metallic cores (dynamos), and currents transiently generated by impact-produced plasmas (*Weiss et al.*, 2010a). Of these three field sources, only dynamo fields are generated by internal geophysical processes and would therefore place direct constraints on planetesimal differentiation and thermal evolution.

Paleomagnetic studies over the last five decades have found that many chondrites and achondrites contain remanent magnetization. However, until recently, the origin of this magnetization has been unclear. Over the last decade, a burst of measurements (Fig. 5) combined with a deepening understanding of meteoritics and the fundamentals of rock magnetism and dynamo theory has led to major advances in our understanding of meteorite magnetism. Paleomagnetic analyses have identified remanent magnetization in angrites and howardite-eucrite-diogenite (HED) meteorites, two groups of basaltic achondrites (*Fu et al.*, 2012; *Tarduno and*

*Cottrell*, 2012; *Weiss et al.*, 2008), and main-group pallasites (*Tarduno et al.*, 2012). The slow cooling rates experienced by these meteorites through the Curie points of their ferromagnetic minerals on their parent bodies [e.g., at least thousands of years for the angrite Angra dos Reis and the eucrite Allan Hills (ALH) A81001] are inconsistent with impact-generated plasmas as the field source, which are only thought to persist at most for ~1000 s on asteroidal bodies (*Fu et al.*, 2012). The relatively young age of magnetization in these bodies (i.e., <4.557 Ga for Angra dos Reis and 3.69 Ga for ALH A81001) likely excludes magnetic fields in the solar nebula. By comparison, consideration of the physics of dynamo action on planetesimals suggests that magnetic fields could persist on these bodies on timescales ranging from several million years (*Sterenborg and Crowley*, 2013) up to ~200 m.y. after the formation of CAIs (*Elkins-Tanton et al.*, 2011; *Tarduno et al.*, 2012; *Weiss et al.*, 2008). Therefore, it was concluded that all three parent bodies generate dynamo magnetic fields.

Paleomagnetic analyses of the Allende CV carbonaceous chondrite have identified a unidirectional magnetization blocked up to 290°C in bulk samples (*Butler*, 1972; *Carporzen et al.*, 2011; *Nagata and Funaki*, 1983) and some chondrules (*Fu et al.*, 2014b; *Sugiura and Strangway*, 1985). The unidirectional orientation of this component requires that it was acquired after accretion on the CV parent planetesimal in a field of ~60 µT (see Fig. 7 of *Weiss and Elkins-Tanton*, 2013). This is consistent with the fact that the ferromagnetic minerals in Allende (pyrrhotite, magnetite, and awaruite) are secondary alteration products widely interpreted to have formed as a result of fluid-assisted metasomatism on the CV planetesimal (*Brearley and Krot*, 2012). Furthermore, the formation of these minerals was accompanied by or followed by thermal metamorphism to temperatures of 300°–500°C. These processes should have imprinted a thermoremanent or crystallization-remanent magnetization on the meteorite if a field was present. Although the actual age of the ferromagnetic minerals is uncertain, I/Xe thermochronometry suggests that the thermal event occurred at least 9–10 m.y. after the formation of CAIs. Because the solar nebula is only thought to have persisted for 3–6 m.y. after CAI formation, this likely postdates the existence of putative nebular magnetic fields. Therefore it was concluded that the most likely magnetic field source was an interior core dynamo, such that the CV parent body was partially differentiated with a molten metallic core and an unmelted (but variably metasomatized) relic chondritic crust (*Carporzen et al.*, 2011; *Elkins-Tanton et al.*, 2011). Dynamo generation by flow of briny fluids is extremely unlikely because of their extremely low conductivities (see *Schubert et al.*, 1996).

This proposal, which has roots in the early modern era of meteoritics, challenges the dominant view that individual planetesimals have homogenous structures that are either unmelted, partially melted throughout, or fully melted (*Weiss and Elkins-Tanton*, 2013). It proposes that planetesimals could have reached a continuum of differentiation end states that individual bodies could have restricted regions that varied in their degrees of differentiation. It therefore implies

**Fig. 5.** Modern magnetic field paleointensity measurements from meteorites. Shown are paleointensities measured for individual meteorites from the angrite parent body, the main group pallasite parent body, the eucrite parent body, the CV chondrite parent body, and the CM chondrite parent body, all of which have been interpreted as possible records of planetesimal dynamo magnetic fields (Weiss *et al.*, 2008; Tarduno *et al.*, 2012; Fu *et al.*, 2012; Carporzen *et al.*, 2011; Cournède *et al.*, 2015). Paleointensity records of the nebular magnetic field from chondrules from the Semarkona LL ordinary chondrite (Fu *et al.*, 2014b) are shown for comparison. Also shown are the surface magnetic field on the Earth, the inferred lunar surface field from 3.56 to 3.9 Ga (Weiss and Tikoo, 2014), fields from the T Tauri Sun and transient flares at 0.2 AU (Weiss *et al.*, 2010a; Vallee, 2003), and the present-day solar wind field and surface field of Mercury (Anderson *et al.*, 2010).

that some chondrite and achondrites could have originated from a single parent body (Fig. 1). The recent identification of unidirectional magnetization in CM chondrites (Cournède *et al.*, 2015) may provide evidence for another partially differentiated chondrite parent body, although the old age of this magnetization makes it difficult to exclude an external nebular magnetic field source.

Recently, it has been proposed that the unidirectional magnetization in CV chondrites could be the product of impact-generated magnetic fields rather than a core dynamo (Bland *et al.*, 2014). In this scenario, the precursor lithologies of chondrites were heated by an impact-induced compaction event that simultaneously generated an impact plasma field, leading to the acquisition of a unidirectional thermoremanence without requiring partial differentiation. However, it is unclear whether impacts are likely to generate strong magnetic fields with sufficient duration and occurring in the appropriate location to magnetize rocks. For

example, paleomagnetic studies of terrestrial craters have identified no evidence of impact-generated fields (Weiss *et al.*, 2010b). Furthermore, the peak temperatures predicted for carbonaceous meteorites by the impact-compaction hypothesis exceed the Curie temperatures of their constituent ferromagnetic minerals (pyrrhotite and magnetite, 320° and 580°C, respectively), such that the millimeter–centimeter samples studied by Carporzen *et al.* (2011) would be predicted to have magnetization blocked up to 580°C rather than the observed 290°C temperature. Finally, the ferromagnetic minerals in Allende and other CV chondrites are thought to have been produced mostly by secondary metasomatic and aqueous processes on their parent body. In particular, the presence of sulfide veins crosscutting chondrules and into the surrounding matrix (Krot *et al.*, 1998) requires that much of the ferromagnetic minerals postdate any putative compaction event and therefore could not have been magnetized in an associated impact-generated field.

### 4.3. Asteroidal Magnetism

Paleomagnetic studies of meteorites indicate that some asteroids could be magnetized by an internally generated dynamo (for bodies that formed advecting cores) or could acquire large-scale magnetization during accretion by torques associated with a background field in the nebula. These conclusions could be directly tested by direct measurements of remanent magnetic fields around asteroids. Because of the inverse-cube dependence of dipolar fields with distance from the field source, direct detection of asteroidal magnetic fields requires *in situ* magnetometry measurements from spacecraft. Spacecraft have attempted this thus far near six asteroids — (21) Lutetia, (243) Ida, (433) Eros, (951) Gaspra, (2867) Šteins, and (9969) Braille — but none have unambiguously detected a remanent field from these bodies (Kivelson et al., 1995; Richter et al., 2012). One possible exception is Deep Space 1's flyby of the 0.78-km-radius Q-/S-type asteroid (9969) Braille, which observed a weak ( $\sim$ 1–2 nT) change in the ambient magnetic field upon closest approach (28 km) (Richter et al., 2001). However, this field change is near the sensitivity limit of the investigation, as demonstrated by a mismatch between the measured x-component of the field and the best-fit dipole model for the asteroidal field. Another possible exception is Galileo's flyby of the 8-km-radius S-type asteroid (951) Gaspra, during which it was thought to have detected magnetic field rotations produced by interaction of the solar wind with an intrinsic asteroidal magnetic field (Kivelson et al., 1993, 1995). However, it has been subsequently proposed that the observed plasma waves do not require the presence of a significant asteroidal magnetic field but could rather be explained purely by variability of the background solar wind (Blanco-Cano et al., 2003).

The lack of magnetic field detections near some of these asteroids places stringent constraints on the total magnetic moments of these asteroids. In particular, if it is assumed that the asteroids are uniformly magnetized, then the inferred upper limit on the magnetizations of asteroids (21) Lutetia (Richter et al., 2012) and (433) Eros (Acuña et al., 2002) are below that measured for virtually all known meteorites. This means that either these asteroids are made of materials not yet recognized as meteoritic materials on Earth or, more likely, they are made of materials resembling known meteorites but that are nonunidirectionally magnetized at spatial scales exceeding that of meteorite hand samples ( $>10$  cm) (Wasilewski et al., 2002). Therefore, magnetic field measurements of asteroids do not presently support or refute the inference made from meteorite paleomagnetic studies that many asteroids, including fully melted objects and possibly also partially differentiated bodies, likely generated dynamo magnetic fields.

### 4.4. Meteorite Evidence for Partial Differentiation

The existence of chondrites, primitive achondrites, and achondrites indicates that at least localized regions of planetesimals either did not melt, underwent partial melting, or

completely melted. These topics are extensively reviewed elsewhere in this volume (see the chapters by Wilson et al. and Scott et al.). Here we focus on meteorite evidence for partial differentiation.

As discussed in sections 2.3 and 4.3, thermal models of asteroid differentiation and paleomagnetic studies of chondrites indicate that some bodies may have partially differentiated, such that more than one of these meteorite lithologies could have formed on the same body. In fact, the recent discovery of primitive achondrites, thought to be the residues of partial melting of chondritic precursors, as a third major category of meteorite lithologies intermediate between chondrites and achondrites provides *prima facie* evidence for the existence of partially differentiated bodies. Moreover, there is broad consensus that the primitive achondrite group winonaites are derived from the same parent body as IAB iron meteorites (Benedix et al., 2000), which demonstrates that partially differentiated bodies contained regions that experienced a large degree of melting. Three key questions that remain are how common the formation of such bodies was in the early solar system, whether they preserved chondritic crusts, and whether they formed large-scale regions of silicate and iron metallic magmas.

As reviewed extensively by Weiss and Elkins-Tanton (2013), affiliated chondrites and achondrites could be recognized by their isotopic compositions, cosmic-ray exposure age distributions, and/or radioisotopic impact age distribution. The chemical compositions of the achondrites should also be consistent with fractionations expected from igneous differentiation of their chondrite protoliths. Particularly strong evidence would come from the identification of chondritic and achondritic materials that share these properties and are co-located within a single polymict meteorite.

Possible examples of affiliated chondrite and achondrite groups include the H chondrites and the silicate-bearing IIE iron meteorites. The silicates in these rocks share a common oxygen isotopic composition and bulk elemental composition, while the IIE iron meteorites also contain a diversity of silicate lithologies ranging from relic chondritic fragments, to achondritic unmelted chondrites with relic chondrules, to metamorphosed chondrites, to partial melts (Ruzicka, 2014). A connection between enstatite chondrites, aubrites, and recently discovered primitive achondrites of enstatite chondritic parentage has long been considered (Keil, 2010; Watters and Prinz, 1979). The paleomagnetism of at least CV chondrites has been interpreted as evidence for a core dynamo (Carporzen et al., 2011; Elkins-Tanton et al., 2011). Oxygen and Cr isotopic data indicate strong affiliations between CV chondrites and the ungrouped basaltic achondrite Northwest Africa (NWA) 8186 (Agee et al., 2014). There are also numerous “type 7” chondrites, which appear to have been heated to temperatures at or just below metal-sulfide melting (Irving et al., 2005), including metamorphosed clasts within the CV breccias Mokoia and Yamato 86009 (Jogo et al., 2013). Furthermore, oxygen isotopic data link the very primitive CR chondrite group to several highly metamorphosed (type 6) chondrites such as NWA 2994 as well

as to achondrites such as NWA 5131 (*Bunch et al.*, 2008; *Wittke et al.*, 2011). It would be surprising if chondrite parent bodies were heated to temperatures either just below the solidus or else above the silicate liquidus throughout their entire volumes such that virtually no intermediate partially differentiated bodies formed in between these end members.

## 5. CONCLUSION

There were many competing and interacting processes occurring in small bodies in early solar system history, and differences in bulk composition and accretionary history would have led to highly diverse outcomes, only a few of which may be represented in extant meteoritic and asteroidal material.

Aluminum-26 was probably the primary energy source for the heat needed to cause large-scale differentiation, while impacts caused only local melting. Progressive heating above  $\sim 200^{\circ}\text{C}$  generated free fluids that could have been exhaled or have participated in thermal convection, although the enstatite chondrite parent bodies may have had insufficient permeability for large-scale fluid flow. Beyond  $950^{\circ}\text{C}$ , molten metal may have begun to percolate downward and form a core, although this may require even higher temperatures. The formation of a core and the fraction of the planetesimal's total metal content that would migrate there depends on the peak temperature reached and duration of heating. These factors in turn strongly depend on body size and accretion rate.

Silicate melting will commence around  $1100^{\circ}\text{C}$ . If volatiles were not already sufficiently depleted, then volatile-rich silicate melt could rise to eject or form a crust. It could also transport  $^{26}\text{Al}$  away from the interior, cooling the body more quickly and slowing core growth. Alternatively, volatile-depleted melt would be negatively buoyant, thereby permitting the preservation of a chondritic or primitive achondritic crust over a differentiated interior.

On bodies heated sufficiently to form a magma ocean, initial fractional solidification as the magma ocean cools would produce only olivine before a high crystal fraction suppressed fractional solidification and caused bulk solidification. This explains the presence of olivine found in pallasites and its absence from the rest of the meteorite collection. It is difficult to predict how core solidification would have proceeded since the adiabat is shallow and sulfur content is the main factor determining the solidus. However, the different solidification regimes predict different locations of sulfur-rich late-crystallizing material.

Post-accretional remanent magnetization has been found in both chondrites and achondrites, and an internal dynamo is considered the likely magnetic field source. Magnetic fields have not been decisively detected on asteroids, probably because they are non-uniformly magnetized such that they have weak total magnetic moments.

Aspects of differentiation models can be further refined to make better predictions and inferences as solar system exploration continues. For example, the hypothetical process and effects of oxidation of iron in the presence of volatiles, followed by reduction as temperature rises, should be a

topic of further research. Further work permitting thermal modeling of bodies rich in ice and other volatile compounds, which are particularly likely to be present in the outer solar system, would also permit greater understanding of early solar system processes.

Early forming asteroids greater than ~50 km in diameter underwent extensive thermally driven differentiation, causing heating to a range of maximum temperatures. Some reached the stage of melting of initially incorporated water ice and experienced a range of temperature-dependent aqueous alteration processes; others underwent thermal metamorphism; yet others segregated metal cores; and some were heated to the point of extensive silicate melting, leading to volcanic intrusions or eruptions, controlled in part by the stresses induced in the crust by the prior internal evolution. We review advances in both the theoretical modeling of the migration of the various fluids involved in these processes and the experimental analyses of meteorites that provide constraints on the theoretical models. There is still uncertainty about many issues. Evidence from chondrite chemistry, petrography, and material properties is consistent with limited migration of aqueous fluids (essentially a closed system), although the oxygen isotope record has been used to support both open- and closed-system models, and remains a subject of debate. Opinions seem to be converging on the need for between 5% and 10% silicate melting to allow dense metallic melts to segregate to form cores. However, the locations of large bodies of silicate melt remain controversial, ideas being polarized between retention in asteroid mantles as magma oceans and rapid transfer to the base of the crust to pond as massive intrusions. Direct observations of (4) Vesta by the Dawn spacecraft have at least partially clarified our understanding of the chemical and tectonic states of differentiated asteroid crusts, but much remains to be understood about large-scale geodynamic processes.

## 1. INTRODUCTION

Largely due to the recovery of huge numbers of meteorites from cold and hot deserts, the number of asteroidal meteorites in captivity has increased tremendously in recent years to about 50,000 (*Meteoritical Bulletin Database*, 2014). Study of these meteorites indicates that all asteroids have experienced some degree of parent-body thermal alteration due to internally produced heat. *Keil* (2000) estimated that the world's meteorite collections sample at least ~27 primitive, chondritic and ~108 partially and totally melted asteroids, and *Burbine et al.* (2002) similarly estimate this number to be ~100–150 distinct asteroids. The thermal alteration effects range from aqueous and hydrothermal alteration, notably in various classes of carbonaceous chondrites (CCs), to thermal

metamorphism and recrystallization, notably in ordinary and enstatite chondrites of high petrologic types (4–6), to partial and possibly complete melting, including core formation in various classes of achondrites. We summarize in Table 1 the meteorite classes that have experienced aqueous and hydrothermal alteration. In Table 2 we list those meteorite classes that have experienced heating to metamorphic temperatures that caused solid-state recrystallization. We also list those that experienced partial and complete melting, beginning with partial melting of the Fe,Ni-FeS cotectic, including partial melt removal and core formation, and those that experienced silicate partial to total melting.

Many meteorites have had complex histories. Some are breccias from the impact-shattered and reworked regoliths and megaregoliths of the above types of asteroid. Yet others

appear to be aggregates of fragments from multiple source bodies that individually encountered the above range of histories. Any attempt to disentangle the origins and histories of these most complex meteorites requires that we begin by understanding in detail the thermal histories controlling fluid migration in the first generation of asteroids.

TABLE 1. Classification of chondritic meteorites.

Class/Group	Petrologic Types	Peak Metamorphic Temperature (°C)	Water/Rock Mass Ratio
<i>Carbonaceous</i>			
CI	1	<150	>0.6
CR	2.0–3	<150	0.1–0.6
CM	2.0–2.9	<80	0.1–0.6
CO	3.0–3.8	~600	<0.2
CV	3.0–3.6	~600	<0.2
CK	3–6	~800	<0.2
CB	3.0	unmetamorphosed	unaltered
CH	3.0	unmetamorphosed	unaltered
<i>Ordinary</i>			
H	3–6	~950	<0.2
L	3–6	~950	<0.2
LL	3–6	~950	<0.2
R	3–6	~950	<0.2
<i>Enstatite</i>			
EH	3–6	~950	unaltered
EL	3–6	~950	unaltered

## 2. ASTEROID FORMATION, HEAT SOURCES, AND THERMAL HISTORIES

The ways in which the earliest planetesimals accreted and evolved to form the present asteroid population is still debated (Weidenschilling, 2011; Johansen *et al.*, 2014). Much work is concerned with the rates at which body sizes grew and orbits evolved with time in order to understand the present small-body size population in the solar system. Major redistributions of the semimajor axes of the earliest-forming planetesimals may have been caused by the significant inward and subsequent outward migration of the giant planets (Walsh *et al.*, 2011) during the first 3–4 m.y. after the formation of calcium-aluminum-rich inclusions (CAIs), the oldest solar system solids dated in meteorites, commonly regarded as marking “zero time” in the history of the solar system (Amelin *et al.*, 2002; Connelly *et al.*, 2012). Coupled with the possibilities of subsequent gravitational interactions with the accreting planetary embryos, this suggests that the present locations of asteroids may not necessarily be a good indicator of their distances from the Sun during the first few million years after CAI time (DeMeo and Carry, 2014), the critical period for asteroid differentiation. This is a strong argument for modeling the thermal histories of asteroids using a wide range of initial temperatures and volatile, especially water ice, contents.

However, understanding the evolution of differentiated asteroids within which fluid migration took place also requires knowledge of initial porosity and strength as well as composition and temperature (Binzel *et al.*, 2003; Binzel and

TABLE 2. Meteorites undergoing high-temperature modification.

Meteorite Group	Composition	Melting Amount	Observed Melt Fate *	Predicted Melt Fate †
Ordinary chondrites	Ordinary chondrite	Limited silicate	Limited migration	Limited migration
Enstatite chondrite-like	Enstatite chondrite?	~20% silicate	Extensive migration	Extensive migration
Acapulcoite-lodranite parent	Between ordinary and enstatite chondrite	1–4% Fe,Ni-FeS in acapulcoites; 5–20% Fe,Ni-FeS and silicate in lodranites	Limited migration	Limited to extensive
Brachinites	Primitive (R?) chondrite (volatile-rich)	13–30 % silicate	Extensive migration, loss by explosive volcanism	
Winonaite-IAB irons	Approx. H to E chondrite (relict chondrules)	Substantial	Not clear; impacted and reassembled	Not clear
Ureilites	Akin to CV chondrite	~30% silicate	Extensive migration, loss by explosive volcanism	No migration expected
Angrites	Akin to CV or CM chondrite	Extensive silicate	Extensive migration	No migration expected
Aubrites	Enstatite chondrite-like	Extensive silicate	Melts removed by explosive volcanism	Extensive migration
HED [(4) Vesta]	Akin to ordinary chondrite	4–15–60% silicate	Extensive eucrite migration	Limited migration
11 iron meteorite groups	Unknown	Extensive Fe,Ni-FeS	Formed core	

\* As inferred from meteorites.

† From Fu and Elkins-Tanton (2014).

(*Kofman*, 2005). Key factors are the mechanisms by which small grains formed and later adhered to one another in low-velocity collisions to form larger objects, and the history of the coalescence or breakup of larger objects as they experienced higher-velocity collisions. For the latter reason, much attention has been paid to the apparent strength of asteroids undergoing impacts (*Holsapple*, 2009). However, in addition to local stresses produced by impacts, progressive gravitational loading was important in large asteroids as they accreted and can be modeled theoretically if impacts are ignored (*Kadish et al.*, 2008). No direct estimate of the internal strength of an asteroid exists and so meteorites are used as proxies. Unfortunately, meteorites are inevitably the strongest parts of meteoroids that survive atmospheric passage, and therefore measurements on them (*Kimberley and Ramesh*, 2011) almost certainly overestimate the bulk strength of asteroids. Inferences from the dynamic behavior of meteoroids as they enter the upper atmosphere (*Popova et al.*, 2011) suggest that many are very weak, but there is no guarantee that these are samples of the interiors of large asteroids. Even if they are, the impact event that removed them from their parent body will have induced mechanical damage reducing their strength. One indirect estimate of the internal strength of an asteroid exists: A fault observed on (433) Eros implies a shear strength of ~1–6 MPa on a 100-m length scale (*Watters et al.*, 2011). Asteroid porosity generally decreases with increasing size (*Britt et al.*, 2002). Some asteroids in the 30–300-km range have porosities between 15% and 25%, whereas another group in the 50–250-km size range have porosities greater than 30%. The latter objects are probably true “rubble piles” and the former are heavily fractured but not totally disrupted bodies.

Various heat sources have been suggested for driving the thermal evolution of asteroids. Mutual impacts between accreting cold bodies can cause intense local heating but not a body-wide temperature rise (*Keil et al.*, 1997; *Davison et al.*, 2010), even allowing for the fact that a greater fraction of the kinetic energy of impact is converted to heat if the colliding bodies are rubble piles rather than coherent masses (*Davison et al.*, 2012). Although most modeling assumes a uniform initial temperature for asteroids, the timescale and dynamics of the accretion process may induce a non-uniform temperature distribution within a body immediately post-formation (*Merk et al.*, 2002; *Šrámek et al.*, 2012). Inductive electrical heating in the early strong solar magnetic field, first proposed by *Sonett et al.* (1970) but subsequently largely discounted (*Wood and Pellas*, 1991), may nevertheless have contributed a minor component to asteroid heating within a few astronomical units of the Sun in some circumstances (*Menzel and Roberge*, 2013).

However, the dominant heat source in early-forming asteroids was clearly the decay of short-lived radionuclides (*McCoy et al.*, 2006a), the presence of which is confirmed by technological advances (e.g., *Wadhwa et al.*, 2006) allowing detection of excess amounts of their daughter products. The most important radiogenic heat source was  $^{26}\text{Al}$  (*Schiller et al.*, 2010a), which has a half-life of ~0.72 m.y.

(*Castillo-Rogez et al.*, 2009) and decays to  $^{26}\text{Mg}$ . Thus whenever excess  $^{26}\text{Mg}$  is detected in the meteorites from an asteroid that has undergone large-scale melting, that asteroid must have formed within a very few million years of CAI time. Although  $^{60}\text{Fe}$  that decays to  $^{60}\text{Ni}$  with a half-life of ~1.5 m.y. was considered to be the second most important radiogenic heating source (*Cohen and Coker*, 2000), recent high-precision Fe-Ni isotope measurements of bulk meteorites and their components (*Tang and Dauphas*, 2012, 2014) showed very low initial abundance of  $^{60}\text{Fe}$  in the solar system ( $^{60}\text{Fe}/^{56}\text{Fe}$ )  $< \sim 1.5 \times 10^{-8}$ ). Even if initially uniformly distributed in accreting asteroids, radiogenic isotopes would not remain so. Core segregation increases the residual mantle’s  $^{26}\text{Al}$  content. Also, aluminum partitions preferentially into basaltic melts, so migration of basalts from the mantle to form a crust depletes the mantle and enriches the crust in  $^{26}\text{Al}$ . Thus both core formation and mantle melting dramatically influence the subsequent thermal history of an asteroid (*Zhou et al.*, 2013). Finally, downward settling of dense compounds to form a core is itself a heat source as potential energy is converted to heat, although this heat is not available until an asteroid’s interior temperature has already reached the point where  $\text{Fe},\text{Ni}-\text{FeS}$  melting and separation begin. In contrast to Earth-sized planets, the core formation heat source for asteroids is small: The maximum theoretical temperature rise (which neglects heat loss while the core is forming and therefore is an overestimate) scales as the square of the diameter for a fixed density (*Rubie et al.*, 2007). For differentiated bodies with diameters 1000 and 500 km, the temperature increase would be ~200 K and 50 K, respectively, but would be only ~2 K for a 100-km-diameter asteroid.

Whatever the heat source(s), an asteroid’s thermal structure is always strongly influenced by a thermal boundary layer extending inward from the surface, within which conduction of heat from the interior controls the temperature profile (*Wilson et al.*, 2008). This layer can be defined as the lithosphere on the basis of its rheology determined by the temperature profile. On the lifetime,  $\tau$ , of the  $^{26}\text{Al}$  heat source, a few million years, the boundary layer thickness  $\lambda$  [=  $(\kappa\tau)^{1/2}$ , where  $\kappa = \sim 10^{-6} \text{ m}^2 \text{ s}^{-1}$  is the thermal diffusivity of silicates (*Whittington et al.*, 2009)], is ~10 km, with small uncertainties depending on the extent of any regolith or megaregolith that exists (*Warren*, 2011a). The mean surface temperature is determined by a dynamic equilibrium between incoming heat from the Sun and outgoing radiation from the surface.

The above considerations show that the critical parameters needed in modeling the internal evolution of an asteroid are the formation time after CAIs, including the duration of accretion if this is not a short period; the bulk composition, insofar as this determines the  $^{26}\text{Al}$  content; the mean orbital distance from the early Sun, which controls the initial temperature, the surface temperature, and the ice content; and the size and bulk density of the body at the end of accretion. The most general thermal history of an asteroid includes heating to the onset of ice melting, silicate hydration by aqueous fluids, dehydration of silicates, thermal metamorphism, formation of an  $\text{Fe},\text{Ni}-\text{FeS}$  fluid potentially leading

to core formation, silicate melting, and, in the most extreme cases, melting of Fe,Ni metal before conductive cooling eventually overtakes radiogenic heating. Clearly, some of these stages are bypassed if ice is not initially present, and the sequence may be truncated at any point for asteroids that accrete too late or with too little radiogenic heat source.

### 3. ASTEROIDS THAT EXPERIENCED AQUEOUS/HYDROTHERMAL ALTERATION

#### 3.1. Classes of Altered Bodies

Carbonaceous chondrites are among the most primitive materials available to us. However, the mineralogy, petrography, oxygen-isotope compositions, and short-lived isotope chronology of aqueously/hydrothermally formed minerals clearly indicate that extensive alteration occurred within CC parent bodies (e.g., Zolensky and McSween, 1988; Brearley, 1988; Krot et al., 2006; Zolensky et al., 2008; Brearley and Krot, 2012). Based on bulk chemical and oxygen-isotopic compositions, mineralogy, and petrography, 14 chondrite groups, comprising three major classes — carbonaceous [CI (Ivuna type), CR (Renazzo type), CM (Mighei type), CO (Ornans type), CV (Vigarano type), CK (Karoonda type), CB (Bencubbin type), and CH (metal-rich)], ordinary (H, L, LL) + Rumuruti type (R), and enstatite (EH, EL) — are currently recognized (Krot et al., 2014a). Chondrites that cannot be classified into the existing groups are called ungrouped [e.g., Tagish Lake (Brown et al., 2000)]. It is assumed that each chondrite group originated on a separate parent body. However, it has recently been suggested that CV and CK chondrites may have formed on the same parent body (Greenwood et al., 2010).

Most chondrites experienced different levels of aqueous alteration and/or thermal metamorphism on their parent bodies. To provide a guide to the degree of thermal and aqueous alteration experienced by chondrites, they are divided into petrologic types from 1 to 6. The sequence type 3 to type 6 represents an increasing degree of chemical equilibrium and textural recrystallization due to thermal metamorphism. Type 3 chondrites, commonly called unequilibrated, are widely considered the least modified by thermal metamorphism and aqueous alteration. The type 3 ordinary, CO, and CV chondrites are subdivided into 10 subtypes (3.0–3.9), of which 3.0 is the least metamorphosed (e.g., Grossman and Brearley, 2005). Type 2 represents a higher degree of aqueous alteration compared with type 3. The CM and CR chondrites have been subdivided into 10 subtypes (2.9–2.0), of which 2.0 is the most aqueously altered (Rubin et al., 2007; Harju et al., 2014). In this classification scheme, type 1 is reserved for CI chondrites that consist almost entirely of aqueously formed minerals and probably never contained abundant chondrules. We note that this classification scheme of aqueously altered chondrites is not universally accepted (e.g., Alexander et al., 2013; Beck et al., 2014), and completely aqueously altered CM and CR chondrites are often referred to as CM1 and CR1, respectively.

Based on thermodynamic modeling (e.g., Zolensky et al., 1989; Zolotov and Mironenko, 2008; Zolotov, 2012) and oxygen-isotopic compositions of aqueously formed minerals (e.g., Leshin et al., 1997; Clayton and Mayeda, 1999; Benedix et al., 2003; Guo and Eiler, 2007; Schrader et al., 2011), it is inferred that the CI, CM, and CR chondrites experienced low-temperature aqueous alteration (<150°C) under variable, but relatively high, water/rock (W/R) mass ratios (0.1–0.6 or even higher). The CV, CO, and ordinary chondrites of petrologic type 3 appear to have experienced aqueous alteration at higher temperatures (100°–300°C) and lower W/R mass ratios (<0.2) than the CI, CM, and CR chondrites (e.g., Zolotov et al., 2006; Doyle et al., 2015).

#### 3.2. Chondrule Ages, Ages of Aqueous Alteration, and Chondrite Accretion Ages

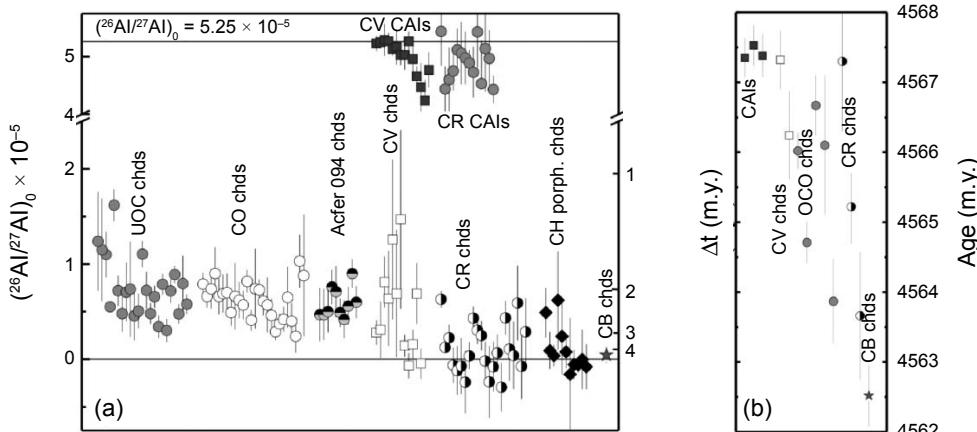

In exploring the hydrothermal history of primitive planetesimals, we must first place a constraint on the timing of their accretion because it largely defines the abundance of  $^{26}\text{Al}$  that is generally accepted to be the major internal heating source of planetesimals. Planetesimals that accreted “early” in solar system history would have incorporated enough  $^{26}\text{Al}$  to drive melting and differentiation; bodies that accreted “late” close to the snow line (the distance from the Sun where water ice was stable) could have retained unmelted ices. Most chondrites appear to have been derived from objects somewhere between these extremes — incorporating sufficient  $^{26}\text{Al}$  to drive melting of ice, aqueous alteration, and low-level thermal metamorphism, but not enough to cause silicate melting and differentiation (Tables 1 and 2). However, some recent models have questioned this simple interpretation, postulating early accretion of an object that experienced differentiation at <1.5 m.y. after the beginning of the solar system formation into a convecting magma ocean and Fe,Ni-metal core (notably with a core dynamo), followed by continual accretion of primitive material onto this object, building an undifferentiated crust (Elkins-Tanton et al., 2011; Cournède et al., 2014). Meteorite chronology data may potentially allow us to test and develop some of these ideas.

Most chondrite groups consist of three major components: chondrules, refractory inclusions [CAIs and amoeboid olivine aggregates (AOAs)], and fine-grained matrices. The only exceptions are CI chondrites, which consist almost entirely of hydrated matrix and are virtually devoid of chondrules and refractory inclusions. Since chondrites could not have accreted prior to the formation of chondrules they enclose, the  $^{207}\text{Pb}$ - $^{206}\text{Pb}$  absolute ages and  $^{26}\text{Al}$ - $^{26}\text{Mg}$  relative ages of chondrules define an upper limit on the host chondrite accretion time. Note, however, that because (1) chondrule ages could be easily disturbed or even reset during even mild thermal metamorphism (e.g., Kita and Ushikubo, 2012) and (2) some chondrules may have formed by collisions between chondritic planetesimals (e.g., Krot et al., 2005; Johnson et al., 2014), some caution must be exercised when using the youngest chondrule age to constrain the host chondrite accretion age.

It is generally accepted that aqueous alteration of chondritic meteorites occurred exclusively on their parent bodies that accreted water ices together with anhydrous minerals and subsequently experienced aqueous alteration, which resulted in formation of diverse secondary minerals including phyllosilicates, carbonates, magnetite, and fayalite. As a result, dating of aqueously formed minerals provides an upper limit of the accretion ages of chondrite parent bodies. The chapter by Krot et al. in this volume summarizes recently published  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages ( $^{53}\text{Mn}$  decays to  $^{53}\text{Cr}$  with a half-life of 3.7 m.y.) of carbonates and fayalite in several groups of carbonaceous (CI, CM, CR, CO, CV) and ordinary (L, LL) chondrites (see their Fig. 9). The  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  chronology of carbonates and fayalite indicates that aqueous activity on the carbonaceous chondrite parent bodies started almost contemporaneously, ~3.5–5 m.y. after CV CAIs, consistent with  $^{26}\text{Al}$  being the major heat source of these bodies. The  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of aqueous alteration,  $^{26}\text{Al}$ - $^{26}\text{Mg}$  ages of chondrule formation, and peak metamorphic temperatures reached by the carbonaceous chondrite parent bodies suggest that they accreted ~2.5–4 m.y. after CV CAIs; the accretion of ordinary chondrites appears to have predated accretion of CCs by ~0.5 m.y. Below we summarize the recently published chondrule ages of the least-metamorphosed ordinary and CCs.

Variations in  $^{238}\text{U}/^{235}\text{U}$  ratio have been recently reported in CV CAIs (Brennecka et al., 2010). The U-corrected  $^{207}\text{Pb}$ - $^{206}\text{Pb}$  ages for CV CAIs are  $4567.18 \pm 0.50$  m.y. (Amelin et al., 2010) and  $4567.30 \pm 0.16$  m.y. (Connelly et al., 2012). Because of the observed variations of  $^{238}\text{U}/^{235}\text{U}$  ratio in CAIs (Brennecka et al., 2010), the  $^{207}\text{Pb}$ - $^{206}\text{Pb}$  absolute

age dating of individual chondrules requires measurements of their  $^{238}\text{U}/^{235}\text{U}$  ratios, which may be also variable. Due to generally small chondrule size (<1 mm), the U-isotope measurements of individual chondrules are technically a very challenging task, and as a result, the U-corrected  $^{207}\text{Pb}$ - $^{206}\text{Pb}$  absolute ages of chondrules are very limited and so far have been reported only for ~10 individual chondrules from the CV3.6 carbonaceous chondrite Allende, the CR2 carbonaceous chondrite Northwest Africa (NWA) 6043, the L3.1 ordinary chondrite NWA 5697 (Connelly et al., 2012; Bollard et al., 2014), and the CB carbonaceous chondrite Gujba (Bollard et al., 2013) (Fig. 1). Note that Connelly et al. (2012) observed no variations in  $^{238}\text{U}/^{235}\text{U}$  ratios in bulk chondrites, achondrites, and individual chondrules. These authors concluded that  $^{238}\text{U}/^{235}\text{U}$  ratio is uniform in the solar system, except in the region(s) where CAIs formed, and suggested using the measured value  $137.786 \pm 0.013$  as the representative solar system value. If confirmed, measurements of  $^{238}\text{U}/^{235}\text{U}$  ratio in chondrules will not be required. Analysis of two individual Allende chondrules found ages of  $4567.32 \pm 0.42$  Ma and  $4566.24 \pm 0.63$  Ma (Connelly et al., 2012). Bollard et al. (2014) reported ages of  $4567.3 \pm 1.0$  Ma,  $4565.22 \pm 0.53$  Ma, and  $4563.66 \pm 0.91$  Ma in the CR2 chondrite NWA 6043. Four chondrules from the L3.1 chondrite NWA 5697 have ages of  $4566.67 \pm 0.43$  Ma and  $4564.71 \pm 0.30$  Ma (Connelly et al., 2012), and  $4566.1 \pm 1.0$  Ma and  $4563.87 \pm 0.60$  Ma (Bollard et al., 2014). Three Gujba chondrules dated have ages ranging from  $4562.61 \pm 0.28$  to  $4562.32 \pm 0.48$  Ma, with a weighted average of  $4562.52 \pm 0.44$  Ma (Bollard et al., 2013).

**Fig. 1.** (a) Inferred initial  $^{26}\text{Al}/^{27}\text{Al}$  ratios and relative ages of CAIs from CV and CR carbonaceous chondrites and porphyritic chondrules from unequilibrated ordinary (UOC), CO, Acfer 094 (ungrouped), CR, CH, and CV chondrites. Data from Hutcheon and Hutchison (1989), Kita et al. (2000), Mostefaoui et al. (2002), Kunihiro et al. (2004), Kurahashi et al. (2008), Makide et al. (2009), Villeneuve et al. (2009), Hutcheon et al. (2009), Kita and Ushikubo (2012), Ushikubo et al. (2013), Nagashima et al. (2014), Schrader et al. (2014), and Krot et al. (2014a). The inferred initial  $^{26}\text{Al}/^{27}\text{Al}$  ratio in CV CAIs is from Jacobsen et al. (2008). (b) Absolute U-corrected  $^{207}\text{Pb}$ - $^{206}\text{Pb}$  ages of individual CAIs and chondrules. Data from Amelin et al. (2010), Connelly et al. (2012), and Bollard et al. (2013, 2014).

It appears that after an epoch of CAI formation characterized by heterogeneous distribution of  $^{26}\text{Al}$  (Krot *et al.*, 2012),  $^{26}\text{Al}$  was relatively uniformly distributed in the inner part of the protoplanetary disk at the level of  $^{26}\text{Al}/^{27}\text{Al} \sim 5 \times 10^{-5}$ , called the “canonical” value (Jacobsen *et al.*, 2008; Kruijer *et al.*, 2014); for an alternative view see Larsen *et al.* (2011) and Bizzarro *et al.* (2014). The canonical ratio was defined on the basis of high-precision Al-Mg isotope measurements of CAIs from CV chondrites (Jacobsen *et al.*, 2008; Larsen *et al.*, 2011; MacPherson *et al.*, 2011), and the  $^{26}\text{Al}$ - $^{26}\text{Mg}$  ages of chondrules are calculated relative to the CV CAIs having the canonical  $^{26}\text{Al}/^{27}\text{Al}$  ratio. Relative  $^{26}\text{Al}/^{27}\text{Al}$  ages of chondrules have been measured in several weakly metamorphosed chondrites: Semarkona (LL3.0), Yamato 81020 (CO3.0), Acfer 094 (C3.0 ungrouped), CR2, CH3, and CV3.2–3.6 chondrites (Mostefaoui *et al.*, 2002; Kunihiro *et al.*, 2004; Kurahashi *et al.*, 2008; Hutcheon *et al.*, 2009; Kita *et al.*, 2013; Ushikubo *et al.*, 2013; Nagashima *et al.*, 2014; Schrader *et al.*, 2014; Krot *et al.*, 2014b). The results of these measurements are summarized in Fig. 1. Note that the  $^{26}\text{Al}$ - $^{26}\text{Mg}$  system in chondrules from CV3.2–3.6 chondrites may be disturbed by thermal metamorphism experienced by the CV chondrite parent body (LaTourrette and Wasserburg, 1998; Bonal *et al.*, 2006). The mean values (and one standard deviation) of  $(^{26}\text{Al}/^{27}\text{Al})_0$  in chondrules from Semarkona, CO, and Acfer 094 chondrites are  $(0.78 \pm 0.3) \times 10^{-5}$ ,  $(0.62 \pm 0.19) \times 10^{-5}$ , and  $(0.57 \pm 0.15) \times 10^{-5}$ , respectively, which correspond to  $1.9 \pm 0.4$ ,  $2.2 \pm 0.3$ , and  $2.3 \pm 0.3$  m.y. after CV CAIs. We note that these age uncertainties cannot be considered as estimates for the duration of chondrule formation recorded by these chondrite groups, because they all contain multiple generations (contemporaneously formed objects) of chondrules, as indicated by a wide range of U-Pb ages of chondrules within a chondrite group (Connelly *et al.*, 2012; Bolland *et al.*, 2014). Instead, they may provide upper limits on the formation of the dominant generation of chondrules within a chondrite group, and possibly the average abundance of  $^{26}\text{Al}$  in their host parent body (if the body accreted rapidly after formation of the dominant generation of chondrules).

Relative  $^{26}\text{Al}/^{27}\text{Al}$  chondrule ages broadly agree with their  $^{207}\text{Pb}$ - $^{206}\text{Pb}$  absolute ages, indicating that ordinary and carbonaceous chondrite chondrules were still forming at 3.5–5 m.y. after CV CAIs. These data show that there is no age gap between CAI formation and chondrule formation (Connelly *et al.*, 2012; Bolland *et al.*, 2014). It appears that accretion of ordinary, CO, CR, and CV carbonaceous chondrites was not finished at least 3.5 m.y. after CV CAIs.

In constraining accretion time, the chronometry data provide a valuable guide to the effectiveness of  $^{26}\text{Al}$  as a heat source [assuming that  $^{26}\text{Al}$  was uniformly distributed in the protoplanetary disk with an initial  $^{26}\text{Al}/^{27}\text{Al}$  ratio of  $\sim 5.2 \times 10^{-5}$  as observed in many CAIs (e.g., Jacobsen *et al.*, 2008)]. Taken together, they also allow us to discriminate between models of primordial planetesimals. The observation that chondrules in an individual meteorite formed throughout the lifetime of the protoplanetary disk (e.g., Connelly *et*

*al.*, 2012) does not appear to be consistent with first-order predictions of a model that posits continual accretion of primordial material onto an early formed differentiated object (e.g., Johansen *et al.*, 2014). Instead, the fact that the majority of chondrules in a primitive chondrite [e.g., Semarkona (LL3.0), Acfer 094 (ungrouped carbonaceous 3.0), Yamato 81020 (CO3.0), and CRs] have a relatively narrow range of initial  $^{26}\text{Al}/^{27}\text{Al}$  ratios (Fig. 1a) implies that most chondrules in the chondrite formed during the narrow time period, rapidly accreted after formation into the host meteorite parent body, and defined an average abundance of  $^{26}\text{Al}$  in this body.

### 3.3. Alteration Modeling

Numerous studies have modeled asteroidal aqueous alteration and thermal metamorphism (Grimm and McSween, 1989; Cohen and Coker, 2000; Coker and Cohen, 2001; Young *et al.*, 1999; McSween *et al.*, 2002; Young *et al.*, 2003; Travis and Schubert, 2005). In each case, large-scale fluid flow was predicted, frequently over tens of kilometers. But whether flow took place as a single-pass “exhalation” (Young *et al.*, 1999), or in convecting cells (e.g., Grimm and McSween, 1989; Travis and Schubert, 2005), the movement of liquid water through rock is expected to have fractionated soluble elements. However, CI chondrites (the most aqueously altered chondrite group) have approximately solar element abundances: Of 56 rock-forming elements analyzed in CI chondrites, 41 have abundances within 15% of the solar photosphere (Palme *et al.*, 2014). Recent estimates of solar chemical composition not only confirm the excellent agreement between photospheric and CI chondrite abundances (Grevesse *et al.*, 2007; Palme *et al.*, 2014), they also show no evidence for fractionation of soluble elements: For example, there is no difference, within error, between photosphere and meteorite compositions in the subset of elements that are considered more soluble (~25% of the total) and the larger dataset. Because fractionation of the soluble elements has not occurred, aqueous alteration (by definition) must have been isochemical. Other chondrite groups show monotonic depletions from solar composition in volatile and moderately volatile elements (e.g., Krot *et al.*, 2014b, and references therein); elements with very different chemical affinity, related only by similarity in equilibrium condensation temperature. It should also be noted that there are no differences in bulk chemical compositions of meteorites aqueously altered to various degrees within a chondrite group (e.g., CM1, CM2.0–2.6 or CR1, CR2.0–3.0). The difficulty in establishing these depletions by any geological process has prompted generations of cosmochemists to interpret volatile depletion in chondrites as a nebular process. However, as a counterpoint, Young *et al.* (2003) (also personal communication) have suggested that solubility essentially mimics volatility (as defined by condensation temperature). In this formulation, differences in bulk chemistry between the chondrite groups are a result of aqueous alteration. If this were the case, the observation that CCs show solar abundances or monotonic depletions

from solar, rather than being evidence *against* fluid flow, may in fact be evidence *for* fluid flow. There are a number of arguments that can be made against this. For instance, one of the most soluble elements that is demonstrably highly mobile during aqueous alteration is Ca (carbonates, hedenbergite, andradite, kirschsteinite). Calcium is highly refractory. Large fractionation of Ca from Al, which has a similar condensation temperature, is one of the key arguments in favor of low-temperature aqueous alteration resulting in formation of Al-free Ca-rich secondary phases. The same is true for Mn and Cr. This is the basis for  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  dating of aqueously formed carbonates, fayalite, and kirschsteinite. In addition, elements with very different volatility are highly mobile during aqueous alteration (e.g., Sr and Zn).

Although it is the consensus view that isochemical alteration requires the flow of liquid water to be minimal (*Brearley*, 2003), i.e., a closed system over length scales greater than hundreds of micrometers, this conclusion is not inconsistent with the presence of short (less than hundreds of micrometers) veins in some aqueously altered meteorites, or diffusion over similar distances. Closed system  $\neq$  zero flow. Rather, it means that over the timescale that aqueous alteration is occurring, flow was restricted to relatively short length scales. The presence of these features indicates that redistribution of elements occurred largely between chemically distinct chondrite components — refractory inclusions, chondrules, and matrices (e.g., *Brearley and Krot*, 2012). Finally, chemical analyses of small (10–100 mg) bulk chondrite aliquots support this conclusion, showing remarkable reproducibility between samples and no evidence for element mobility (*Wulf et al.*, 1995). Similarly, analyses of the trace-element composition of fine-grained materials in CCs indicate minimal aqueous mobility (*Bland et al.*, 2005). Although sulfate veins in CIs were initially thought to be a result of extensive fluid flow, there is now ample evidence that remobilization of sulfates occurred in the terrestrial environment (*Gounelle and Zolensky*, 2001). The fact that no chondrite contains large veins, or an interconnected vein network with diffusion/alteration gradients away from veins (as observed in terrestrial hydrothermal systems), can be taken as petrographic evidence against large-scale flow through a vein/fracture network.

Oxygen-isotopic data from CCs have been interpreted as consistent with both a closed-system two-reservoir model (*Clayton and Mayeda*, 1999) and an open-system model (*Young et al.*, 1999). In the former, water/rock is fixed and CC parent bodies are compositionally and mineralogically distinct; in the latter, down-temperature flow produces zones that resemble CV, CM, and CI meteorites. In particular, carbonate grains in a number of CMs exhibit a large range in  $\delta^{18}\text{O}$ , interpreted as suggesting open-system water-rock interaction [varying water/rock ratio with varying temperature (*Young et al.*, 1999)]. Earlier CM calcite oxygen-isotope data have been interpreted as consistent with both closed-system, two-reservoir models (but with a larger matrix-water fractionation factor), and also with fluid-flow in a restricted region of a CC parent body (*Benedix et al.*, 2003). More recent

carbonate oxygen data have been interpreted as requiring water/rock reactions involving flowing water as a result of a temperature gradient. But it should be noted that achieving this oxygen-isotope heterogeneity at the thin-section scale would require a dense network of channels — a feature that is not observed petrographically. With regard to different interpretations of oxygen-isotope data (*Clayton and Mayeda*, 1999; *Young et al.*, 1999; *Benedix et al.*, 2003), given that the arguments center around fixed vs. varying water/rock ratios, it would be interesting to explore the possibility that material properties might have changed during alteration [e.g., by compaction of highly porous primordial materials by impact (*Bland et al.*, 2014), porosity change related to growth of alteration minerals, or flow of the matrix itself as an unconsolidated mud (*Bland et al.*, 2013)].

The numerical modeling results appear to contradict much of the meteorite data — all the modeling studies (*Grimm and McSween*, 1989; *Cohen and Coker*, 2000; *Coker and Cohen*, 2001; *Young et al.*, 1999, 2003; *McSween et al.*, 2002; *Travis and Schubert*, 2005) suggest that alteration occurred in an open system with asteroid-scale fluid flow, whereas meteorite chemistry and petrography suggest that alteration was isochemical, with minimal flow (the debate continues regarding oxygen). Fundamental to fluid flow is rock permeability. Initial permeability estimates of  $10^{-13}$ – $10^{-11}$  m<sup>2</sup> for chondritic asteroids (*Grimm and McSween*, 1989) were based on what were felt to be appropriate terrestrial analog materials: a consolidated tuff from the Waiora formation in New Zealand with 39% porosity and grain size of 50–100  $\mu\text{m}$ ; and an unconsolidated lunar soil with 50% porosity and 60–100- $\mu\text{m}$  grain size (*Mercer et al.*, 1975; *Lambe and Whitman*, 1969; *Costes and Mitchell*, 1970). The permeability values used by *Grimm and McSween* (1989) were adopted in all subsequent studies (*Cohen and Coker*, 2000; *Coker and Cohen*, 2001; *Young et al.*, 1999, 2003; *McSween et al.*, 2002; *Travis and Schubert*, 2005). But are these terrestrial and lunar analogs appropriate for CC precursors? *Bland et al.* (2009) explored this question in some detail. Matrix grain size in CCs that have experienced minimal alteration is ~100 nm (*Greshake*, 1997; *Nuth et al.*, 2005), far smaller than in the analog materials. The petroleum industry is understandably interested in constraining flow in porous media. The familiar Blake-Kozeny-Carman equation (*Dullien*, 1992) is used throughout the industry to predict permeability based on grain sizes and porosities in the range of interest for us (given reasonable estimates of the hydraulic tortuosity coefficient). The value of the Blake-Kozeny-Carman equation is illustrated by the fact that predicted values for the Waiora tuff and lunar soil are identical to measured values. For grain sizes appropriate for primitive CC matrices (tens to hundreds of nanometers), the Blake-Kozeny-Carman equation yields values ranging from  $10^{-17}$ – $10^{-19}$  m<sup>2</sup>, even in a high-porosity matrix (~40%). Matrix grain size dictates mean pore-throat diameter, and therefore is a key control on permeability (which scales with the inverse of grain size squared). But independent measurements of mean pore size have also been made (*Bland et al.*, 2009). Nuclear magnetic resonance cryoporometry shows

a pore-volume distribution for Acfer 094 at extremely low pore diameters. From 200 nm down to the smallest pore diameter currently measurable by this technique in these meteorites ( $\sim 20$  nm), the pore volume distribution averages  $3 \pm 1 \text{ } \mu\text{l nm}^{-1} \text{ g}^{-1}$ , with no sign of a drop-off at low pore diameters. Estimating the mean pore size is difficult, as the smallest pores in Acfer 094 are below the resolution of these measurements. However, a geometric mean pore size in the range 10–100 nm is reasonable based on the available data. Although permeability measurements on meteorites that have experienced geological processing must be treated with some care, these estimates are in line with permeability measurements on chondritic meteorites. Corrigan *et al.* (1997) significantly expanded the gas permeability dataset for chondrites. The average permeability for all the meteorites analyzed was  $8.3 \times 10^{-17} \text{ m}^2$ . CM chondrites — included in this average — proved to be an analytical challenge due to the presence of cracks caused by desiccation while on Earth (Corrigan *et al.*, 1997, and personal communication), occasionally resulting in relatively high permeabilities. For the most mineralogically primitive meteorites in their suite (samples of Vigarano, Efremovka, Leoville — all reduced CV3s), Corrigan *et al.* (1997) found an average permeability of  $2.5 \times 10^{-18} \text{ m}^2$ . To summarize, if this suite of permeability data had been available at the time, it is likely that Grimm and McSween (1989) would have made use of it in their seminal paper, rather than data from coarse-grained analog materials. As noted above, all subsequent numerical modeling studies incorporated Grimm and McSween (1989) permeabilities as inputs. Given much smaller permeability “default” values, we can expect that those studies would have predicted much lower flow in chondritic asteroids as a model output. Although debate continues with respect to the interpretation of chondrite oxygen-isotope data (particularly varying carbonate compositions), an amended “default” permeability value would appear to reconcile the numerical modeling with meteorite compositional data showing isochemical alteration, and petrographic observations suggesting restricted flow. It should be noted that higher permeabilities have been proposed for early accreting chondrite parent bodies resulting from large fracture networks (Fu *et al.*, 2015). Certainly, fracture networks could result in arbitrarily high permeabilities, allowing for asteroid-scale flow. However, as noted previously, alteration in chondrites does not appear to have been controlled by fluid-filled fractures: The petrography of primitive meteorites is not defined by altered zones around fractures; rather, the entire sample (on the scale of thin sections to a large mass such as Murchison) is homogeneously altered.

Various physical consequences of aqueous alteration are predictable. Melting of ice to liquid water involves a volume decrease providing space, in addition to any initial void space, for water vapor and for the gases such as H<sub>2</sub> and CO<sub>2</sub> produced in the alteration reactions (Grimm and McSween, 1989; Browning and Bourcier, 1996; Wilson *et al.*, 1999). However, the alteration process results in an increase in the volume of silicates largely compensating for this (Grimm

and McSween, 1989). Thermal models show that, depending on the nature of pathways for gas to escape to the surface, gas production rates are high enough for significant pressures to build up in asteroid interiors (Wilson *et al.*, 1999). These can exert extensional stress on the primitive crust to the point where the likely tensile strength of a few megapascals could be exceeded on asteroids with radii greater than several tens of kilometers, leading to normal faulting of the crust. Gas escape through fractures could elutriate fine-grained material from asteroid interiors. Wilson *et al.* (1999) suggested that it was possible, in extreme cases, for asteroids with radii between  $\sim 20$  and  $\sim 40$  km to be explosively disrupted by the gas escape, especially if they had unusually well-ice-cemented crusts. In many cases the resulting fragments would reaccrete into heterogeneous mixtures of variably altered components of the original body. Although debate continues regarding the degree to which chondrites were closed systems with respect to aqueous fluids, it is extremely unlikely that they were closed systems with respect to gases.

#### 4. ASTEROIDS THAT EXPERIENCED CORE FORMATION

The first non-aqueous melt to be produced during the heating of any asteroid with at least approximately chondritic bulk chemistry is an Fe,Ni-FeS cotectic liquid forming at  $\sim 1250$  K (e.g., Kubaschewski, 1982; Keil and Wilson, 1993; Benedix *et al.*, 1998). There is still conflicting evidence as to the control of the contact angle between liquid and solid silicate grains on the critical amount of this liquid that must form to allow core formation by percolation along grain boundaries in silicate bodies of asteroidal composition and size. The dihedral angle is a function of both total pressure and oxygen partial pressure: High values reduce the likelihood of percolation without silicate melting. Terasaki *et al.* (2008) inferred that pressures in the interiors of asteroids smaller than  $\sim 2500$  km in diameter were low enough that Fe,Ni-FeS liquid could segregate without silicate melting, but many other studies suggest that several percent (Yoshino *et al.*, 2003, 2004; Roberts *et al.*, 2007; Mann *et al.*, 2008) or even more than 10% (Terasaki *et al.*, 2005; Walte *et al.*, 2007; Bagdassarov *et al.*, 2009; Holzheid, 2013) silicate melting is needed. Matrix deformation may aid interconnection of melt pockets in a partially molten system (Bruhn *et al.*, 2000; Walter, 2000; Rushmer *et al.*, 2000). Rushmer *et al.* (2005) suggested that impacts onto the surfaces of asteroids may have generated transient stress perturbations inducing dilation and local pressure gradients (Petford and Koenders, 2003), driving interconnection of melt pockets, although Walte *et al.* (2011) doubt the efficiency of this process. Direct evidence of some Fe,Ni-FeS liquid migration with limited silicate melting is found in two meteorites, Graves Nunataks (GRA) 95209 and Elephant Moraine (EET) 84302, intermediate in properties between acapulcoites and lodranites (McCoy *et al.*, 2006b).

The total melt fraction in a partially molten system controls the permeability of the remaining solid silicate matrix allowing Darcy flow, but Šrámek *et al.* (2012) point out that

this is not the only factor limiting core formation. Segregation of any liquid requires viscous deformation and compaction of the residual matrix, limited by its bulk viscosity. An order of magnitude estimate of the timescale for core formation can be obtained (Šrámek *et al.*, 2012) by balancing the gravitational deviatoric stress  $\Delta\text{pgd}$  against the viscous resistance of the matrix,  $\eta(v/d) = \eta/\tau$ , where  $\Delta p = \sim 5000 \text{ kg m}^{-3}$  is the density difference between Fe,Ni-FeS and silicate solid,  $g$  is the acceleration due to gravity,  $d$  is the length scale at which the process must occur,  $\eta = \sim 10^{18} \text{ Pa s}$  is a plausible matrix viscosity,  $v$  is the typical deformation velocity, and  $\tau$  is the timescale. For a laboratory experiment  $d$  is  $\sim 10 \text{ mm}$  and  $g = \sim 10 \text{ m s}^{-2}$  so  $\tau = \eta/(\Delta\text{pgd})$  is on the order of 100 m.y., ensuring that no separation is seen. For differentiating asteroids,  $d$  ranges from  $\sim 30 \text{ km}$  (the smallest bodies undergoing significant heating) to  $\sim 100 \text{ km}$  [the mantle of (4) Vesta] and the corresponding values of  $g$  at mid-mantle depths range from  $\sim 0.01$  to  $\sim 0.1 \text{ m s}^{-2}$ . Thus  $\tau$  takes the values  $\sim 20,000$  and  $\sim 600 \text{ yr}$ , respectively. Even the longest of these timescales is much less than the half-life of  $^{26}\text{Al}$ , implying that mantle matrix deformation and Darcy flow in asteroids could allow core formation even though liquid separation is not seen in laboratory experiments.

The above arguments assume that only solids and liquids are present during core formation. However, Keil and Wilson (1993) suggested that any volatiles present at this stage in an asteroid's evolution could have been trapped as gas bubbles in the Fe,Ni-FeS liquid, greatly changing the density contrast between liquid and solid, and possibly even driving the first-forming cotectic liquids upward rather than downward, to be lost to space in explosive activity at the surface. This mechanism could explain the apparent S-depletion of IVA- and IVB-group iron meteorites.

## 5. ASTEROIDS THAT EXPERIENCED SILICATE MELTING

### 5.1. Evidence for Silicate Melting

Numerous types of meteorites are samples of asteroid mantle rocks from which partial silicate melts formed and were removed. Table 2 shows that the maximum degree of partial silicate melting that is inferred to have occurred in the interiors of these differentiated asteroids varies widely, from only a few percent to at least 50% and possibly  $\sim 100\%$ . In some cases, the melts were emplaced on and intruded beneath the surface to form a basaltic crust. This is true of (4) Vesta (McSween *et al.*, 2013) and also of (1459) Magnya (Lazzaro *et al.*, 2000), (1904) Massevitch (DeMeo *et al.*, 2009), and possibly several other small bodies (Moscovitz *et al.*, 2008). In the other cases, the corresponding basalts are not found as discrete meteorites or, except very rarely (Keil *et al.*, 2011), as clasts within breccias, implying that the melts migrated to the surface and, especially for small asteroids, were lost into space as small pyroclasts ejected at greater than escape velocity in explosive volcanic eruptions (Wilson and Keil, 1991).

### 5.2. Modeling Approaches

Various models of the physics and chemistry of silicate melt formation and migration in asteroids have been proposed. Some papers focus on the geochemistry of the processes involved and the consequences for the petrology of meteorites, especially the howardite-eucrite-diogenite (HED) meteorites from (4) Vesta (Righter and Drake, 1997; Nyquist *et al.*, 2003; Weichert *et al.*, 2004; Greenwood *et al.*, 2005; Yamaguchi *et al.*, 2011; Mandler and Elkins-Tanton, 2013; Barrat and Yamaguchi, 2014). Papers focusing on the physics alone include those of Ghosh and McSween (1998), Hevey and Sanders (2006), Sahijpal *et al.* (2007), Goodrich *et al.* (2007), Wilson *et al.* (2008), Gupta and Sahijpal (2010), Moscovitz and Gaidos (2011), Elkins-Tanton *et al.* (2011), Neumann *et al.* (2012), Wilson and Keil (2012), Formisano *et al.* (2013), and Neumann *et al.* (2014). None of these treatments attempts to model all the physical processes taking place. Thus Ghosh and McSween (1998), Sahijpal *et al.* (2007), and Gupta and Sahijpal (2010) segregate a core downward and silicate melt upward when specific temperature or melt fractions are reached without specifying a detailed process. Hevey and Sanders (2006) ignore core formation and transfer heat by conduction until 50% mantle melting occurs, after which heat moves by convection beneath the cool boundary layer. Elkins-Tanton *et al.* (2011) form a core after 10% mantle melting and then postulate heat transfer by convection until late-stage cooling intervenes. Moscovitz and Gaidos (2011), Neumann *et al.* (2012), Formisano *et al.* (2013), and Neumann *et al.* (2014) all move melt by percolation through the unmelted matrix; Neumann *et al.* (2014) also add convection after 50% melting. Finally, Goodrich *et al.* (2007), Wilson *et al.* (2008), and Wilson and Keil (2012) do not treat core formation but assert that the formation of vein and dike networks, on length scales much greater than the sizes of the mantle mineral grains, very greatly increases the efficiency of silicate melt transfer to shallow levels. As a result the mantle melt fraction never exceeds a few percent in these models, and conditions never favor convection.

### 5.3. Magma Oceans

The understanding that, if no other mechanism intervened, percolation along grain boundaries was a slow process in asteroids gave rise to the assumption that melt would be largely retained in mantles until the volume fraction was sufficiently great,  $\sim 40\text{--}50\%$ , for convection to begin. This logically gave rise to the concept of asteroid magma oceans (Righter and Drake, 1997; Greenwood *et al.*, 2005, 2014; Gupta and Sahijpal, 2010; Schiller *et al.*, 2010b; Elkins-Tanton *et al.*, 2011; Yamaguchi *et al.*, 2011; Mandler and Elkins-Tanton, 2013). This use of the term differs from its use in respect to the Moon (and other large planetary bodies), where only the outer layers became molten as a result of the extremely rapid accretion of the body while the inner parts initially remained solid, eventually warming to the point

where partial melting began long after the magma ocean had cooled. In the case of asteroids, the accretion process itself did not result in extreme heating (*Merk et al.*, 2002; *Šrámek et al.*, 2012), but subsequent accumulation of heat from the decay of  $^{26}\text{Al}$  in asteroids that accreted sufficiently soon after CAIs caused all their interiors beneath the conductively controlled outer ~10-km boundary layer to reach temperatures potentially well in excess of the silicate solidus. This implies that extensive melting should have taken place and there is much geochemical (*Greenwood et al.*, 2005, 2014; *Schiller et al.*, 2010b) and petrological (*Yamaguchi et al.*, 2011; *Mandler and Elkins-Tanton*, 2013) evidence for this. However, it does not follow that extensive degrees of melting led to the entire mantles of asteroids becoming largely molten magma oceans. This is because, as argued by *Goodrich et al.* (2007), *Wilson et al.* (2008), and *Wilson and Keil* (2012), and supported by measurements on acapulcoite and lodranite meteorites (*McCoy et al.*, 1997), silicate melts may be able to migrate readily from asteroid interiors after small (~5%) degrees of silicate partial melting have established complex interconnected melt pathways within the mantle, and either erupt at the surface or accumulate in shallow intrusions at the base of, or within, the lithosphere. These shallow accumulations of melt may be very extensive and could themselves qualify as magma oceans.

#### 5.4. Physical Considerations

Melt migration requires a driving force. Local forces, such as the pressurization of a liquid film formed at the contact between two mineral grains when the liquid has a lower density than the material from which it forms, and therefore occupies a larger volume, can drive melt movement in any direction and encourage linking of liquid films along grain boundaries (*Muenow et al.*, 1992). *Sleep* (1988) showed how differential stresses can cause melt to migrate from smaller veins into larger ones, expanding small numbers of large veins at the expense of large numbers of small ones. However, large-scale upward silicate melt separation from a partially molten mantle can only realistically be driven by buoyancy. This can be due to the melt having a lower density than the residual unmelted matrix or due to the melt containing gas bubbles, or both. The upward melt segregation by percolation along grain boundaries (*Maaloe and Schie*, 1982; *Kelemen et al.*, 1997) requires deformation of the unmelted matrix (*McKenzie*, 1984, 1985; *Richter and McKenzie*, 1984; *Scott and Stevenson*, 1984, 1986; *Ribe*, 1985; *Spiegelman and McKenzie*, 1987) and melt networks may develop on scales larger than the mineral grain size (*Maaloe*, 2003; *Spence et al.*, 1987; *Sleep*, 1988; *Hart*, 1993). Partial melt zones in Earth's mantle develop networks of veins and dikes on millimeter to meter scales (*Nicolas and Jackson*, 1982; *Sleep*, 1984, 1988; *Fowler*, 1985; *Nicolas*, 1986; *Petford and Koenders*, 1998; *Bons and van Milligen*, 2001; *Brown*, 2004), allowing very efficient transfer of melt (*Valentini et al.*, 2007).

*Wilson et al.* (2008) used the above concepts to derive a mathematical model of melt extraction from asteroid interi-

ors. They applied the model to the ureilite parent body and found that melt transfer times from deep interior to shallow depth could be as small as a few months, with only ~2% of the asteroid interior being occupied by melt at any one time. This rapid transit time is consistent with geochemical evidence (*Goodrich et al.*, 2007) that negligible chemical interactions had taken place between ascending melts and unmelted host rocks. Care is needed in generalizing this result because it was derived for the ureilite parent body, which was inferred by *Goodrich et al.* (2007) to have been ~100 km in radius and to have produced melts containing copious CO gas generated by smelting, the reaction between graphite and various metal oxides. However, *Wilson and Goodrich* (2012) revisited the model assuming that no gas was present to enhance the buoyancy of the melts and found that transfer timescales were still only on the order of one year provided that volatile-free melts were ~10% less dense than their host rocks. Furthermore, the transit time is inversely proportional to the asteroid radius, so even the smallest (~30 km radius) differentiated asteroids should have required no more than three years to transfer melts from the interior to shallow levels.

The issue of melt buoyancy was raised by *Fu and Elkins-Tanton* (2014), who pointed out that it is not guaranteed that the silicate melts formed in asteroids will be less dense than the residual mantle. Also, they reasoned that volatile species were probably driven from the interiors of asteroids as temperatures rose toward the silicate solidus and therefore argued that it was not safe to rely on entrained gas bubbles to provide positive buoyancy. They therefore calculated the densities of volatile-free melts using experimentally determined partial melt compositions from starting materials having bulk mineralogies equivalent to those of the H, LL, CV, CM, and EH chondrite groups. They found that silicate melts from the CV and CM compositions were likely to be negatively, rather than positively, buoyant, and argued that as a result the melts would be retained in magma oceans and never erupted or intruded to shallow levels. The absence of surface volcanism would allow the retention of primitive chondritic crusts on bodies with these compositions. Table 2 attempts to link the theoretical model of *Fu and Elkins-Tanton* (2014) with the empirical implications of deductions about melt migration on various meteorite parent bodies. In some cases (ordinary chondrites, enstatite chondrites, aubrites) the result is good agreement; however, in other cases it is marginal disagreement (acapulcoite-lodranites, HEDs) to an extreme mismatch (ureilites, angrites).

Two possible reasons for the discrepancies suggest themselves. The first is that the compositions assumed for the calculations are inappropriate. For example, most differentiated asteroids may have completed their accretion before the main period of chondrule formation and, therefore, chondrule accretion (*Kleine et al.*, 2005; *Amelin and Krot*, 2007; *Rudraswami et al.*, 2008; *Kleine et al.*, 2009; *Nyquist et al.*, 2009), and so it may be unsafe to assume that each differentiated body had an initial composition identical to that of one or other of the classes of chondrite meteorites. The observed

differences in Cr- and Ti-isotopic compositions of differentiated meteorites and known groups of chondritic meteorites (Warren, 2011b) support this conclusion. The second possible reason is that the degassing of asteroids during heating is not as efficient as *Fu and Elkins-Tanton* (2014) propose. Although these authors make a good case for the complete loss of H<sub>2</sub>O and any trapped CO, the laboratory experiments of *Muenow et al.* (1992, 1995) suggest that ~400 ppm of S or Cl (or both) may be present in at least the early stages of silicate melting in chondrites. The effectiveness of small quantities of gas in reducing the density of silicate melts depends strongly on the pressure — the higher pressures in larger asteroids increase the gas density and reduce the buoyancy contribution. Using the formulae for internal pressures in asteroids given by *Wilson et al.* (2008), it is easy to find the bulk density of melts containing 400 ppm of molecular weight ~64 kg kmol<sup>-1</sup> (S<sub>2</sub> or SO<sub>2</sub>; Cl<sub>2</sub> would be similar at ~71 kg kmol<sup>-1</sup>) at the pressures corresponding to the middle and top of the mantle of asteroids of a given radius. For radii 30, 50, 100, and 200 km, the amounts by which the bulk melt density is less than the matrix density are 580, 265, 80, and 24 kg m<sup>-3</sup>, respectively, at mid-mantle depths and 660, 410, 210, and 105 kg m<sup>-3</sup>, respectively, at lithosphere-base depths. These positive buoyancy values are to be compared with the negative buoyancies of ~500 and ~200 kg m<sup>-3</sup>, respectively, calculated by *Fu and Elkins-Tanton* (2014) for CM and CV compositions. It is clear that small amounts of retained gases may overcome the buoyancy problem for small asteroids but there would still be an issue for larger bodies. However, if volatile amounts were larger, e.g., on the order of 4000 ppm as measured by *Muenow et al.* (1992, 1995), the density reductions given above would increase to 2115, 1485, 650, and 225 kg m<sup>-3</sup>, for mid-mantle depths and 2210, 1830, 1280, and 800 kg m<sup>-3</sup>, respectively, for lithosphere-base depths, almost completely eliminating all buoyancy problems.

## 5.5. Magma Transport to Shallow Levels

If, as proposed by *Wilson et al.* (2008), networks of veins and dikes develop to allow efficient transport of silicate magma out of asteroid mantles to form intrusions or feed eruptions, buoyancy is not the only parameter controlling the process. The melt production rate is also critical. This is because the final stage of the melt transport to shallow levels must be via a dike that is wide enough to allow a fast enough magma flow rate to avoid excessive cooling as the melt passes through cooler rocks in the outer thermal boundary layer of the asteroid. Furthermore, for surface eruptions, the stress regime produced by the combination of magma pressure and country rock load must be such as to allow a stable dike to exist that has a great enough vertical length to penetrate completely through the thermal boundary layer, i.e., the lithosphere. *Wilson and Keil* (2012) summarized maximum melt-production rates from the asteroid differentiation models of *Hevey and Sanders* (2006), *Wilson et al.* (2008), and *Moskovitz and Gaidos* (2011) to show that, for early forming asteroids with radii in the range 25–250 km, total magma

generation rates should be in the range 3–3000 m<sup>3</sup> s<sup>-1</sup>. *Wilson et al.* (2008) pointed out that not all the melt produced in an asteroid interior will be channeled to the surface through a single dike. Rather, geometry dictates that ~5 roughly equant volumes of the interior will each feed a separate dike, with each zone producing ~0.6–600 m<sup>3</sup> s<sup>-1</sup> of melt. These are maximum rates soon after silicate melting begins; melt production rates inevitably decrease as <sup>26</sup>Al decays.

Using these values, *Wilson and Keil* (2012) modeled the formation of dikes that evolved in size and shape until the dike geometry allowed the volume flow rate of magma to match the volume flux from the source zone. They found that, for all asteroids smaller than ~200 km in radius, direct eruptions to the surface are forbidden because of excessive magma cooling as dikes pass through the crust, implying that at least the earliest melts moving upward from an asteroid mantle will form intrusions in the form of sills or magma reservoirs at, or not far above, the base of the lithosphere. Any surface eruptions would be fed by magmas derived from these reservoirs as a result of their subsequent physicochemical development. A similar conclusion was reached for the ureilite parent body by *Wilson et al.* (2008), who argued that the unmodified primitive crust of an asteroid would probably be fractured by impacts and would be of lower density than at least some of the melts approaching from below, so that a density trap, and to some extent a mechanical/rheological trap, would exist. Melts would intrude the base of the less-competent material in much the same way as magmas appear to have invaded the brecciated zones beneath the floors of floor-fractured craters on the Moon (*Jozwiak et al.*, 2012). The extent of the intrusions would be very much greater on asteroids, however, because of the magma volumes involved. Models that infer efficient removal of melt from asteroid mantles in the early stages of partial melting (*Wilson et al.*, 2008; *Moskovitz and Gaidos*, 2011) have difficulty achieving more than ~30% partial melting of the mantle because aluminum, including the <sup>26</sup>Al heat source, preferentially partitions into the basaltic melt. Using 30% melting as an upper limit, and making due allowance for the volume of the outer thermal boundary layer of the asteroid that never reaches melting temperatures, *Wilson and Keil* (2012) investigated the consequences of erupting and intruding the implied volumes of melt at shallow levels in asteroids of a wide range of sizes. The total melt volume exceeds the volume of the lithosphere for asteroids with radii greater than ~100 km.

If all this melt were to erupt from the mantle directly onto the surface, it would not modify the original primitive crustal material significantly by heating it from above — each lava flow or pyroclast layer would cool so quickly that little of its heat would be transported downward to any significant depth. However, the erupted materials would progressively bury the original crust on asteroids with radii > 100 km to the extent that the geotherm would migrate up into the crust and cause it to become part of the melting mantle; all primitive material would be eliminated. It is not surprising, therefore, that no sign of primitive crustal material is seen in any of the HED meteorites from (4) Vesta. However, *Wilson*

and Keil (2012) point out that it is surprising that primitive clasts are not reported in breccias from smaller differentiated bodies such as the ureilite or aubrite parent asteroids.

### 5.6. Lithospheric Magma Reservoirs

Mantle melts intruded beneath or within the lithosphere could form discrete magma reservoirs or a global sill. A single global sill on a ~250-km-radius body [i.e., (4) Vesta] would have an average thickness of ~22 km; its thickness on asteroids with radii 200, 150, 100, and 50 km would be about 16, 11, 6, and 2 km, respectively (Wilson and Keil, 2012). Depending on the configuration (basal global sill or more equant magma bodies), the extent of thermal metamorphism of the primitive crust could be extensive. The fact that basaltic melts bring with them the  $^{26}\text{Al}$  heat source means that, if they initially accumulate to form a large reservoir quickly enough to offset losses by conduction from the reservoir margins, a very considerable temperature increase can occur before enough  $^{26}\text{Al}$  has decayed that cooling dominates. The concept of a global sill is attractive in that it is, in effect, a magma ocean with 100% melt. The main difference between this shallow version of a magma ocean and the deeper mantle version previously assumed by many authors is that the subsequent cooling and geochemical evolution takes place at lower pressures and more quickly. Among the deep magma ocean models applied to (4) Vesta, that of Neumann *et al.* (2014) comes closest to combining both concepts. These authors extract melt efficiently from a deep ~45% molten ocean (as a result of convection rather than by enhanced porous flow in a vein-dike network) and accumulate it into a shallow magma ocean, i.e., a global sill, for subsequent evolution. Such a picture is probably compatible with the geochemical arguments of Mandler and Elkins-Tanton (2013) and Greenwood *et al.* (2014), who infer a homogeneous source for melts with heterogeneous subsequent evolution. The presence of multiple discrete magma reservoirs at various depths in the outer parts of (4) Vesta is implied by spectral observations of 15 vestoid asteroids (Mayne *et al.*, 2011). Both monomineralic (eucrite or diogenite alone) and mixed (eucrite and diogenite together) compositions are indicated, implying that homogeneous units >5 km in size and smaller-scale heterogeneities at the <1-km scale both exist in the outer 10–20 km of (4) Vesta excavated by impacts to form the vestoids. Additional evidence for this may be implied by the heterogeneous distribution of trace elements in diogenites (Mittlefehldt *et al.*, 2012).

Little attention has been paid to the physical evolution of magma reservoirs, whatever their geometry, in the lithospheres of differentiated asteroids. Wilson *et al.* (2008) considered the growth and stability of discrete magma reservoirs against heat loss, and modeled cyclic eruptions triggered by the buildup of pressure in a reservoir as new magma was injected from below. However, their treatment was specifically directed at the ureilite parent body, where the magmas were inferred to be very positively buoyant due to their extremely large amounts (~20%, i.e., 200,000 ppm)

of CO gas generated by smelting [reaction between graphite and metal, mainly Fe, oxides (Goodrich *et al.*, 2007)]. Wilson and Keil (2012) modeled the development and intermittent eruptive activity of lithospheric magma reservoirs assuming more moderate amounts (~3000 ppm) of CO or similar molecular mass gas in line with the measurements of Muenow *et al.* (1992, 1995). However, none of these treatments considered in detail the likely changes in the density and rheology of reservoir magma as a result of its chemical evolution. Much more work is needed on this topic, taking into account the evolution with time of the magma supply rate from the mantle, the evolving magma composition, and the likely evolution of the density and porosity structure of the lithosphere. Conditions will differ significantly between smaller, more volatile-rich asteroids that lose most of their basalts to space in energetic explosive eruptions and larger, volatile-poor bodies that accumulate lavas on their surfaces. In the latter case, the progressive burial of the first-forming reservoirs will change both the internal pressure and the external lithostatic stress conditions that control their eruptive behavior. Burial of erupted materials will produce compressive stresses, as occurs on Io (Leone *et al.*, 2011), possibly large enough to produce reverse (i.e., thrust) faults (Jaeger *et al.*, 2003). In contrast, intrusions in the lower lithosphere will induce extensional forces leading to normal faulting. For dikes to be able to propagate up to the surface to feed eruptions, extension must exceed compression, at least locally.

### 5.7. Surface Eruptions

Explosive activity is almost inevitable when magmas erupt onto the surface of bodies without atmospheres as free volatiles attempt to decompress to the essentially zero pressure. Volatile expansion will tend to tear apart the host liquid into droplets with sizes in the range 30  $\mu\text{m}$  to 4 mm (Wilson and Keil, 1996b), consistent with the sizes expected for pyroclasts on the Moon (Wilson and Head, 1981) and sampled in the lunar regolith by Apollo astronauts (Taylor, 1982). The concept of explosive volcanic activity ejecting melts at greater than escape velocity has been widely adopted to explain the absence of meteoritic samples of the basalts that should have been erupted onto asteroid surfaces (Wilson and Keil, 1991, 1996b, 1997; Keil and Wilson, 1993; Warren, 2008; Wilson *et al.*, 2008, 2010; Keil, 2010; Keil *et al.*, 2011). The critical requirement is that a sufficiently large mass fraction of free gas should be present to guarantee disruption of the magma reaching the surface into pyroclastic droplets and to provide the energy needed to accelerate the erupting gas-droplet mixture to escape velocity. Fu and Elkins-Tanton (2014) have questioned the retention of sufficient volatiles during the heating processes that preceded silicate melting to allow this mechanism to operate, but no other explanation for the missing basalts has yet been put forward.

The escape speed from an asteroid is a function of its size and mass, and the mean velocity of ejecta in an explosive eruption is a function of the square root of the mass fraction of gas available to expand and accelerate gas and entrained

pyroclasts (Wilson, 1980). Wilson and Keil (1991) combined these ideas to show that pyroclasts could readily escape, especially from small, volatile-rich asteroids. The required critical gas mass fraction is proportional to the square of the asteroid radius, e.g., 50 ppm, 5000 ppm, and 5% gas for radii 30, 100, and 300 km, respectively. In more detail, however, it is necessary to take into account the fact that only the smallest pyroclastic droplets will have essentially the same speed as the gas. Larger clasts will lag behind the gas by a speed equal to their terminal velocity through the gas, and the largest clasts may fall back onto the asteroid surface while all smaller clasts are lost (Wilson and Keil, 1996b). These issues were treated in detail by Wilson et al. (2010) and applied by Keil et al. (2011) to the interpretation of a composite clast, part Fe,Ni-FeS and part basaltic glass, found in an aubrite meteorite.

When the asteroid size is too large or the magma volatile content is too small to allow escape of pyroclasts, fire fountains must form over explosive vents (Wilson and Keil, 1997), and the physics controlling these features will be analogous to that of the umbrella-shaped “plumes” seen on Io (Kieffer, 1982) but with important differences. When the volume discharge rate of magma is relatively high and the volatile content of the magma is relatively low, the small size of pyroclasts in fire fountains on airless bodies can cause the fountains to be optically dense (Wilson and Head, 1981, 2001; Wilson and Keil, 1997, 2012). Only in the outermost shell of the fountain can clasts radiate heat into space. Clasts in the interior of the fountain fall back to the surface still at magmatic temperatures and coalesce into a hot lava pond that feeds surface flows. This process explains the sizes of the thermally eroded ponds around the sources of sinuous rilles on the Moon (Wilson and Head, 1981) and Mars (Wilson and Mouginis-Mark, 2001). It is generally argued that (4) Vesta was very volatile poor, although Sarafian et al. (2013) have described evidence for small amounts of fluorine, chlorine, and some H<sub>2</sub>O in apatite grains in eucrite meteorites. The fire-fountain models imply that explosive activity driven by low-volatile-content magmas would not have broadcast cool pyroclasts over wide areas of (4) Vesta’s surface, a prediction consistent with the findings of Singerling et al. (2013), who specifically looked for frozen pyroclastic droplets as glasses in howardites and failed to identify any. Instead, weakly explosive eruptions on bodies more than ~100 km in radius would have commonly generated hot lava ponds feeding lava flows.

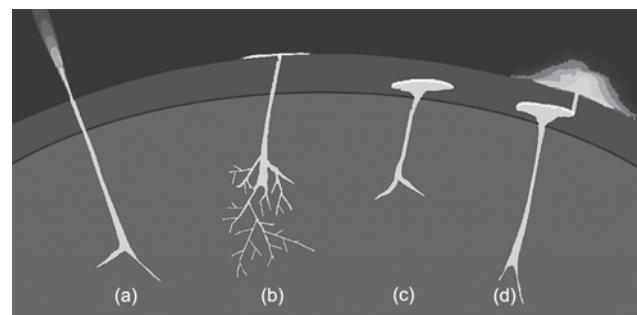

Lava flows on asteroids will have had very different morphologies from flows on larger bodies. Early attempts to predict flow morphology (Wilson and Keil, 1996a) assumed that magma reached the surface directly from the mantle, but the finding that most eruptions took place from shallow magma reservoirs (Wilson and Keil, 2012) increases the implied eruption rates. Maximum rates in the early stages of volcanism on large asteroids may have exceeded those common now on Earth by an order of magnitude. The low acceleration due to gravity on asteroids less than ~100 km in radius would have caused basaltic flows on such bodies to

be much thicker than those on the larger terrestrial planets, possibly forming features more akin to silicic lava domes on Earth than to long, narrow, channelized flows (Wilson and Keil, 2012).

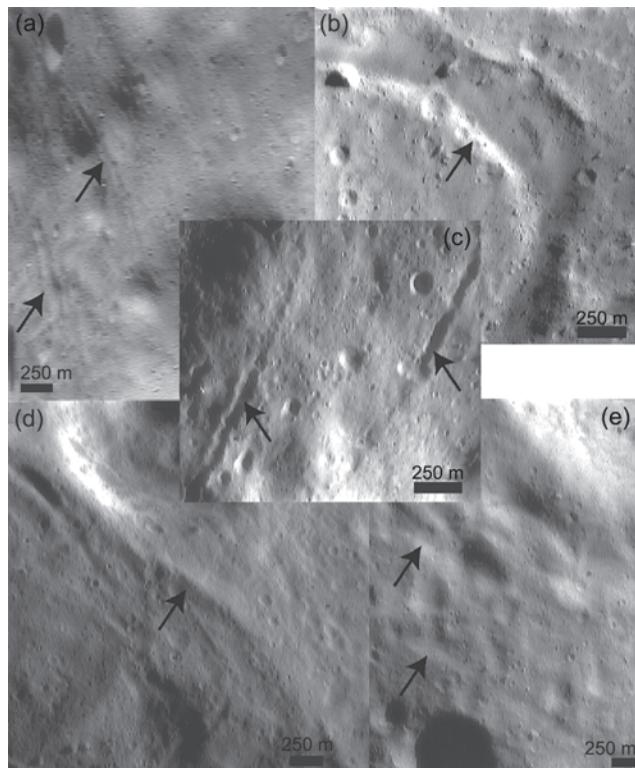

The various silicate melt transfer and eruption processes discussed above are summarized in Fig. 2. Sadly, the only largely intact differentiated asteroid on which we might have hoped to look for examples of the surface features implied, (4) Vesta, has been modified so extensively by post-volcanism impacts that no trace of surface flow morphology remains (McSween et al., 2013).

## 6. TECTONIC PROCESSES ON ASTEROIDS: INSIGHT INTO INTERNAL STRUCTURE AND DENSITY

Various types of linear structural features have been observed on a number of asteroids (e.g., Ververka et al., 1994; Sullivan et al., 1996; Prockter et al., 2002), including (951) Gaspra, (243) Ida, (253) Mathilde, (433) Eros, (25143) Itokawa, (2867) Steins, (21) Lutetia, and (4) Vesta. These lineaments include grooves, troughs, pit crater chains, ridges, and elongate hills (Fig. 3) (Buczkowski and Wyrick, 2014). Grooves have been characterized as shallow, v-shaped gashes and are most likely the result of simple fracturing of the surface, although they may also be the surface representations of larger fractures whose distinct edges have been muted by burial under regolith and crater ejecta. Troughs are wider than grooves and have distinct walls and floors; they may be the result of reactivation of preexisting grooves or fractures, perhaps by later impacts causing further widening of existing cracks. Pit crater chains are linear assemblages of small depressions, theorized to be grooves or troughs that were covered by regolith that may now be draining into the underlying structure (e.g., Thomas et al.,

**Fig. 2.** Scenarios of silicate melt transfer from mantle to surface. **(a)** Direct transfer from mantle to surface with loss of gas and pyroclasts into space by explosive volcanism. **(b)** Direct transfer from mantle to surface to form lava flow. **(c)** Transfer from mantle to shallow intrusion. **(d)** Shallow intrusion feeds explosive fire-fountain from which pyroclasts accumulate into lava pond. In **(b)** an impression of the complex vein/dike network facilitating melt flow is given. Scenarios **(c)** and **(d)** are most likely on large differentiated asteroids.

**Fig. 3.** Examples of various asteroid lineation morphologies. Arrows point to features on NEAR-Shoemaker images: (a) Grooves (image 143673751, resolution 9.48 m/pixel). (b) Flat-floored trough (image 134011958, resolution 4.76 m/pixel). (c) Pit chains (image 135344864, resolution 4.91 m/pixel). (d) Ridge (image 131011232, resolution 9.91 m/pixel). (e) Shallow troughs (image 131034292, resolution 9.18 m/pixel).

1979; Horstman and Melosh, 1989; Wyrick *et al.*, 2004). Ridges and elongate hills are linear topographic highs, as determined by image illumination and/or topographic data. While ridges are probably the surface representation of thrust faulting under a compressive state of stress (Prockter *et al.*, 2002), elongate hills have been proposed to be representative of structurally controlled magmatism (Buczkowski *et al.*, 2014; Buczkowski and Wyrick, 2014).

Since small solar system bodies (<200 km radius) do not have sufficient internal heat energy to drive terrestrial-style tectonics (Thomas and Prockter, 2010), determining how these structural features formed yields important information about the nature and geological history of such lineated asteroids. Proposed formation mechanisms for the various lineaments include (1) formation by impact (Thomas and Veverka, 1979), (2) fabric inherited from a parent body (e.g., Veverka *et al.*, 1994; Thomas *et al.*, 2002), (3) downslope scouring (e.g., Head and Cintala, 1979; Wilson and Head, 1989), and (4) thermal stresses (Dombard and Freed, 2002). Each stage in the thermal evolution of the interior of a differentiated asteroid will in principle have involved volume changes that exerted stresses on the cold outer layers of the lithosphere. As shown in earlier sections, these will most

likely have been extensional in bodies that underwent only aqueous alteration, leading to normal faulting, and could be either compressional or extensional in bodies experiencing silicate volcanism, so that both normal and reverse faults might be found.

Most of the lineaments identified on imaged asteroids have been attributed to impact, including Gaspra, Ida, Mathilde, Eros, Lutetia, and Vesta (Buczkowski and Wyrick, 2014). In addition, some features on both Gaspra (Veverka *et al.*, 1994) and Eros (Thomas *et al.*, 2002) suggest that they formed on a parent body. Both of these formation mechanisms suggest a strong and coherent asteroid. However, the few lineaments on Itokawa have been attributed to boulder movement on its surface (Sasaki *et al.*, 2006). As such, their presence does not require a coherent interior.

Vesta is both larger than the other lineated asteroids (525 km diameter) and is differentiated, meaning that internally driven tectonics and magmatism are both theoretically possible (Buczkowski and Wyrick, 2014), and various indications of magmatic processes have been identified. Raymond *et al.* (2013) identified a high Bouger gravity anomaly associated with the topographically elevated region Vestalia Terra, indicating that the plateau is comprised of a denser material than the rest of Vesta's near-surface material. Supporting this conclusion, Vestalia Terra is not cut by the equatorial flat-floored troughs that dominate the rest of the equatorial region of Vesta (Buczkowski *et al.*, 2012), suggesting that the plateau is composed of stronger and denser material than the surrounding region. Raymond *et al.* (2013) suggested that the density difference is due to an ancient mantle plume underlying the plateau. Another possibility is that Vestalia Terra is the location of one of the sill-like intrusions theorized to be at the base of Vesta's lithosphere (Wilson and Keil, 2012).

While the equatorial troughs do not disrupt Vestalia Terra, three long pit-crater chains are observed on the surface of the plateau (Buczkowski *et al.*, 2012, 2014). Pit-crater chains are hypothesized to form when dilatational motion on buried normal faults causes overlying material to collapse into the opening portions of the buried fault (Wyrick *et al.*, 2004), and it has thus been suggested that the pit-crater chains on Vestalia Terra are representative of subsurface faulting of the plateau (Buczkowski *et al.*, 2012). Interestingly, the pit-crater chain Albalonga Catena changes along its length from a topographically low string of merged pits into a topographically high elongate hill (Buczkowski *et al.*, 2014). Named Brumalia Tholus, this hill is 36 km wide and 68 km long, and topographic profiles indicate that it is dome-shaped along both its long and short axes (Buczkowski *et al.*, 2014). Buczkowski *et al.* (2014) suggested that Albalonga Catena does represent a buried normal fault, while Brumalia Tholus formed as a magmatic intrusion (perhaps a laccolith) that utilized the preexisting subsurface fault as a conduit. Molten material traveled toward the surface, intruding into and deforming the rock above it.

This hypothesis was tested by spectroscopic investigation of the core material of Brumalia Tholus. Teia crater impacts the northern face of Brumalia Tholus, and thus its ejecta

likely samples Brumalia's core material (Buczkowski et al., 2014). The Teia ejecta spectra show that they are comprised of a more plutonic material (diogenite) than the background rocks (eucrites and howardites) (De Sanctis et al., 2014). This is consistent with Brumalia Tholus being the surface representation of a magmatic intrusion that cooled slowly at depth, allowing larger crystals to form.

The source of the molten material that putatively formed Brumalia Tholus requires further consideration. The fact that Brumalia Tholus appears to be diogenitic rather than eucritic (or cumulate eucrite) indicates that the magma that formed this potential intrusion was magnesium rich, and less evolved than typical eucrite. One possibility is that the material might be diogenitic impact melt associated with the formation of the Rheasilvia basin (Buczkowski et al., 2014), similar to impact melt dikes identified around the Sudbury (Riller, 2005) and Vredfort (Reimold and Gibson, 2006) impact basins on Earth. In this hypothesis, Rheasilvia impact melt drained through fractures in the basin's floor and invaded the Albalonga fault, forming Brumalia Tholus (Buczkowski et al., 2014). However, modeling indicates that impact melt production on asteroids should be limited, due to the lower impact velocities of main-belt impactors (Keil et al., 1997), and to date only a small amount of impact melt associated with Rheasilvia has been tentatively identified (Schenk et al., 2012; McSween et al., 2013; Williams et al., 2014), suggesting that an igneous rather than impact origin is more likely (Buczkowski et al., 2014). Simple models of the thermal evolution of asteroidal bodies suggest that volcanism on Vesta would have ceased by 10–100 m.y. after formation, i.e., >4.4 Ga (e.g., Schiller et al., 2010b; McSween et al., 2011). However, there is no reason that the Albalonga fault could not pre-date the end of vestan volcanism, as superposition principles suggest that of Vestalia Terra, on which Albalonga Catena outcrops, is one of the oldest intact features on Vesta (Buczkowski et al., 2014). The magmatic material injected into an ancient Albalonga fault could have been sourced by (1) the magma plume theorized by Raymond et al. (2013), (2) the sill-like intrusions hypothesized by Wilson et al. (2008), and Wilson and Keil (2012) or (3) one of the diogenitic intrusions into the eucritic crust predicted by Barrat et al. (2010).

## 7. SUMMARY

While many advances in technology used for the analysis of meteorites and in theoretical modeling of physical and geochemical processes relevant to asteroids have been made in the last decade, there are still numerous unresolved issues. Further laboratory experiments may help, but decisive evidence must come from meteorites. Unfortunately, the stresses to which meteoroids are subjected while passing through Earth's atmosphere tend to cause disassembly along planes of weakness. Thus, while representative bulk chemistry and mineralogy may be preserved, the internal physical structures of asteroids on scales greater than ~1 m are poorly sampled in the meteorite collection.

Most chondrite parent bodies accreted water ices together with anhydrous silicates and subsequently experienced aqueous alteration and fluid-assisted thermal metamorphism. The  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of aqueous alteration, the  $^{207}\text{Pb}$ - $^{206}\text{Pb}$  and  $^{26}\text{Al}$ - $^{26}\text{Mg}$  ages of chondrule formation, and the peak metamorphic temperatures reached by the chondrite parent bodies all suggest they accreted ~2.5–4 m.y. after CAIs, too late to become melted by decay of  $^{26}\text{Al}$ . Although there are significant variations in the degree of aqueous alteration within and among different chondrite groups, the mineralogy, petrography, and bulk chemical compositions of aqueously altered meteorites suggest that they experienced nearly isochemical alteration with a limited fluid flow.

In contrast, the asteroids that experienced silicate melting and core formation must have accreted within ~1–1.5 m.y. of CAI formation. The specific conditions that allowed migration of Fe,Ni-FeS melts downward to form cores and silicate upward to form crusts under the relatively low pressure conditions in asteroid interiors are still unclear. The current consensus is that between 5% and 10% silicate melting is needed to allow dense metallic melts to begin to sink to form cores. Ideas on the maximum amount of silicate melt present at any one time in asteroid mantles are polarized between up to at least 50% melting with retention of melt in mantles as magma oceans and no more than ~30% melting with rapid transfer of melt to the base of the crust to pond as massive intrusions. In the latter case, only a few percent melt would be present in the mantle at any one time, but the intrusions would contain 100% melt.

The Dawn encounter with (4) Vesta has helped enormously to provide data and clarify thinking about the outer layers of a differentiated asteroid. It has also provided guidance on how remote sensing observations of other asteroids are to be interpreted. However, sample return from asteroids must be an important goal for the future. Perhaps a good target for a future spacecraft mission would be a body such as (15) Eunomia, which may be a cross-section from crust to core of its parent asteroid (Gaffey et al., 2002).

Differentiated asteroids and igneous meteorites present numerous challenges to our understanding of the impact and dynamical evolution of asteroids and meteorite parent bodies. Igneous meteorites, including irons, achondrites, and stony-iron meteorites, testify to the prior existence of ~100 differentiated bodies. Destruction of these bodies by hypervelocity impact over 4 G.y. would have required numerous giant impacts, although this is inconsistent with the preservation of Vesta's basaltic crust and the lack of differentiated asteroid families. We review recent advances in elucidating the early chronology of meteorites, spectroscopic observations of likely differentiated asteroids, petrological studies of differentiated meteorites, impact disruption of differentiated planetesimals during accretion, and dynamical scenarios for capturing material into the asteroid belt. Together, these advances suggest a new paradigm in which planetesimals accreted rapidly in the inner solar system and were melted by  $^{26}\text{Al}$  less than 2 m.y. after the formation of calcium-aluminum-rich inclusions (CAIs). While molten they were disrupted by grazing hit-and-run impacts during the accretion of planetesimals. Later, when still hot, the survivors were disrupted by hypervelocity impacts. Impact debris from the differentiated bodies was transferred from the newly formed terrestrial planet region to stable orbits in the asteroid belt. This evolutionary history leaves many questions unanswered but suggests new paths for future exploration of the asteroid belt and petrological and isotopic studies of meteorites.

## 1. INTRODUCTION

Laboratory studies of igneously formed meteorites suggest that numerous meteorite parent bodies were melted to form metallic cores and silicate mantles. Studies by the Dawn spacecraft confirm that (4) Vesta melted in this way (*McSween et al.*, 2013; see the chapter by Russell et al. in this volume). In principle, one would think the origin of iron and stony-iron meteorites and achondrites would be straightforward to investigate, but this is not the case. If disrupted Vesta-like differentiated bodies were once common in the main belt and

they were the ultimate source of the differentiated meteorites, one might expect collisions to have created enormous numbers of V-type asteroids that were not derived from Vesta, as well as ample numbers of mantle and core fragments compared to the rest of the main-belt population. This is not observed. Instead, only limited examples of asteroids composed predominantly of core metallic Fe-Ni (possibly some M-type asteroids) or mantle olivine (some A-type asteroids) have been identified. Very few of these bodies are members of asteroid families, with those in families having orbits and sizes most consistent with being interlopers.

Differentiated asteroids and meteorites provide many other challenges to our understanding of the formation and evolution of the asteroid belt. How could core samples have been extracted from numerous large differentiated bodies when Vesta's basaltic crust was preserved (*Davis et al.*, 1985)? Where are the meteorites from the olivine-rich mantles of the parent bodies of the 12 groups of iron meteorites and the ~50–70 parent bodies of the ungrouped irons, the two groups of pallasites, and the type 4–6 ungrouped pallasites — “the great dunite shortage” (*Bell et al.*, 1989)? We also lack mantle and core samples from the parent asteroids of the angrites and the ungrouped eucrites like Northwest Africa (NWA) 011 and Ibitira (*Krot et al.*, 2014). Where is the missing Psyche family of silicate-rich asteroids (*Davis et al.*, 1999)? Why are meteorites derived from far more differentiated parent bodies than chondritic parent bodies even though the asteroid belt is dominated by C and S complex chondritic asteroids (*Bottke et al.*, 2006)?

We reassess ideas about the dynamical origin and early impact histories of differentiated asteroids and meteorites in the light of major advances since *Asteroids III*. These include advances in our understanding of the chronology of the early solar system, the distribution of short-lived isotopes including  $^{26}\text{Al}$ , the identification of pristine chondrites and differentiated meteorites that escaped prolonged alteration or metamorphism, the thermal histories of differentiated meteorites, the nature of S asteroids, impact modeling during accretion, and dynamical studies of planetesimal accretion. Together, these advances suggest a new paradigm (*Bottke et al.*, 2006; *Goldstein et al.*, 2009) in which planetesimals accreted rapidly in the inner solar system and were rapidly melted by  $^{26}\text{Al}$  less than 2 m.y. after CAI formation. While they were still molten or semimolten, planetesimals were disrupted — first by grazing impacts during the accretion that harvested the objects making slow, direct hits (*Asphaug et al.*, 2006), and later by hypervelocity impacts when larger bodies excited their orbits. Impact debris from the differentiated bodies was tossed into the asteroid belt. Most iron meteorites did not cool slowly inside insulating silicate mantles, like Vesta's core, but rapidly with little or no silicate insulation less than 5 m.y. after CAI formation. In this scenario, Vesta — the dominant single source of differentiated meteorites, viz., the howardites, eucrites, and diogenites (HEDs) — is not a typical differentiated asteroid.

In this chapter, we first describe the isotopic evidence that has been used to establish a new chronology for melting and solidification of igneous meteorites and to identify the heat source. Then we review the types, properties, and abundances of differentiated asteroids and asteroid families. Next, we describe the various types of igneous meteorites, focusing on evidence that their parent bodies were disrupted by impacts while they were still partly or wholly molten. Finally, we discuss numerical simulations of grazing impacts between differentiated planetesimals during accretion (“hit-and-run” impacts), and dynamical studies that suggest how planetesimals could have been scattered into the asteroid belt from 1 to 2 AU.

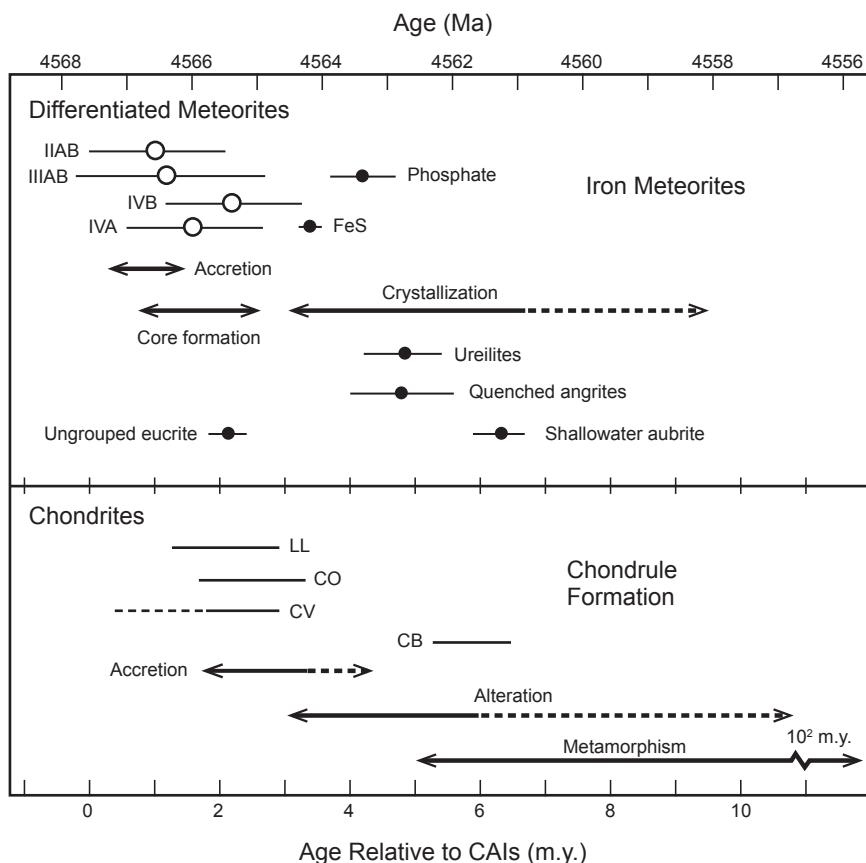

## 2. MELTING AND SOLIDIFICATION OF ASTEROIDS

### 2.1. When Were Meteoritic Bodies Melted and Solidified?

Advances in the use of short-lived and long-lived radioisotopes for dating meteorites since *Asteroids III* have revolutionized our understanding of the timescales for early solar system processes (*Davis and McKeegan*, 2014). The U-Pb system provides two isotopic clocks with different half-lives:  $^{238}\text{U}$  decays to  $^{206}\text{Pb}$  with a half-life of 4469 m.y., and  $^{235}\text{U}$  decays to  $^{207}\text{Pb}$  with a half-life of 704 m.y. Measurements of  $^{207}\text{Pb}/^{204}\text{Pb}$  and  $^{206}\text{Pb}/^{204}\text{Pb}$  can provide ages with precisions of 0.1–1 m.y. in favorable cases. After allowance for small variations in the  $^{238}\text{U}/^{235}\text{U}$  ratio (*Wadhwa*, 2014), the Pb-Pb technique gives ages of 4567.2 to 4568.2 Ma for CAIs from CV3 chondrites, which provide our best estimate of the formation age ( $t_0$ ) of the first solid materials in the solar system. Figure 1, which shows ages of early solar system materials, was constructed using a mean value of 4567.5 Ma for  $t_0$ . [The small difference between this value and that preferred by *Davis and McKeegan* (2014) of  $4567.3 \pm 0.2$  Ma from *Connelly et al.* (2012) is of no consequence in this discussion.]

Short-lived chronometers like  $^{26}\text{Al}$ , which decays to  $^{26}\text{Mg}$  with a half-life of 0.71 m.y., and  $^{182}\text{Hf}$ , which decays to  $^{182}\text{W}$  with a half-life of 8.90 m.y., provide relative ages. For example, CAIs have inferred initial ratios of  $^{26}\text{Al}/^{27}\text{Al}$  that are roughly 8 ( $= 2^3 \times$ ) higher than most chondrules, and so formed about 2 ( $3 \times 0.71$ ) m.y. before chondrules. Manganese-53, which decays to  $^{53}\text{Cr}$  with a half life of 3.7 m.y., also provides valuable relative ages but cannot be used to date CAIs because Mn is depleted in CAIs and Cr shows mass-independent isotopic anomalies. The short-lived and long-lived chronometers are cross-calibrated using angrites — achondrites that crystallized 4–11 m.y. after CAIs and escaped extensive metamorphism and shock heating (*Brennecke and Wadhwa*, 2012; *Kleine et al.*, 2012). The oldest, fine-grained angrites such as D'Orbigny are especially important anchors for the short-lived chronometers as they crystallized and cooled very rapidly (in days).

Radioactive isotopic systems record the time at which diffusion of the parent and daughter isotopes between minerals effectively ceased. Thus ages of slowly cooled rocks depend on cooling rates (*Ganguly and Tirone*, 2001). Many igneous and metamorphosed meteorites cooled slowly at around  $10\text{--}10^3\text{ }^\circ\text{C m.y.}^{-1}$ , so that radiometric ages based on isotopic systems in various minerals with closure temperatures that range from  $\sim 300^\circ$  to  $1100^\circ\text{C}$  could differ by  $\sim 50$  m.y. or more for slowly cooled meteorites, but only  $\sim 1$  m.y. for quickly cooled meteorites. For example, Hf-W closure temperatures for pyroxene are  $\sim 750\text{--}900^\circ\text{C}$ , depending on grain size and cooling rate (*Kleine et al.*, 2008). However, zircons may crystallize from melts above their Hf-W closure temperatures and so record the time of crystallization. Closure temperatures for Pb-Pb ages of phosphates in or-

**Fig. 1.** Chronology of differentiated meteorites and chondrites inferred from their radiometric ages. Core formation ages of the IIAB, IIIAB, IVA, and IVB iron meteorite parent bodies are 1–2 m.y. after the CAI formation age, which is 4567.5 Ma. Their parent bodies probably accreted 0.5 to 1.5 m.y. after CAIs. Ages of phosphate and troilite in iron meteorites, ureilites, quenched angrites, the ungrouped eucrite, Asuka 881394, and the Shallowwater aubrite indicate crystallization and cooling within 2–7 m.y. of CAIs. Ages of chondrules in the least-metamorphosed LL, CO, and CV chondrites, which are shown by horizontal lines, suggest that the parent bodies of most chondrites accreted later than the differentiated asteroids — around 2–3 m.y. after CAI formation. The metal-rich CB chondrites accreted much later, at around 5 m.y. after CAIs. Alteration and metamorphic minerals in chondrites formed 5–100 m.y. after CAIs. Dashed lines indicate less common features. (See text for sources of data.)

dinary chondrites range from ~500° to ~750°C depending on the cooling rate (Ganguly *et al.*, 2013), whereas closure temperatures for Pb-Pb ages of pyroxene are ~700–900°C (Amelin *et al.*, 2005).

Radiometric ages based on the  $^{182}\text{Hf}$ - $^{182}\text{W}$ ,  $^{26}\text{Al}$ - $^{26}\text{Mg}$ , and  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  isotopic records for angrites and CAIs are reasonably concordant with the Pb-Pb ages showing that all three short-lived isotopic systems are robust chronometers (Kleine *et al.*, 2013; Kruijer *et al.*, 2014). However, small but significant discrepancies between isotopic chronometers require further study (Davis and McKeegan, 2014). Because of the major advances in the four radiometric dating systems described above and the discovery of pristine chondrites and achondrites that largely escaped alteration, metamorphism, or impact processing after their formation, we now have a

radically new chronology for the inner solar system. Figure 1 summarizes various ages of differentiated meteorites and chondrites and their components based on these four chronometers.

Key evidence that differentiated planetesimals formed soon after CAIs and before the chondrite parent bodies comes from Hf-W isotopic measurements of chondrites, CAIs, and differentiated meteorites (Kleine *et al.*, 2005). Deviations in the  $^{182}\text{W}/^{184}\text{W}$  ratio in parts per 10<sup>4</sup>, which are called  $\varepsilon^{182}\text{W}$  values, can be attributed to separation of metal and silicate when  $^{182}\text{Hf}$  was still decaying to  $^{182}\text{W}$  because tungsten is siderophile (metal-loving) whereas hafnium is lithophile (silicate-loving). The  $\varepsilon^{182}\text{W}$  values of most iron meteorites were fixed when molten metal segregated into metallic cores as the radioactive  $^{182}\text{Hf}$  was retained in the silicate and are

very close to the inferred initial  $\epsilon^{182}\text{W}$  value in CAIs. Figure 1 shows that core formation ages inferred from  $\epsilon^{182}\text{W}$  values for four groups of iron meteorites, IIAB, IIIAB, IVA, and IVB, range from 1.0 to 2.2 m.y. after CAIs (Kruijer *et al.*, 2012, 2013).

Additional isotopic evidence for the early accretion of differentiated planetesimals comes from high-precision Mg isotopic measurements of achondrites (Bizzarro *et al.*, 2005; Davis and McKeegan, 2014). For example, Baker *et al.* (2012) used this technique to infer that the parent body of the main-group pallasites differentiated  $1.2 \pm 0.3$  m.y. after CAIs. The oldest achondrite, Asuka 881394, which is an ungrouped eucrite, crystallized 2 m.y. after CAIs according to Pb-Pb, Al-Mg, and Mn-Cr isotopic constraints (Fig. 1) (Wadhwa *et al.*, 2009). Virtually all vestan eucrites cannot be dated using these techniques, probably because of extensive thermal processing after they crystallized.

Contrary to the expectations of many workers, the new chronology shows that chondrites are not derived from the first generation of planetesimals. Ages of most chondrules based on  $^{26}\text{Al}$ - $^{26}\text{Mg}$  and Pb-Pb isotopic systems are 1.5–2.5 m.y. after CAIs (Fig. 1) (Kita and Ushikubo, 2012; Wadhwa, 2014). These ages are consistent with formation of chondrules by splashing when largely molten planetesimals collided at low speed during accretion (Asphaug *et al.*, 2011; Sanders and Scott, 2012). Since chondrite accretion postdates the formation of the constituent chondrules, most chondrites accreted 2–3 m.y. after CAIs. Although the origin of most chondrules remains uncertain, chondrules in the metal-rich CB chondrites have unique isotopic and chemical signatures indicating that they probably formed in a giant impact that created melt droplets and vapor condensates  $\sim 5\text{--}6$  m.y. after CAIs (Krot *et al.*, 2005, 2010).

## 2.2. Heat Source for Melting

Isotopic data from meteorites provide strong evidence that  $^{26}\text{Al}$  was the most potent heat source for melting planetesimals in the early solar system. Two other short-lived nuclides,  $^{10}\text{Be}$  and  $^{36}\text{Cl}$ , which were not uniformly distributed in the solar system, formed in a late-stage irradiation, but this was insufficient to account for the abundance of  $^{26}\text{Al}$ . An external source is therefore required for this nuclide — probably the winds from a massive star prior to its explosion (Davis and McKeegan, 2014). Some rare CAIs with large isotopic anomalies of nucleogenetic origin appear to have formed before  $^{26}\text{Al}$  was homogenized in the disk by radial mixing (Krot *et al.*, 2012). However, the concordance between isotopic chronometers described above suggests that  $^{26}\text{Al}$  was quickly homogenized. The initial  $^{26}\text{Al}/^{27}\text{Al}$  ratio of  $5.2 \times 10^{-5}$  in CAIs can therefore be used to estimate the heating energy available in dry chondritic material due to the decay of  $^{26}\text{Al}$  (Fig. 2) (Sanders and Scott, 2012). At the time that most CAIs were formed ( $t_0$ ), 6.6 kJ g $^{-1}$  of heat was available from  $^{26}\text{Al}$  decay, which is about four times larger than the 1.6 kJ g $^{-1}$  needed to melt dry chondritic dust in the insulated interior of a planetesimal (Sanders and

Scott, 2012). Thus well-insulated planetesimals with radii of more than 20 km that accreted less than 1.5 m.y. after CAIs (about two half-lives of  $^{26}\text{Al}$ ) were melted. Bodies that accreted soon afterward were heated but not melted. It is likely that  $^{26}\text{Al}$  was also the dominant heat source for alteration on wet asteroids, as most well-dated alteration minerals in carbonaceous chondrites formed 3–6 m.y. after CAIs (Sugiura and Fujiya, 2014; see also the chapter by Krot *et al.* in this volume). For further details on the thermal modeling of melted planetesimals, see Hevey and Sanders (2006), Moskovitz and Gaidos (2009), Sanders and Scott (2012), and Neumann *et al.* (2012).

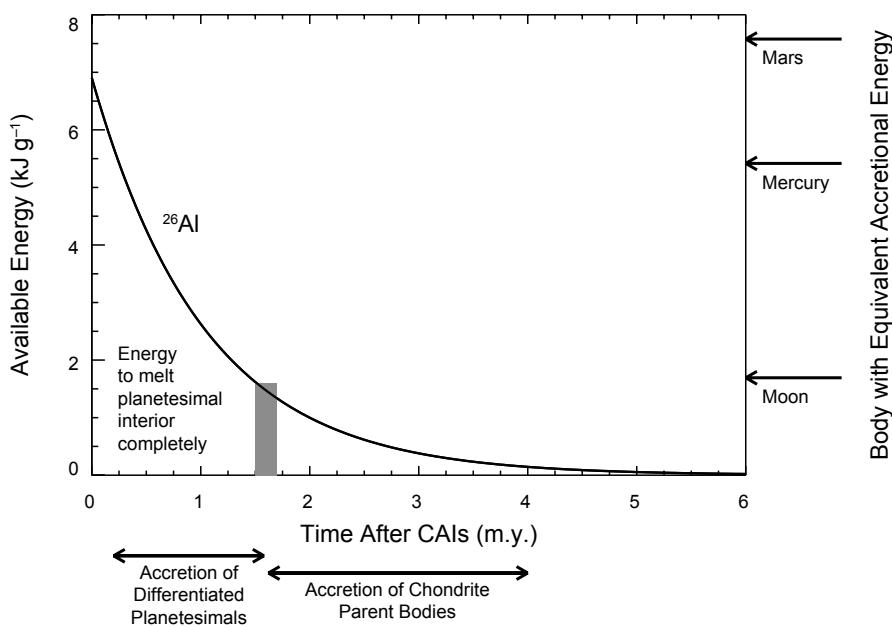

Although  $^{60}\text{Fe}$  has been considered as a second possible source of radioactive heat, the current best estimate for the solar system initial  $^{60}\text{Fe}/^{56}\text{Fe}$  ratio of  $(1.0 \pm 0.3) \times 10^{-8}$  indicates that heating from  $^{60}\text{Fe}$  decay would have been negligible ( $<20$  K increase in temperature) (Tang and Dauphas, 2012). Alternative heating mechanisms such as electromagnetic induction do not appear to have played a major role in heating asteroids (e.g., Marsh *et al.*, 2006). Impacts cannot cause global heating and melting of asteroids, even very porous ones (Keil *et al.*, 1997). Nevertheless, impacts into highly porous targets can cause localized heating, which may have played a role in the formation of certain igneous meteorites like IAB and IIE irons (Davison *et al.*, 2012, 2013; Ciesla *et al.*, 2013; Wasson and Klemme, 2002). In addition, the Portales Valley H chondrite, which contains centimeter- to millimeter-wide metallic veins with a Widmanstätten pattern like iron meteorites, probably formed by impact heating or impact-induced frictional heating of a hot target (Kring *et al.*, 1999; Rubin *et al.*, 2001).

## 3. DIFFERENTIATED ASTEROIDS

Asteroid compositions have traditionally been established via spectroscopic observations at visible and near-infrared wavelengths (Burbine, 2014). Feature-based taxonomic systems (e.g., DeMeo *et al.*, 2009) allow mapping of spectral classes to broadly defined compositional groups, while detailed modeling of mineral absorption features can yield specific compositional information (see the chapter by Reddy *et al.* in this volume). Asteroids derived from igneously differentiated parent bodies range from those with prominent absorption features and reasonably constrained compositions (e.g., V-types), to those that are challenging to characterize due to muted or absent absorption features (e.g., M-types). Here we focus on asteroids that may have been heated to high enough temperatures to melt or partially melt silicate or metal-sulfide ( $>950^\circ\text{C}$  and  $>1050^\circ\text{C}$  respectively) and to mobilize these melts. We exclude asteroids like (1) Ceres that may have experienced silicate-water differentiation (see the chapter by Rivkin *et al.* in this volume).

### 3.1. Basaltic Crust: V-Types

Named after their archetype, the 530-km-diameter (4) Vesta, V-type asteroids have long been spectroscopically

**Fig. 2.** Available thermal energy from  $^{26}\text{Al}$  decay in dry chondrites as a function of time since CAI formation (after Sanders and Scott, 2012). Differentiated planetesimals accreted within 1.6 m.y. of CAI formation when the available energy from  $^{26}\text{Al}$  exceeded  $1.6 \text{ kJ g}^{-1}$ , which is the energy needed to melt a chondrite completely. The parent bodies of nearly all chondrites accreted 1.6–4 m.y. after CAIs formed (see Fig. 1). The righthand axis shows the equivalent accretional energy (or gravitational binding energy) of the Moon, Mercury, and Mars.

linked to the basaltic HED meteorites (McCord *et al.*, 1970; Consolmagno and Drake, 1977; Cruikshank *et al.*, 1991; Binzel and Xu, 1993; Burbine *et al.*, 2001; McSween *et al.*, 2013). Compositional analyses support this link (Duffard *et al.*, 2004; Mayne *et al.*, 2011; De Sanctis *et al.*, 2011). V-type asteroids, apart from Vesta, are small,  $<10$  km in diameter, and the vast majority of V-types are part of the Vesta asteroid family, which spans the inner main belt between the  $v_6$  secular resonance along the inner main belt's periphery at 2.1–2.3 AU (depending on inclination) and the 3:1 mean-motion resonance with Jupiter near 2.5 AU (Carruba *et al.*, 2005; Nesvorný *et al.*, 2008; Moskovitz *et al.*, 2010; see also the chapter by Nesvorný *et al.* in this volume). Most of the Vesta family probably stems from the impact events that made the 500-km basin Rheasilvia, with a crater retention age of  $\sim 1$  Ga, and the 400-km basin Veneneia, with a crater retention age of  $>2$  Ga (Marchi *et al.*, 2012; see also the chapter by Marchi *et al.* in this volume).

Several examples of non-Vesta V-type asteroids have been discovered in the middle and outer main belt beyond 2.5 AU (Lazzaro *et al.*, 2000; Roig *et al.*, 2008; Moskovitz *et al.*, 2008; Duffard and Roig, 2009; Solontoi *et al.*, 2012). These V-types are dynamically separated from Vesta by one or more of the Kirkwood gaps and show a wide range in semimajor axis, eccentricity, and inclination. They are therefore unlikely to have been dynamically transported from the Vesta family to their current locations and are probably

composed of fragments from other Vesta-like bodies (e.g., Nesvorný *et al.*, 2008). In a few cases, compositional analyses suggest that these outer-belt V-types are compositionally distinct from Vesta and the vestoids (Harden *et al.*, 2004; Burbine, 2014).

### 3.2. Olivine-Rich Mantle: A-Types

The spectra of A-type asteroids closely resemble those of olivine-dominated compositions, with slope differences potentially due to the effects of space weathering (e.g., Hiroi and Sasaki, 2001). Some A-types have magnesian olivine compositions consistent with differentiation of ordinary chondrites; others contain ferroan olivine like that found in R-chondrites or igneous differentiates from R-chondrite-like parent bodies (Sunshine *et al.*, 2007; Burbine, 2014). A-types with magnesian compositions tend to be olivine-rich ( $\sim 70$ –90% abundance) with small amounts of pyroxene that produce subtle 2- $\mu\text{m}$  absorption features, whereas the ferroan A-types have spectra consistent with a monomineralic interpretation, i.e., no 2- $\mu\text{m}$  band (Sanchez *et al.*, 2014). A-type asteroids and their meteoritic counterparts (e.g., pallasites, brachinites, R-chondrites) are rare.

If the asteroid belt had been composed largely of highly reduced meteorites like enstatite chondrites and achondrites, which have virtually no  $\text{Fe}^{2+}$ , the apparent lack of meteorites and asteroids composed mainly of olivine would be

understandable, as chondrites have atomic Mg/Si ratios of around 1, like enstatite ( $\text{MgSiO}_3$ ). However, most meteorites and asteroids are much more oxidized with significant concentrations of  $\text{Fe}^{2+}$ , so we should expect differentiated bodies to contain major amounts of olivine ( $(\text{Mg}, \text{Fe})_2 \text{SiO}_4$ ). We discuss the dearth of dunite in section 7.

### 3.3. Metal-Rich: Some M-Types

M-types have traditionally been linked to iron meteorites. An M-type classification is not exclusively a spectroscopic designation, but instead requires knowledge of albedo (10–30%) to distinguish their largely featureless spectra from others within the broad X-complex (Tholen, 1984). Focused studies have suggested that additional information like high radar albedo (Shepard et al., 2010), spectral observations around 3  $\mu\text{m}$  to look for signatures of hydrated minerals (Rivkin et al., 2000; see also the chapter by Rivkin et al. in this volume), and near-infrared continuum curvature (Clark et al., 2004) can be used to further distinguish metal-rich M-types from other spectrally degenerate asteroids. However, it is unclear what fraction of taxonomic M-types are truly metal-rich. Most of the M-types that are inferred to be metal-rich from radar studies also show 1- and 2- $\mu\text{m}$  silicate spectral features (Ockert-Bell et al., 2010). Neeley et al. (2014) found that for one-third of the Xc and Xk objects, the best spectral match was an iron meteorite; one-fifth were matched best by E chondrites. Xk-type asteroids have also been linked with mesosiderites (Vernazza et al., 2009).

The largest of the iron-rich M-types, which is (16) Psyche, with dimensions of  $240 \times 185 \times 145$  km, possibly came from a Vesta-sized differentiated body that completely lost its crust/mantle silicates via one or more hit-and-run collisions (see section 5). (216) Kleopatra is another canonical M-type but has a relatively low density of  $3600 \pm 400 \text{ kg m}^{-3}$  (Descamps et al., 2011), suggesting it may be a highly porous collection of collisionally evolved core fragments.

### 3.4. Chemically Reduced Crust: E-Types

The E-type asteroids are also a part of the X-complex and are distinguished by a high albedo, >30%. These properties are consistent with a link to aubrites, igneous enstatite-rich meteorites that formed in chemically reducing conditions. This link to aubrites is consistent with compositional interpretations of the Rosetta mission target asteroid (2867) Šteins (e.g., Barucci et al., 2008). E-types are scattered within the inner main belt, but they dominate the Hungaria region ( $1.78 < a < 2.0 \text{ AU}$ ,  $e < 0.18$ ,  $16^\circ < i < 34^\circ$ ) and are associated specifically with the Hungaria family (Warner et al., 2009; Milani et al., 2010). These asteroids may represent the best available analogs to the precursor material from which the terrestrial planets formed. It is also possible that they were an important source of impactors on Earth during the late heavy bombardment (Bottke et al., 2012; see also the chapter by Morbidelli et al. in this volume).

### 3.5. Melt Byproducts: S-Complex

Most S-type asteroids are probably composed of ordinary chondrite material (Vernazza et al., 2014; see also the chapter by Vernazza et al. in this volume) rather than differentiated material (e.g., Bell et al., 1989). However, several subclasses within the S-complex (e.g., Sv, Sa, Sr) may be linked to fully or partially differentiated parent bodies (Burbine, 2014). Compositional analysis of several of the largest members in the Merxia and Agnia S-type families, as well as asteroid (17) Thetis, suggest that their ratio of high-calcium pyroxene to total pyroxene is greater than ~40% (Sunshine et al., 2004). Among meteorites, only the eucrites have such high values, suggesting that these S-types may have experienced a history consistent with igneous activity. However, Vernazza et al. (2014; see also the chapter by Vernazza et al. in this volume) find that the Merxia and Agnia asteroid families are likely parent asteroids of H chondrites.

Compositional analyses of the S-type near-Earth object (1036) Ganymed and the main-belt family associated with (170) Maria suggest that these objects may be collisional agglomerations of basalt and metal analogous to mesosiderites (Fieber-Beyer et al., 2011a,b). This raises the interesting possibility that highly collisionally evolved differentiated asteroids could be masquerading as S-type asteroids (see the chapter by Vernazza et al. in this volume).

### 3.6. Spectral End Members and Partial Differentiation

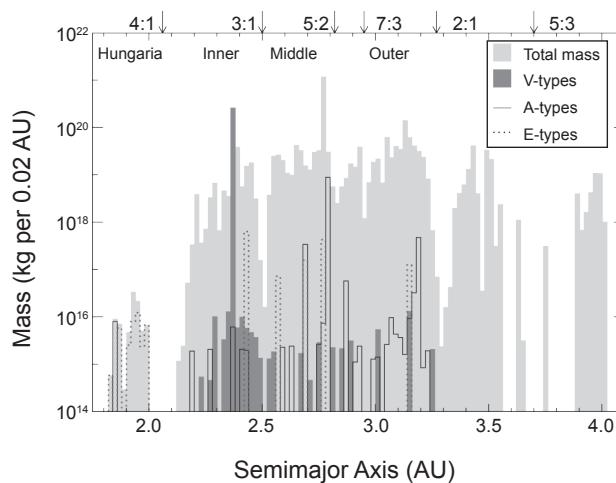

Two objects stand out as the only known members of their respective taxonomic classes: the O-type asteroid (3628) Božněmcová and the R-type asteroid (349) Dembowska. Compositional interpretations of these unusual objects have been varied and include putative links to the angrites in the case of Božněmcová (Cloutis et al., 2006) and some form of pyroxene-olivine melt or melt residual in the case of Dembowska (Burbine, 2014). Neither of these objects have good spectral analogs among meteorites or terrestrial samples.

The K-type taxonomic class has also seen varied compositional interpretations. Both the Eos family (Mothe-Diniz and Carvano, 2005; Mothe-Diniz et al., 2008) and the Eunomia family (Nathues et al., 2005; Nathues, 2010) have been linked to partially differentiated parent bodies.

However, alternative interpretations suggest a link to nondifferentiated CO and CK carbonaceous chondrites (e.g., Clark et al., 2009). The asteroid (21) Lutetia may be a partially differentiated asteroid with a metallic core and a chondritic crust (Weiss et al., 2012; Weiss and Elkins-Tanton, 2013), although this is a point of some debate (Barucci et al. 2012; see also the chapter by Barucci et al. in this volume).

### 3.7. Abundance of Differentiated Asteroids

Figure 3 shows the orbital distribution of the differentiated V-, A-, and E-type taxonomic classes relative to the

**Fig. 3.** Distribution by mass of differentiated asteroids as a function of their semimajor axis (data from DeMeo and Carry, 2013). M-types are omitted due to uncertainty in the identification of metallic varieties. Differentiated asteroids are relatively small, aside from Vesta, and have semimajor axes from 1.8 to 3.3 AU.

total mass in the asteroid belt (from DeMeo and Carry, 2013, 2014). Accounting for all the previously discussed taxonomic types and asteroid families that are associated with igneous histories, the mass of differentiated material among observed bodies is only  $\sim$ 15–20% of the total mass in the main belt, with Vesta alone accounting for  $\sim$ 10%. Table 1 summarizes some of the largest examples of fully differentiated asteroids, including (1459) Magnya, which is the largest V-type asteroid not related to Vesta. The masses in this table are either referenced or were computed assuming mean densities for the respective taxonomic classes (DeMeo and Carry, 2013) and diameters as given.

Differentiated asteroid families are surprisingly scarce. Only four (Hungaria, Vesta, Merxia, and Agnia) of the currently known 76 asteroid families (Masiero et al., 2013) have been linked (or tentatively linked) to fully differentiated parent bodies. Another two (Eos, Eunomia) have been connected to partially differentiated precursors. However, no known asteroid family contains the crust, mantle, and core fragments expected from a differentiated parent body. The majority of other differentiated asteroids are isolated objects

with no associated collisional families, likely representing relic fragments of now fully eroded parent bodies.

Since family members are composed of fragmental debris, it might be argued that they are “camouflaged,” namely covered with small debris that reaccreted immediately after the family-forming event (e.g., see Michel et al., 2004). However, spacecraft flybys of (951) Gaspra, part of the Flora family, and (243) Ida, part of the Koronis family, provide no compelling evidence that their subsurface materials, revealed via numerous impact craters, are different from the surface material (Farquhar et al., 2002).

The lack of differentiated asteroids and families is surprising in light of the large number ( $\sim$ 50–100) of distinct differentiated parent bodies represented by the iron meteorites (section 4). If differentiation was so common, where are the asteroidal relics of this process? This long-standing paradox is most pronounced for differentiated mantle material, which is quite rare among both asteroids and meteorites (Chapman, 1986; Bell et al., 1989; Burbine et al., 1996).

#### 4. DIFFERENTIATED METEORITES

##### 4.1. Types of Differentiated Meteorites

Differentiated meteorites formed by melting and crystallization in planetesimals with bulk compositions that were near solar, or chondritic, except for their volatile contents. For bodies that experienced low degrees of melting, the products resemble ultrametamorphosed chondrites or residues from low degrees of partial melting and have been called “primitive achondrites” (e.g., Krot et al., 2014). For bodies that were largely molten, the igneous products are grossly different from chondrites in their mineralogy and chemical composition. Metallic Fe-Ni and troilite (FeS) formed molten cores from which most iron meteorites appear to have been derived. Silicates formed basaltic crusts and olivine-rich and pyroxene-rich mantles that supply us with achondrites. Impacts created a third type of differentiated meteorite — stony irons — by mixing metal and silicate in roughly equal proportions. Two major types of stony-irons are known. Pallasites are made of Fe-Ni from molten cores that were mixed with fragments of olivine mantles. Mesosiderites are mixtures of molten metal, basalts, and gabbros, and impact melted silicates, with little olivine. The properties of the major types of differentiated meteorites and their fall

TABLE 1. Examples of the largest asteroids within differentiated asteroid classes.

Object	Type	Mass (kg)	Diameter (km)	Inferred composition	References
(4) Vesta	V-type	2.59e20	525.4	Basaltic surface, fully differentiated	McSween et al. (2013)
(434) Hungaria	E-type	2.6e15	11	Enstatite-rich, aubrite	Shepard et al. (2008)
(354) Eleonora	A-type	8.8e18	165	Olivine mantle	Masiero et al. (2011)
(1459) Magnya	Non-Vesta V-type	4.9e15	17	Basaltic crust	Delbo et al. (2006)
(16) Psyche	M-type	2.7e19	248	Metallic core material	Carry (2012)
(216) Kleopatra	M-type	4.64e18	127	Metallic core material	Descamps et al. (2011)

frequencies are summarized in Table 2. Chemical and isotopic data suggest that each type of differentiated meteorite probably comes from a separate body. Winonaites and IAB irons are exceptions as they are genetically related and probably come from the same body.

Below we review the evidence that early impacts were involved in the formation of differentiated meteorites and the constraints on the timing, nature, and speed of the impacts.

## 4.2. Iron Meteorites

Iron meteorites are composed very largely of Fe with 5–60% Ni (mostly 5–10% Ni) with a few volume percent of troilite (FeS), phosphide (Fe,Ni<sub>3</sub>P), and smaller amounts of chromite, carbides, phosphates, and other minerals (Goldstein *et al.*, 2009; Benedix *et al.*, 2014; Krot *et al.*, 2014). Minor and trace amounts of siderophile elements such as Ni, Co, P, Ga, Ge, Ir, Au, As, and W provide important clues to their origin. Moderately volatile elements like Ga and Ge vary enormously in their abundance: Ge/Ni ratios, for example,

range from chondritic proportions (0.1–1× CI chondrites) to 10<sup>-4</sup> of chondritic values. Depletion of volatiles reflects either early accretion in a hot solar nebula or volatile loss during impacts. Germanium concentrations in irons cluster into 14 groups, each of which contains between 5 and ~250 iron meteorites. Other elements like Au (Fig. 4b) and Ir show wide ranges within most groups, which approach the total range shown by all iron meteorites. Since concentrations of the nine major siderophile elements vary systematically within each group, there is little ambiguity in classifying meteorites into groups and locating each meteorite within its group. Mineralogical and isotopic data confirm that group members are closely related and probably formed in a single body. About 15% of irons have compositions that lie outside those of the groups and are called ungrouped irons. A few small, rapidly cooled and S-rich ungrouped irons probably formed by impact melting in ordinary chondrite bodies, e.g., Sahara 03505 (D’Orazio *et al.*, 2009). However, the remaining ungrouped irons appear to be derived from ~50 to 60 separate bodies (Goldstein *et al.*, 2009).

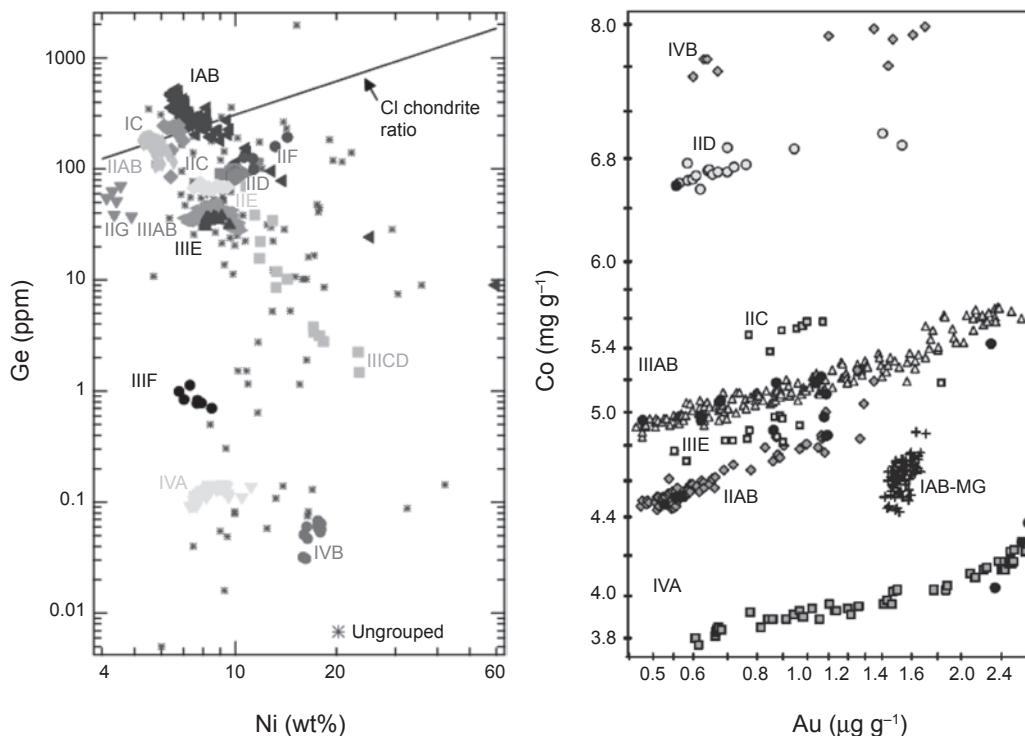

TABLE 2. Classification of differentiated meteorites.

Name	Fall freq.* (%)	Minerals <sup>†</sup>	Origin	References
<i>Iron meteorites</i>				
Groups IIAB, IIIAB, IVA, IVB, etc.	4.3	Metallic Fe-Ni, troilite (FeS)	Fractionally crystallized cores	Goldstein <i>et al.</i> (2009)
Groups IAB and IIE	3.2	Fe-Ni with silicate inclusions	Metallic pools in partly melted bodies	Ruzicka (2014)
	1.1			
<i>Stony irons</i>				
Pallasites	0.27	Fe-Ni, olivine (Fa <sub>10–20</sub> )	Breccias of core and mantle formed in several bodies	Yang <i>et al.</i> (2010a), Benedix <i>et al.</i> (2014)
Mesosiderites	0.6	Fe-Ni, pyroxene (Fs <sub>10–20</sub> ), plagioclase (An <sub>50–80</sub> )	Impact mixtures of basalt, gabbro, and Fe-Ni-S from a Vesta-like body	Benedix <i>et al.</i> (2014)
<i>Achondrites</i>				
Howardites, eucrites, diogenites	5.5	Pyroxene (En <sub>14–79</sub> Wo <sub>2–5</sub> ), plagioclase (An <sub>73–93</sub> ), silica	Breccias of basalts, gabbros, and pyroxenites from Vesta	McSween <i>et al.</i> (2013)
Angrites	0.09	Al-Ti-diopside (Fs <sub>12–50</sub> ), Ca-olivine, anorthite (An <sub>86–100</sub> )	Oldest basaltic meteorites from a fully differentiated asteroid	Keil (2011)
Aubrites	0.8	Enstatite (Fs <sub>0.1</sub> ), minor plag, ol	Igneous rocks: mostly breccias	Keil (2010)
Ureilites	0.5	OI (Fo <sub>74–95</sub> ), pyx (mostly En <sub>68–87</sub> Wo <sub>2–16</sub> ), graphite	Partial melt residues from which basalts were removed	Goodrich <i>et al.</i> (2004)
<i>Primitive achondrites</i>				
Brachinites	<0.1	OI (Fo <sub>64–73</sub> ), pyx (En <sub>40–63</sub> Wo <sub>36–48</sub> ), plag (An <sub>15–33</sub> )	Partial melt residues from FeO-rich body	Keil (2014)
Acapulcoites and lodranites	0.09	OI (Fo <sub>87–97</sub> ), pyx (En <sub>88–93</sub> Wo <sub>2–3</sub> and En <sub>50–54</sub> Wo <sub>43–46</sub> ), Fe-Ni-S, plag (An <sub>12–31</sub> )	Low-degree partial melting residues in one body	Krot <i>et al.</i> (2014)
Winonaites	0.09	OI (Fa <sub>1–4</sub> ), pyx (Fs <sub>1–9</sub> ), plag (An <sub>8–25</sub> )	Metamorphosed chondrites from IAB body	Krot <i>et al.</i> (2014)

\* Source: Meteoritical Bulletin Database (<http://www.lpi.usra.edu/meteor/metbull.php>).

<sup>†</sup> Abbreviations: ol = olivine, pyx = pyroxene, plag = plagioclase; Fa = fayalite mol.%; Fs = ferrosilite mol.%; Wo = wollastonite mol.%; An = anorthite mol. %.

Not listed are the ungrouped irons (~100), ungrouped pallasites (~5), and ungrouped achondrites (~50).

**Fig. 4.** Logarithmic plots showing the bulk compositions of iron meteorites. (a) Ge vs. Ni for grouped and ungrouped iron meteorites. Reproduced from Goldstein *et al.* (2009) by permission; image courtesy N. Chabot. (b) Co vs. Au for seven major groups of irons, which are thought to be derived from asteroidal cores that fractionally crystallized, and the group IAB-MG, which is rich in silicates and shows very different chemical trends. Reproduced from Wasson (2011) by permission.

Except for groups IAB, IIE, and IIICD, which show very different chemical trends from the other groups, chemical variations within each group can be explained by fractionation between solid and liquid Fe-Ni during solidification of a single large metallic magma, probably core material from a melted asteroid (Chabot, 2004; Goldstein *et al.*, 2009). The elements Au, As, Ni, Co, and P prefer liquid to solid Fe-Ni, whereas Ir, Re, and Os are concentrated preferentially in the solid, and Ge and Ga are scarcely fractionated. Chemical trends in fractionally crystallized groups, which are sometimes called “magmatic groups,” are largely consistent with those calculated using fractional crystallization models and experimentally determined solid-liquid partition coefficients. The nonmetals, S, P, and C, which are largely excluded from the crystallizing Fe-Ni so they become enriched in the residual melts, can drastically modify the partition coefficients of the metallic elements. Iron meteorites mostly contain 0.02–2 wt.% S in the form of troilite (FeS), although S is relatively insoluble in solid Fe-Ni (Buchwald, 1975). Troilite nodules in irons, which may have diameters of a centimeter or more, probably formed from melt that was trapped during crystallization. Fractional crystallization modeling suggests that group IVB irons crystallized from a melt that contained <1 wt.% S as the linear trends on log-log interelement plots can be modeled with fixed partition coefficients (Chabot,

2004). However, groups IIAB, IID, IIIAB, IVA appear to have crystallized from magmas with ~5–20 wt.% S and typically show nonlinear trends on log-log plots. The near absence of such S-rich irons is attributed to the low strength of troilite relative to Fe-Ni. Many iron meteoroids survived in space for hundreds of million years as meter-sized objects. Their cosmic-ray exposure ages are roughly 10× longer than nearly all stony meteorites (Herzog and Caffee, 2014).

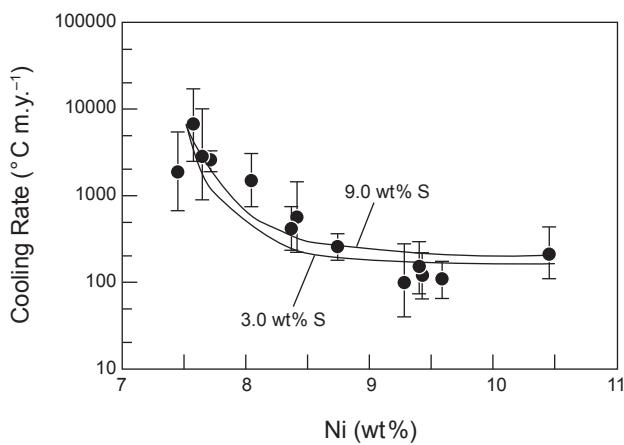

#### 4.2.1. Formation of fractionally crystallized groups.

Three large groups of iron meteorites, IVA, IIIAB, and IVB, have chemical properties consistent with formation in a large metallic core, but other properties indicating they did not cool in a core surrounded by a silicate mantle. For the IVA irons, there are three pieces of evidence. First, their metallographic cooling rates at ~500°C vary from 100° to 6000°C m.y.<sup>-1</sup>, whereas samples from a well-insulated metallic core should have essentially uniform cooling rates at ~1200°C. Second, the ancient Pb-Pb age of troilite in one IVA iron of 4564 Ma (Blichert-Toft *et al.*, 2010) (Fig. 1) is far too old for a core sample from a large asteroid, which would take ~100 m.y. or more to cool. Third, two IVA irons contain abundant silicates with anomalously rapid cooling rates (Haack *et al.*, 1996; Ruzicka, 2014). Although the non-uniform metallographic cooling rates in IVA have been questioned (Wasson and Hoppe, 2012), several features support

a wide range of cooling rates among the IVA irons. These include the dimensions of the submicrometer intergrowth called, “cloudy taenite,” and the composition of the kamacite and taenite and their interface (Goldstein *et al.*, 2014).

The thermal history and age of group IVA irons can be explained if the original IVA asteroid was disrupted after melting to form a metallic body with a radius of  $150 \pm 50$  km surrounded by  $<1$  km of silicate mantle (Yang *et al.*, 2007, 2008). Thermal and fractional crystallization modeling shows a good match between calculated and observed cooling rates for a body that crystallized radially inward (Fig. 5). Separation of core from silicate mantle was probably caused by hit-and-run impacts as conventional hypervelocity impacts are very inefficient at separating core and mantle material (Asphaug *et al.*, 2006; Asphaug and Reufer, 2014) (see section 5).

Group IIIAB, which is the largest group of iron meteorites with over 200 members, has a cooling rate range of  $60^\circ\text{--}300^\circ\text{C m.y.}^{-1}$  and phosphates that cooled through  $\sim 750^\circ\text{C}$  about 4 m.y. after CAI formation (Sugiura and Hoshino, 2003; Yang and Goldstein, 2006) (Fig. 1). These constraints can be accommodated by a metallic body with a radius of several tens of kilometers that cooled with only a few kilometers of silicate mantle (Goldstein *et al.*, 2009). Cosmic-ray exposure ages of IIIAB and IVA irons cluster around 650 and 400 Ma, respectively (Herzog and Caffee, 2014). These ages were previously interpreted as the breakup events for the entire IIIAB and IVA metallic cores (Keil *et al.*, 1994), but it is possible that they date the destruction of relatively small but representative rubble piles of metal fragments (Yang *et al.*, 2008).

**Fig. 5.** Metallographic cooling rates at  $500^\circ\text{C}$  for 13 group IVA irons decrease with increasing bulk Ni. The curves show calculated cooling rates for a metallic body of radius 150 km that lacks a silicate mantle. The depth of each iron in the metallic body is inferred from its Ni concentration and fractional crystallization modeling assuming bulk S contents of 3 or 9 wt.%. The original IVA parent body, which would have had a minimum radius of  $300 \pm 100$  km, is thought to have been disrupted by a hit-and-run collision  $\sim 2$  m.y. after CAI formation. After Yang *et al.* (2008).

Group IVB irons cooled through  $600^\circ\text{--}400^\circ\text{C}$  at rates of  $500^\circ\text{--}5000^\circ\text{C m.y.}^{-1}$  that increase with increasing bulk Ni (Yang *et al.*, 2010b). They appear to be derived from a metallic body that crystallized outward and was  $65 \pm 15$  km in radius when cooling without a silicate mantle. Separation of the mantle from a solid core may have occurred after the core was largely solid and could have been aided by a thin layer of residual metallic melt between core and mantle. In this case, the IVB irons may have crystallized in a mantled core that was somewhat larger ( $70 \pm 15$  km in radius). Group IVB irons are unrelated to any other meteorite type (Krot *et al.*, 2014).

**4.2.2. Formation of silicate-rich irons.** Iron meteorites in groups IAB, IIE, and IIICD, which have very different chemical trends from the fractionally crystallized groups, contain numerous silicate inclusions. Textural and mineralogical evidence suggests they formed by impact-mixing of previously heated silicate and molten metal (Ruzicka, 2014). Group IAB irons contain angular fragments of chondritic material, except for Caddo County and Ocotillo, which contain highly differentiated silicates. The chemical and oxygen isotopic composition of the silicates in IAB and IIICD irons closely match those of silicates in winonaites, which are strongly metamorphosed and partly melted chondrites (Table 2), suggesting they come from the same asteroid. The low degree of silicate melting of winonaites and most silicate inclusions in IAB irons suggests that temperatures were not high enough to allow a metallic core to form in their parent body (Benedix *et al.*, 2014). The time of impact mixing of metal and silicate was inferred by Vogel and Renne (2008) from Ar-Ar ages to be  $\sim 4480$  Ma, but Hf-W and Pd-Ag isotopic systematics favor several impacts  $\sim 2\text{--}10$  m.y. after CAI formation (Schulz *et al.*, 2012; Theis *et al.*, 2013). Low shock levels in the IAB silicates and winonaites suggest that low-speed accretionary impacts mixed metal and silicate, although impacts at the current mean asteroidal impact speed of  $\sim 5$  km s $^{-1}$  are not efficient at creating shocked and melted rock (Marchi *et al.*, 2013) and cannot be excluded.

Group IIE irons have relatively uniform Fe-Ni compositions and diverse silicate inclusions that range from chondritic in composition and texture to highly differentiated basaltic and glassy inclusions. The oxygen isotopic composition and the mineralogy of the chondritic inclusions resemble those of H chondrites, although the IIE silicates appear to be slightly more reduced. They were probably formed by impacts onto an H-like chondritic body, which experienced significantly more melting than the IAB-winonaite body (Ruzicka, 2014). Since most of the IIE irons have highly differentiated silicates, it is possible that the IIE metal was derived from a molten metal core in a body with a chondritic crust (Weiss and Elkins-Tanton, 2013; see also the chapter by Scheinberg *et al.* in this volume). The impact that mixed metal and silicate occurred at  $\sim 4.5$  Ga. During the late heavy bombardment at  $\sim 4$  Ga, the IIE body was presumably still very large as many IIE irons have strongly shocked silicate inclusions with Ar-Ar ages of 3.7–4.0 Ga (Bogard, 2011) (see section 4.4.1).

### 4.3. Stony-Iron Meteorites

Two major types of stony-irons — pallasites and mesosiderites — are known (Table 2). Both appear to have formed in impacts that mixed largely unshocked silicate and molten metallic Fe-Ni (Benedix et al., 2014; Krot et al., 2014). Pallasites, which formed by impact mixing of core metal with mantle olivine, are largely from the so-called “main group.” Five Eagle Station types constitute a second group and there are another ~5–7 ungrouped pallasites.

Diverse cooling rates and paleomagnetic properties show that the main-group pallasites did not cool at the core-mantle boundary of an asteroid (Yang et al., 2010a; Tarduno et al., 2012). Metal and possibly some olivine were probably extracted by a low-velocity impact with a larger body (Asphaug et al., 2006) and deposited in the mantle of the larger body that contained a core-dynamo. Interestingly, there are no iron or olivine-rich meteorites that are genetically related to the main-group or Eagle Station pallasites. [IIIAB irons were once thought to be related to the main group, but their cooling rates and chemical compositions suggest they crystallized inward, whereas the metal in main-group pallasites was probably derived from a core that crystallized outward (Yang et al., 2010a)]. Metal was efficiently mixed with olivine so that olivine-free metal regions are  $\leq 1$  m in size, and olivine mantle chunks without metallic armor were fractured along grain boundaries and are too weak to survive as meteorites. The time of metal-olivine mixing is not well constrained, but Mn-Cr systematics suggest 4558 Ma or possibly earlier for the main group (Lugmair and Shukolyukov, 1998).

Mesosiderites formed by mixing of basaltic and gabbroic silicate from a Vesta-like body with molten Fe-Ni, probably from the core of a second asteroid (Benedix et al., 2014). They cooled through 500°C slower than any other meteorites at  $\sim 0.5^\circ\text{C m.y.}^{-1}$  for  $\sim 700$  m.y. (Goldstein et al., 2014). Argon-argon ages of 3.7–4.0 Ga reflect slow cooling, not impact reheating or excavation (Bogard, 2011). The anomalous mesosiderite Chaunskij contains cordierite, which formed at a pressure of 6 Kbar, probably in a body that was  $>400$  km in radius (Petaev et al., 2000). The time of metal-silicate mixing was previously thought from Sm-Nd ages of clasts to have been  $\sim 100$ –150 m.y. after CAIs (Stewart et al., 1994), but a reinterpretation of these ages by Ganguly and Tirone (2001) suggests that they date slow cooling and that molten metal and silicate were mixed at 4.56 Ga. The low shock levels in pallasites and mesosiderites and the efficient mixing of molten metal with silicate suggest that mixing occurred during accretion in a low-velocity impact.

### 4.4. Achondrites

**4.4.1. Eucrites.** The largest group of achondrites — the howardites, eucrites, and howardites, which are eucrite-diogenite breccias — are almost certainly from (4) Vesta (McCord et al., 1970; Keil, 2002; see also the chapter by Russell et al. in this volume). Vesta is a unique body as it appears to be the only differentiated asteroid that has retained

its core, mantle, and basaltic crust. [For a contrary view, see Consolmagno et al. (2015).] Although the effects of early impacts are commonly neglected, impacts were common during igneous processing, as many diogenites and eucrites have excessively high concentrations of siderophiles. Dale et al. (2012) attribute these high siderophile concentrations and those in other achondrites to chondritic projectiles. However, differentiated projectiles with molten cores and mantles cannot be excluded, as they also have chondritic bulk compositions.

Most eucrites and diogenites were strongly shocked and brecciated at 3.7–4.1 Ga during the late heavy bombardment (Bogard, 2011; Marchi et al. 2013), but a small group of pristine unshocked eucrites with Ar-Ar ages of 4.48 Ga may have been removed from Vesta long before the other eucrites. (This Ar-Ar age should be increased by  $\sim 0.03$  Ga to allow for half-life and other corrections.) Bogard and Garrison (2003) suggested that they were extracted from Vesta by a hypervelocity impact at that time and stored in a small body. Small asteroids that survived the late heavy bombardment intact lack shock-heated meteorites from this era. Large asteroids preferentially retain shocked rocks more efficiently and sustain larger, high-velocity impacts that deposit vastly more impact energy per kilogram of target (see also Marchi et al., 2013).

At least two ungrouped eucrites, NWA 011 and Ibitira, and possibly several others, are isotopically and chemically so different from normal eucrites that they probably come from other bodies (Mittlefehldt, 2005; Scott et al., 2009; Sanborn and Yin, 2014). These bodies were probably  $>100$  km in radius, as smaller bodies would probably have lost their basalts during explosive volcanism (Wilson and Keil, 1991). The ungrouped eucrites, unlike normal eucrites, appear to have escaped the effects of the late heavy bombardment and may have been extracted from their parent bodies before 4.0 Ga, like the 4.48-Ga-old unbrecciated eucrites. The ungrouped eucrites are not related to other types of achondrites or iron meteorites and are plausibly fragments from the small V-type asteroids that orbit far beyond Vesta (section 3.1).

**4.4.2. Angrites.** Angrites are unbrecciated and substantially unshocked igneous rocks of roughly basaltic composition that have preserved a record of early igneous activity in a large asteroid and paleomagnetic evidence for a core dynamo (Weiss et al., 2008; Keil, 2011). Hafnium-tungsten isotopic data show that the core formed  $<2$  m.y. after CAIs but not in a single event from a homogeneous magna ocean. Kleine et al. (2012) infer that planetesimals impacted the angrite parent body during core formation. The lack of shock and breccia features in angrites suggests they were removed from their parent asteroid before the late heavy bombardment (Scott and Bottke, 2011), like the unbrecciated eucrites (Bogard and Garrison, 2003).

**4.4.3. Aubrites.** Aubrites, which are enstatite achondrites, are regolith or fragmental breccias and are probably derived from one or more E-type asteroids in the Hungaria region (section 3.4). The absence of associated metal-rich meteorites or asteroids suggests that these asteroids may

have been emplaced in the Hungaria region after disruption of their parent asteroid. One ungrouped aubrite, Shallowater, which contains about ~15% of inclusions of enstatite chondrite material, provided the first meteorite evidence for very early major impacts that involved a molten planetesimal. *Keil et al.* (1989) inferred that Shallowater formed after a chondritic projectile had disrupted a molten aubritic body during a low-velocity impact. The chondritic material may also have been derived from an unmelted crust on the molten body. The ancient I-Xe age of Shallowater of 4561 Ma (Fig. 1) shows that this impact occurred about 5 m.y. after CAI formation. The thermal history of the metal grains suggests that the parent asteroid suffered two other catastrophic impacts as it cooled (*Keil et al.*, 1989).

**4.4.4. Ureilites.** Ureilites are coarse-grained carbon-bearing ultramafic rocks that formed as residues from partial melting at temperatures of ~1100°C (*Krot et al.*, 2014). The presence of uninverted pigeonite, or nanometer-scale augite exsolution lamellae (*Mikouchi et al.*, 2010), and high-Ca olivine shows that ureilites rapidly cooled from ~1100°C to <650°C in hours, and the high level of shock effects in silicates suggests that this resulted from a hypervelocity catastrophic impact (*Goodrich et al.*, 2004, 2015). To cool in hours, the fragments must have been meter-sized prior to reaccretion. The energy for dispersing the fragments was not solely kinetic as the effect of the impact was analogous to removing the cork from a champagne bottle. The reduction in lithostatic pressure allowed carbon to react with silicates, forming a CO-CO<sub>2</sub> mixture and leaving tiny Fe metal grains on the edges of the olivine grains. Release of gas helped to catastrophically fragment the rock and temporarily disperse the fragments. The impact probably occurred 5 m.y. after CAIs (Fig. 1), as this is the age of basaltic fragments from ureilite breccias containing feldspar crystals and glass (*Goodrich et al.*, 2010, 2015).

#### 4.5. Primitive Achondrites

Several groups of meteorites experienced low degrees of melting and mobilization of silicate and FeNi-FeS phases. They are commonly called primitive achondrites and include acapulcoites, lodranites, brachinites, and winonaites (Table 2) (*Krot et al.*, 2014). The least-metamorphosed acapulcoites and winonaites still contain rare relict chondrules but most primitive achondrites have recrystallized, granular textures and are typically enriched or depleted in low-temperature silicate and metallic melts. None of these meteorites are fragmental breccias and most are unshocked or only lightly shocked (stages S1–S2). Note that there are no clear-cut divisions between achondrites and primitive achondrites. Brachinites, for example, are considered by some authors to be achondrites, and ureilites have also been classed as primitive achondrites.

**4.5.1. Acapulcoites and lodranites.** Acapulcoites have near-chondritic chemical compositions whereas lodranites were heated to higher temperatures and are commonly richer in metal. They clearly formed in close proximity, as some

meteorites contain both types of material due to mixing and rewelding of hot material, and others have intermediate characteristics. These meteorites have two unusual characteristics. First, metallographic cooling rates of seven acapulcoites and lodranites are 10<sup>3</sup>–10<sup>4</sup>°C m.y.<sup>-1</sup> (*McCoy et al.*, 1996, 1997) — one or more orders of magnitude higher than maximum rates for material in undisturbed asteroids heated by <sup>26</sup>Al (*Scott et al.*, 2014). Second, Ar-Ar ages of seven of these meteorites are remarkably similar: 4512 ± 9 Ma (*Bogard*, 2011). Since their diverse textures require different formation locations, their common age and rapid cooling rate suggests they were all extracted from depth by an impact, possibly a catastrophic one, before their parent body had cooled significantly. Given the well-determined Pb-Pb age of Acapulco phosphate of 4556 ± 0.5 Ma (*Göpel and Manhes*, 2010), and the required increase in the Ar-Ar ages by 30–40 m.y. due to errors in the <sup>40</sup>K decay rate (*Bogard*, 2011), it is likely that this large impact occurred 11 m.y. after CAI formation. Thermal models that assume that cooling was undisturbed by impacts (e.g., *Golabek et al.*, 2014) can only provide very approximate constraints on parent-body size and burial depth.

**4.5.2. Brachinites.** Brachinites are ancient unbrecciated and essentially unshocked rocks that are largely composed of FeO-rich olivine and pyroxene (Table 2) with heterogenous  $\Delta^{17}\text{O}$  values consistent with low degrees of melting (*Greenwood et al.*, 2012; *Keil*, 2014). There are no firm constraints on their cooling rates, but CaO concentrations in olivine are 0.08–0.3 wt.%, higher than in acapulcoite-lodranites but not as high as in ureilites (*Krot et al.*, 2014). Thus brachinites cooled rapidly enough to prevent Ca diffusing out of olivine suggesting that, like ureilites and acapulco-lodranites, they were excavated from depth by impact before they had cooled below ~1000°C.

#### 4.6. Differentiated Meteorite Parent Bodies

There are few genetic relationships among differentiated meteorites apart from the link between winonaites and IAB irons, which are probably not derived from core metal. We lack mantle or crust material from the 60-odd parent bodies of the grouped and ungrouped iron meteorites and we lack core material from the parent bodies of the various groups of achondrites and the numerous ungrouped achondrites, such as the ungrouped eucrites, Graves Nunataks (GRA) 06128 and Divnoe, which are listed in the Meteoritical Bulletin Database (see <http://www.lpi.usra.edu/meteor/metbull.php>). Our collection of differentiated meteorites resembles a collection of 1000 pieces from ~100 different jigsaw puzzles with 1–100 pieces from each puzzle. Notably missing are the olivine-rich mantle meteorites from the parent bodies of irons, stony-irons, and achondrites.

Early impacts during the first few million years are needed to remove mantles from core material or mix molten metal and silicate and to explain the properties of IIIAB, IVA, and IVB irons, pallasites, mesosiderites, and the Shallowater aubrite. Disruption of the ureilite body and

formation of CB chondrules require later hypervelocity impacts  $\sim 5$  m.y. after CAI. The IAB irons, acapulcoites and lodranites, brachinites, angrites, and anomalous eucrites were involved in major early impacts that left little evidence for shock consistent with accretionary impacts. However, some of these impacts could have occurred after asteroid accretion given that typical asteroidal impacts at current impact speeds of  $\sim 5$  km s $^{-1}$  create relatively little shocked material (Marchi et al., 2013).

Interestingly, the metal-bearing meteorites that cooled slowest at  $\sim 500^\circ\text{C}$  are the IAB irons, the pallasites, and the mesosiderites. In each case, cooling rates are rather uniform although the meteorites are not from asteroidal cores. Iron meteorites that are probably derived originally from core material, like IIIAB, IVA, and IVB irons, cooled faster than the stony-irons and silicate-rich IAB irons, and each group shows a wide range of cooling rates. This is the exact opposite of what conventional models predict. If the core samples had cooled *in situ*, their cooling rates would be uniform in each group and generally slower than those that cooled in smaller metallic pools. These cooling rates may be understood, however, if differentiated bodies were torn apart during accretion by hit-and-run collisions when the cores were still molten or partly molten (Asphaug et al., 2006). Below, we review how these impacts differ from conventional hypervelocity impacts in the current asteroid belt and how they might explain the meteoritic evidence for early low-speed impacts between planetesimals.

## 5. HIT-AND-RUN COLLISIONS

Conventional hypervelocity impacts are not effective at excavating core material from differentiated asteroids and liberating iron meteoroids as they require exceptionally large projectiles having half the target's size and, in the case of Vesta-sized bodies, exceptionally fast impact speeds (Asphaug, 2010). By contrast, grazing impacts during early planet formation at velocities comparable to the escape velocities of the colliding bodies are remarkably effective at disrupting differentiated bodies (Agnor and Asphaug, 2004; Asphaug et al., 2006; Stewart and Leinhardt, 2012). These collisions result in a very odd assortment of relics by introducing a mechanism for winnowing or stripping the lower-density mantle, crustal, and hydrospheric components from the denser deep mantle and iron core components, forming bodies whose compositions can depart substantially from the chondritic average (Asphaug and Reufer, 2014).

### 5.1. Self-Stirred Populations

Although we do not yet know how planetesimals formed, the modern assumption is that there was a phase of rapid growth that formed bodies 100 km in diameter or larger (Weidenschilling and Cuzzi, 2006; see also the chapter by Johansen et al. in this volume). This means that a population of similar-sized protoplanets or planetary embryos was accreting early on. Similar-sized collisions ( $R_1 \sim R_2$ ) are

remarkably different from cratering impacts, there being no locus to the collision. Due to geometrical effects, most of them are grazing events where the colliding matter continues downrange (Asphaug, 2010).

According to classic theories (Safronov, 1972; Wetherill, 1980), in the absence of damping by nebula gas such a population becomes gravitationally stirred by close mutual encounters, to random relative velocities  $v_{\text{rel}}$  comparable to the escape velocity  $v_{\text{esc}}$  of the largest bodies. The impact velocity  $v_{\text{imp}} = \sqrt{(v_{\text{rel}}^2 + v_{\text{esc}}^2)}$  where  $v_{\text{esc}} = \sqrt{2G(M_1 + M_2)/(R_1 + R_2)}$  is the escape velocity, the speed at which two spherical planets of masses  $M_1 > M_2$  and radii  $R_1$  and  $R_2$  collide if falling from "infinity" with zero relative velocity. It is about equal, in meters per second, to the diameters of the colliding bodies, in kilometers, thus around 100 m s $^{-1}$  during planetesimal accretion and around 10 km s $^{-1}$  during late-stage planet formation. Impacts occurring during planetesimal accretion would not generally have involved shocks.

Relative motions are damped by smaller planetesimals and gas, and are excited by larger embryos and by resonant gravitational perturbations by large planets outside the protoplanetary region. There is always some random relative velocity, so that impacts are always somewhat faster than  $v_{\text{esc}}$ . Accretion is never completely efficient, but the surprising thing is that only a modest random velocity,  $\sim(2/3)v_{\text{esc}}$ , is sufficient to reduce accretion efficiency so that hit-and-run collisions are as frequent as coagulation (Agnor and Asphaug, 2004; Asphaug, 2010). Moreover, it makes the disruption behave in a systematically biased sort of way, as we shall see.

Disruption in turn feeds back into the population of small particles that can damp velocities, so that accretion efficiency can go back and forth as early planet formation continues. Meteorites that constitute the record of this epoch are therefore expected to represent this wide range of outcomes: effective coagulation, and more energetic mantle-stripping impacts. The outcomes that do not ultimately result in accretion into planets are those that are sampled by the meteorite collection.

The accretion efficiency  $\xi$  is defined as  $(M_F - M_1)/M_2$  where  $M_F < M_1 + M_2$  is the mass of the final largest body (Asphaug, 2009). For velocities characteristic of late-stage planet formation,  $0.7 \leq v_{\text{rel}}/v_{\text{esc}} \leq 2.5$ , it has been shown that about half of similar-sized collisions are hit and run ( $\xi \approx 0$ ), in which  $M_2$  bounces off or plows through  $M_1$ , becoming a mantle-stripped relic or chain of iron-rich bodies (Agnor and Asphaug, 2004; Asphaug et al., 2006; O'Brien et al., 2006; Asphaug, 2009; Chambers, 2013).

Higher-velocity collisions with  $v_{\text{rel}}/v_{\text{esc}} \geq \sim 3$  erode increasing fractions of the target ( $\xi < 0$ ). But catastrophic disruption of  $M_1$  requires  $v_{\text{imp}} \gg v_{\text{esc}}$ , so does not occur during accretion. Catastrophic disruption of  $M_2$ , on the other hand, is an intimate aspect of pairwise accretion, even under low relative velocities. The sensitivity of  $\xi$  over the expected velocity range leads to spectacularly diverse non-accretionary outcomes, and to the evolution, by attrition, of a highly varied assortment of unaccreted objects — mantles segregated from cores by hit-and-run events and partial accretions.

## 5.2. Mantle Stripping During Accretion

Mantle stripping during accretion has little to do with blasting material from the target into orbit or into escaping trajectories. This is especially the case for planetesimal accretion, where the collisional velocities are too slow to induce shocks. Rather, it is the two-body interaction that causes mantle material to be lost. It is not blasted off the target; it is unaccreted from the projectile.

Lower-density materials at or near the surface of  $M_2$  (i.e., the mantle, crust, hydrosphere, and atmosphere) are slung onto noncapture trajectories, while higher-density materials can be stopped effectively and sink to join the target core, or can skip off the target and be segregated into chains of iron-rich clumps and iron-poor debris. Before we present simulations of examples of such events, here we simply notice two facts: (1) the diversity of outcomes is enormous, and (2) to first order, hit and run is as common as accretion.

One very important dynamical fact is that mantle stripping by hit and run provides a permanent sink for these “lost” (unaccreted) silicates that are missing from our meteorite collections. Following a hit-and-run collision, the target  $M_1$  is orbiting the Sun along with  $M_2$  on crossing orbits. The collisional cross section of  $M_1$  is larger than  $M_2$  by approximately the geometric cross section  $\sim R_2 \times$  the gravitational focusing  $f = 1 + (v_{\text{esc}}/v_{\text{rel}})^2$ , the latter increasing with  $R \propto v_{\text{esc}}$ . Consequently  $M_1$  accretes most of the stripped mantle from  $M_2$  during the thousands of orbits following a collision.

While  $M_1$  sweeps up most of the debris, it will likewise sweep up  $M_2$  in one or more subsequent collisions, causing  $M_2$  to disappear unless gravitational perturbations or tidal migrations or other collisions isolate it from  $M_1$ . This has sometimes been regarded by dynamical modelers as discounting the relevance of hit-and-run collisions, since eventually all the mess gets swept up by  $M_1$ .

But when one considers the statistics of survivors — i.e., the attrition bias of the relics of planet formation (*Asphaug and Reufer, 2014*) — one finds that in fact survivors of multiple hit-and-run collisions will not only be present, but will be common in typical pairwise-accretion scenarios. If a population of  $N$  bodies accretes forming planets and leaves behind  $N_{\text{final}}$  unaccreted original bodies, then the average number of hit-and-run collisions experienced by the unaccreted remnants will be approximately  $h \sim \ln(N/N_{\text{final}})$ . The stronger the attrition (the smaller  $N_{\text{final}}/N$ ), not only the greater the average  $h$ , but the wider the spread in  $h$  — i.e., the greater the diversity.

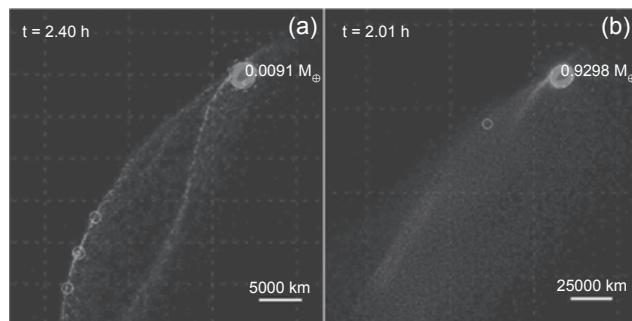

On this basis, *Asphaug and Reufer (2014)* argue that Mars and Mercury, if original remnants of an original  $\sim 20$  bodies that accreted to form Earth and Venus, would be expected to have one survivor of  $\sim 2$  hit-and-run collisions, and one survivor that is relatively unperturbed by unaccretionary collisions. If tens of thousands of planetesimals accreted to form a few thousand asteroid progenitors, then  $h = \sim 3$ . Bodies like (16) Psyche and the stripped cores of the iron meteorite parent bodies could have experienced several hit-and-run collisions as the accretionary mergers

took place, while Vesta would be a survivor of few if any hit-and-run collisions.

While it may seem far-fetched to invoke multiple hit-and-run collisions for mantle stripping of planetesimals and planetary embryos, the theoretical basis for this idea has been established, and is in fact validated to some extent in the latest dynamical models. In the first N-body integrations to track the remnants of hit-and-run collisions, *Chambers (2013)* finds cases where terrestrial protoplanets experience multiple hit-and-run collisions and then become dynamically isolated. Obviously there is much work to be done on understanding the influence of imperfect accretion on the dynamics of planet formation; here we now look more closely at the aftermath of such encounters between planetesimals.

## 5.3. Subsonic Hit-and-Run

Subsonic hit-and-run collisions between planetesimals are as effective at removing mantle silicates as their hypervelocity counterparts between embryos, but do so differently as illustrated by comparison simulations (Fig. 6), where  $M_2/M_1 = 0.20$ ,  $\theta = 30^\circ$ ,  $v_{\text{imp}} = 3 v_{\text{esc}}$ , but one is subsonic, the other supersonic. In each case the core and mantle are effectively segregated, but the collision on the right, into an Earth-mass target, induces strong shocks that vaporize the escaping material and cause its dispersal. The smaller collision on the left, into a target  $0.0091 M_\oplus$  but otherwise similar in scale, shreds  $M_2$  according to subsonic mechanical and gravitational interactions, segregating it by density into chains of metal-rich and metal-free clumps, without shock heating.

**Fig. 6.** See Plate 19 for color version. Simulations of two collisions with the same  $M_2/M_1 = 0.2$ ,  $\theta = 30^\circ$ ,  $v_{\text{imp}} = 3 v_{\text{esc}}$ , but differing in mass by a factor of 100. Both are shown at  $\sim 10$  collision times,  $\tau_{\text{coll}} = 2(R_1 + R_2)/v_{\text{imp}}$ . Silicates (red) are segregated from metals (blue) in the remnants of  $M_2$  and are dispersed downrange in both hit-and-run collisions. The subsonic collision (left;  $R_1 = 1400$  km,  $R_2 = 800$  km) leads to a chain of iron-dominated clumps (white circles) stripped gravitationally and mechanically from a sheet of lower-density mantle material. The supersonic collision (right;  $M_1 = M_\oplus$ ,  $v_{\text{imp}} \approx 30$  km s $^{-1}$ ), produces intense global shocks and fine dispersal of the plume. After *Asphaug and Reufer (2014)*.

Subsonic hit-and-run collisions among accreting planetesimals provide an evolutionary pathway that is perhaps highly relevant to the major asteroids such as Psyche that appear metallic and the parent asteroids of iron meteorites that also lost their mantles (Yang et al., 2007; Goldstein et al., 2009) (section 4.2.1). Removal of mantles from cores by conventional hypervelocity impacts (e.g., Burbine et al., 1996) is a long-standing problem, as it requires repeated giant impacts from projectiles with half the target's size, while leaving Vesta's crust intact (Davis et al., 1985).

Iron fraction and diversity in this scenario are not an aspect of the planetesimals' starting compositions — they all might start out chondritic — but a consequence of varying the number and type of hit-and-run collisions experienced by each survivor. It is unlikely for an asteroid parent body to have suffered repeated hit-and-run collisions during terrestrial planet formation, but it is even less likely for it to have not been accreted. This motivates the attrition bias argument (Asphaug and Reufer, 2014) for the preponderance of hit-and-run relics among asteroids. To not be accreted means to either be dynamically isolated from the accretionary swarm from the beginning ( $h = 0$ ), or to be lucky (unaccreted; hit and run) every time there is a collision with a larger body. So in the end, this selection bias strongly influences the surviving population.

The timing of all these collisions would have been very early, within the first few million years when the planetesimals were growing into protoplanetary embryos. Multiple mantle-stripping impacts while the bodies were solidifying would be the right recipe for a thin-skinned solidifying core such as is inferred from modeling of the IVA iron cooling rates (section 4.2.1). However, detailed modeling is needed that feeds the output of the first hit-and-run collision, into a second hit-and-run collision, and a third.

Of course, as Fig. 6 makes clear, not all the hit-and-run remnants are iron-rich clumps. Some hit-and-run collisions swallow the core and leave the mantle escaping downrange (Reufer et al., 2012). Such impacts could account for the formation of stony-irons (section 4.3). Subsonic hit-and-run collisions leave behind surviving blobs of silicate relics subject to varying degrees of deformation and pressure release (Asphaug et al., 2006), whose genetic relationship to irons would be complex — a topic of further study.

## 6. COLLISION AND DYNAMICAL EVOLUTION MODELS

If differentiated asteroids were derived from numerous Vesta-like bodies as a result of impacts in the asteroid belt, the distribution of differentiated asteroids would be very different from what we observe today. Collision and dynamical evolution modeling indicates the asteroid belt has experienced a limited amount of collisional evolution over its history (see the chapter by Bottke et al. in this volume). The existence of a very small number of differentiated asteroid families in the current main belt, the survival of Vesta's crust, and the fact that Vesta only has two very large basins collectively

suggest that comminution in the asteroid belt has been insufficient to disrupt numerous differentiated bodies down to their cores and erase silicate fragments. It appears likely that only a modest number of large fully and partially differentiated bodies ever existed in the main belt, and most of these (like Vesta) were large enough to survive intact to recent times.

To test this assertion, we have explored a scenario where Vesta once had "sister" objects in the main belt (Bottke, 2014). The idea would be that the asteroid belt once had considerably more mass in its primordial era, including several Vestas, but that most of this material was eliminated by a dynamical depletion process, such as sweeping resonances associated with planet migration, ejection of material by interaction with planetary embryos, or Jupiter migrating across the asteroid belt in the Grand Tack model (Walsh et al., 2011, 2012; see also the chapter by Morbidelli et al. in this volume). This would potentially allow ancient cratering events on Vesta's long-lost sisters to explain the V-types seen in the central and outer main belt.

Our simulations used *Boulder*, a collisional code capable of simulating the dynamical depletion and collisional fragmentation of multiple planetesimal populations using a statistical particle-in-the-box approach (Morbidelli et al., 2009). We input into *Boulder* an estimate of the primordial main-belt size distribution stretched across many semimajor axis zones as well as a preset number of Vesta-like objects. The primordial main belt was assumed to be  $N$  times larger than the currently observed population and simulations were run with 1, 2, 3, . . . ,  $N$  Vestas in that population. We tracked these populations and their fragments for hundreds of millions of years until the putative time of late giant planet migration at  $\sim 4$  Ga. At that time, we assumed that a dynamical depletion event took place that removed most of the main belt's excess mass. From that point, collisional grinding over the next 4 G.y. was set to reproduce the current main-belt population. Over all this, we assumed that impacts on Vesta-like objects would produce fragments that were distinct (in spectroscopic signatures, colors, and albedos) from background asteroids, as the V-types are today in the main belt. When the model reached the current time, a successful run was one that was able to reproduce the current main belt and the observed V-type size distributions in the inner and central/outer main belt within tolerance limits.

Our results, while still preliminary, suggest the history of Vesta and her putative sisters can be used to constrain main-belt history. We find that an excited primordial main belt with more than 3–4 Vestas after the first few million years of its history produces too many V-type fragments compared to observations; collisional and dynamical evolution over 4.5 G.y. cannot get rid of all the evidence. Accordingly, it is likely that fewer than 3–4 Vestas existed in the main-belt region after the first few million years of its history. Collisions on these bodies prior to their dynamical removal are a plausible way to explain the V-types seen in the central/outer main belt, provided dynamical mechanisms allow one to get rid of Vesta's sisters at a later time. These results are also consistent with dynamical work indicating that the

primordial asteroid belt only lost, at best, a factor of  $\sim 1\text{--}4 \times$  its population during giant planet migration as described by the Nice model (see the chapter by Morbidelli et al. in this volume). Perhaps more importantly, this scenario shows how difficult it is for collisional evolution in the main belt to produce the putative core and mantle fragments observed today; if impacts could easily extract this material from the depths of differentiated asteroids like Vesta, one would also expect to see many more V-type and related asteroids.

### 6.1. Differentiated Planetesimals and Their Fragments from the Terrestrial Planet Region

To glean insights into the origin of the differentiated material in the asteroid belt, it is useful to take a step back and consider this issue from the perspective of planetesimal formation, namely accretion timescales and planetesimal heating mechanisms.

While precise accretion timescales for planetesimals forming all across the inner solar system are unknown (see the chapter by Johansen et al. in this volume), modeling work suggests they probably vary with swarm density and semimajor axis, such that accretion timescales become longer with increasing heliocentric distance, at least until the so-called “snowline” is reached. Given that  $^{26}\text{Al}$  was the major heat source for melting asteroids (section 2.2), the earliest planetesimals would have formed in the terrestrial planet region and they are more likely to be heavily metamorphosed or differentiated compared to same-sized bodies forming in the asteroid belt. Interestingly, this internal heating trend is largely consistent with trends observed among large main-belt asteroids: S-complex asteroids, believed to be analogous to metamorphosed but unmelted ordinary chondrites, dominate the inner main belt, while C-complex asteroids, many analogous to more primitive carbonaceous chondrites, dominate the outer main belt (see the chapter by DeMeo et al. in this volume).

The best place to form large differentiated planetesimals may also be the most likely location for them to undergo hit-and-run collisions. In the first few million years of solar system history, the terrestrial planet region was filled with planetary embryos and differentiated planetesimals (see the chapter by Morbidelli et al. in this volume). Collisions between these bodies would have been common, with the outcome leading to terrestrial planets. Hit-and-run collisions between differentiated planetesimals and larger protoplanets in the interim would have led to numerous aggregates made up of diverse proportions of crust, mantle, and core, as well as a sea of smaller fragments. These bodies would then undergo their own collisional and dynamical evolution, with the vast majority lost by comminution, by accretion with larger bodies in the terrestrial planet region, or by being ejected out of the inner solar system via a Jupiter encounter. Only the largest, strongest, or most fortunate bodies would survive for very long. We speculate that the population of objects left behind by hit-and-run collisions includes the M-type asteroids, some which are exposed core material, and others of which may be a “hodgepodge” of crust, mantle, and core (referred to here

as hodgepodge worlds). In addition, these collisions would have generated A-type asteroids and possibly some S-types that are also hodgepodge bodies. (We infer that V-types have deep spectral features with little space weathering because they lack metal and troilite, and that metal/troilite mixed with differentiated material will be space weathered so that it has spectral properties like S-type asteroids.)

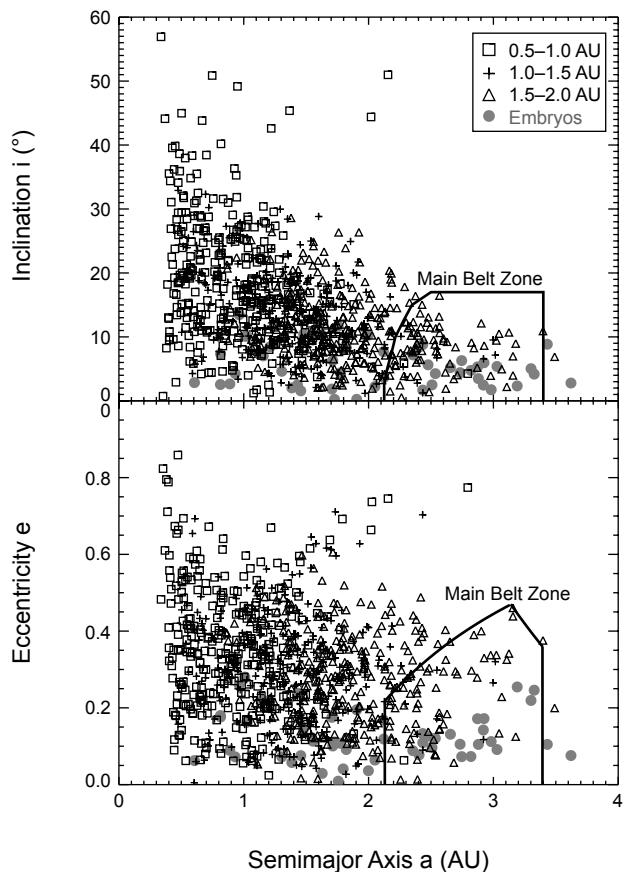

*Bottke et al.* (2006) argued on these grounds that some fraction of the differentiated planetesimals made their way into the main belt region via early dynamical processes. Subsequent evidence for the early destruction of molten or semimolten parent bodies of iron meteorites (section 4.2) suggests that the flux of material from the terrestrial planet region into the asteroid belt may have been dominated by debris from differentiated planetesimals. This process helps to explain why the asteroid belt has a larger-than-expected number of fragments that appear to come from differentiated planetesimals, yet could still be dominated by nondifferentiated material. The wide variety of parent bodies represented in iron meteorites would also be naturally explained as a byproduct of collisional and dynamical evolution of planetesimals and protoplanets in the terrestrial planet region. We infer that the parent bodies of non-Vestan differentiated meteorites were largely disrupted before they were inserted into the asteroid belt, rather than “battered to bits” *in situ* within the asteroid belt (*Burbine et al.*, 1996).

### 6.2. Dynamical Scenarios for Captured Assemblages of Differentiated Materials

Here we present several dynamical scenarios that could plausibly move material from the terrestrial planet zone to stable orbits within the main-belt region.

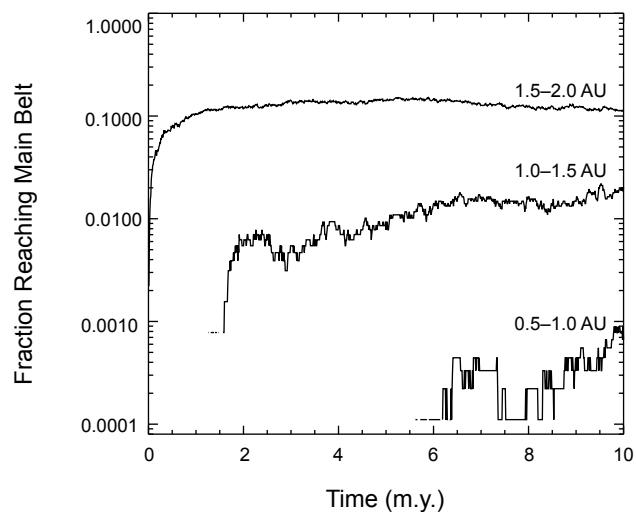

The first, and arguably the simplest, involves gravitational scattering among planetary embryos (*Bottke et al.*, 2006). Here planetesimals and their fragments evolved amid a swarm of Moon- to Mars-sized bodies spread between Mercury’s current location to within the asteroid belt. In this scenario, the S- and C-complex asteroid populations that dominate the various zones of the asteroid belt (e.g., *Petit et al.*, 2002; *DeMeo and Carry*, 2014) were assumed to form more or less *in situ*, such that only a rather limited amount of material was scattered outward from the terrestrial planet region into the asteroid belt.

Numerical runs show that even a few million years is sufficient to scatter a small fraction of terrestrial planet material onto stable orbits within the main-belt zone, provided the planetary embryos are distributed as suggested by *Bottke et al.* (2006) (Figs. 7 and 8). A compelling element to these runs is that they are consistent with the limited degree of semimajor axis mixing of large S- and C-type asteroids in the main belt (i.e., no exceptional process is needed here). Some key questions for this model, however, are whether planetary embryos ever existed in the asteroid belt, and if they did, how long they resided there before being dispersed by the formation and/or migration of Jupiter (see the chapter by Morbidelli et al. in this volume).

**Fig. 7.** Inclinations, eccentricities, and semimajor axes of planetesimals and planetary embryos in the inner solar system after 10 m.y. of dynamical evolution (Bottke et al., 2006). The planetesimals were given uniform semimajor axis between 0.5 and 2.0 AU and low random eccentricities and inclinations. The squares, crosses, and triangles show what happens to 1000 planetesimals started with semimajor axes of 0.5–1.0 AU, 1.0–1.5 AU, and 1.5–2.0 AU, respectively. The black line shows the location of the main asteroid belt. Numerous planetary embryos, which are shown as gray dots, are distributed between 0.5 and 3.6 AU. We see that numerous planetesimals from different zones were driven into the main belt by gravitational interactions with planetary embryos. After Bottke et al. (2006).

A second scenario involves scattering/capture opportunities within the so-called Grand Tack model, which assumes that Jupiter interacted with the nebular disk and migrated across the primordial asteroid belt within the first few million years of solar system history (Walsh et al., 2011, 2012; see also the chapter by Morbidelli et al. in this volume). Here planetesimals and fragments from the terrestrial planet region would have had the opportunity to reach stable main-belt orbits via interactions with Jupiter. As Jupiter migrated inward across the asteroid belt, main-belt planetesimals would have been scattered onto highly eccentric orbits within the terrestrial planet region, mixing with planetesimals scattered by planetary embryos. When Jupiter turned around and migrated back outward toward its current orbit, many eccentric

**Fig. 8.** The fraction of inner solar system planetesimals from 0.5–1.0 AU, 1.0–1.5 AU, and 1.5–2.0 AU scattered into the main belt by gravitational interactions with planetary embryos (see Fig. 7) (Bottke et al., 2006). The largest proportion of test bodies reaching the main belt is from the adjacent 1.5–2.0-AU zone. For the 1.0–1.5-AU zone, 0.8–2% are injected into the main belt after a delay of 2 m.y., while for 0.5–1.0 AU we find that 0.01–0.1% enter after 6 m.y. This shows that material from the terrestrial planet region may be found in the main belt today. Key factors here are the existence of planetary embryos in all zones of interest and the formation time of Jupiter, which is assumed to have had a hand in eliminating embryos from the main belt. Note that giant planets are neglected in this model. After Bottke et al. (2006).

planetesimals would have been implanted in the main-belt zone, thereby providing a source for differentiated material. Jupiter's migration also implants planetesimals from the Jupiter-Saturn zone into the main-belt zone, where they potentially would make up the C-complex population. Finally, the Grand Tack model allows planetary embryos to reside in the primordial main belt prior to Jupiter's early migration. This means the implantation scenario discussed above would also be active until Jupiter scattered the planetary embryos out of the main-belt region.

A key question here is whether the implantation of differentiated material can be used to test the Grand Tack; too much material, or too little, could place constraints on this putative planet-formation mechanism. An addendum to this model would be to consider how much terrestrial planet material was placed into the main belt prior to the migration of Jupiter via the first scenario, which presumably took place a few million years after CAI formation.

In a third scenario, we present promising but preliminary work within the context of the Nice model (see the chapter by Morbidelli et al. in this volume). Here the giant planets were assumed to reside for hundreds of millions of years on nearly circular, coplanar orbits in a much more compact configuration than they have today (all between 5 and 12 AU). This not only means that their mean-motion resonances were

once in different locations than we see them today, but also that they once may have been stabilizing for objects trapped inside [e.g., Neptune's mean-motion resonances are stabilizing for Pluto and other resonant Kuiper belt objects (*Levison et al.*, 2008)]. This could also explain why primordial “Kirkwood gaps” associated with the original locations of the giant planets have not yet been found in the main-belt region. By simulating how planetary perturbations affected test bodies started outside the primordial main-belt region, we found that a small fraction of bodies scattering off Mars were able to enter into the primordial main belt on low-eccentricity, low-inclination orbits via “fossil” mean-motion resonances, where they stayed for hundreds of millions of years. These bodies become permanently captured when the host resonances moved during late giant planet migration.

An intriguing method to test this hypothesis may involve the M-type asteroids. Let us assume for the moment that the M-types are remnants of planetesimals that went through hit-and-run collisions, as discussed above. Thus we will assume that these bodies include both exposed core material [e.g., (16) Psyche] as well as core-enriched gravitational accumulations of leftover debris referred to as hodgepodge worlds [e.g., we speculate that (21) Lutetia might be an example]. Much of the other crust and mantle would have been pulverized or altered beyond recognition by the associated effects (i.e., hydrostatic unloading, shock, reduction, and depletion) and/or subsequent collisional evolution in the terrestrial planet region.

As described above, a few M-types might survive by finding a dynamical pathway onto stable orbits within the main-belt region. This could result from any of the three scenarios discussed above. The first two, gravitational scattering among planetary embryos (*Bottke et al.*, 2006) and the Grand Tack model, would predict that M-types should be distributed in modestly random fashion across the main belt, with perhaps the highest concentrations in the inner main belt near the adjacent terrestrial planet region. In contrast, the 26 M-types with diameter  $D > 50$  km (see *Neese*, 2010) appear to be located at preferential values of semimajor axis  $a$ , and almost none are found in the inner main belt (Fig. 9). In addition, of the eight M-types with  $i < 5^\circ$ , three are at  $a = 2.42$  AU and four more are at  $a = 2.67$  AU. None show signs of coming from a family-forming collision at either locale (i.e., no clustered orbits; no associated fragment size distributions).

These values instead suggest that the third scenario related to the Nice model may be the most preferable solution. To check this idea, we performed proof-of-concept simulations that track how these kinds of planetary perturbations affect test bodies approaching the primordial main-belt region (Fig. 9). Interestingly, for particles initially scattered off Mars, we found that a small but notable fraction not only entered into the primordial main belt via these “fossil” mean-motion resonances, but they also stayed there until the end of the simulation 300 m.y. later. Additional evidence for this scenario comes from the orbits of all our large M-type asteroids (Fig. 9). If we assume Jupiter was originally located at 5.55 AU prior to the onset of late giant planet migration, we can explain why many M-types are found near primordial

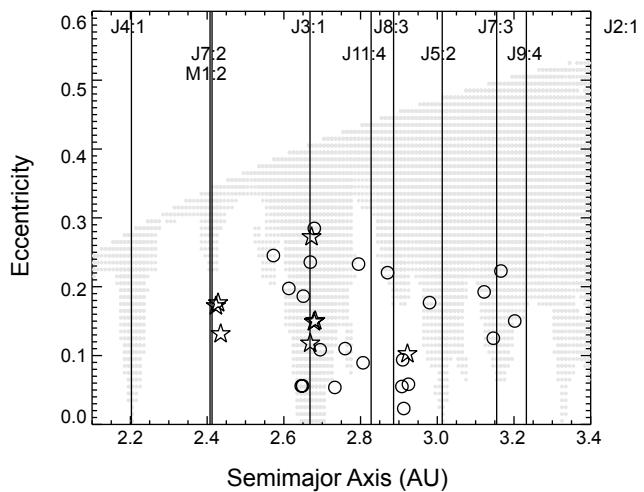

Jovian mean-motion resonances like the J3:1 (2.67 AU) and others in the central/outer main belt. The ones we cannot yet fit also show signs of promise (i.e., the J7:2 “stalactite” at 2.4 AU in Fig. 9 is close to the M-types there).

These results do not yet fit all the M-types, possibly because we lack the appropriate initial conditions for our captured asteroids as well as the starting orbits of the giant planets. Getting all the giant planets in the correct primordial configuration, while including effects like the possibility of lost giant planets (*Nesvorný*, 2011; *Nesvorný and Morbidelli*, 2012), will require a suite of careful and numerically expensive simulations.

In summary, we consider it plausible that some M-types, A types, V-types, and possibly other exotic asteroids were captured within the primordial main belt by the mechanisms discussed above. In fact, we cannot yet rule out the possibility that a large differentiated body like Vesta formed elsewhere as well, although we caution that low capture probabilities make it difficult to construct a compelling case for this idea at this time. Future studies of these scenarios, and any new ones that may arise, will be useful because they may eventually provide us with constraints on the timing and nature of planetesimal and planet formation as well as the initial orbits of the giant planets prior to early migration.

## 7. SUMMARY AND FUTURE WORK

Given the difficulties that conventional collisional processes have in explaining the differentiated meteorite record, our

**Fig. 9.** M-type asteroids ( $D > 50$  km) in the main belt are shown next to the putative primordial location of Jupiter's resonances. Here we assumed Jupiter's initial semimajor axis was 5.5 AU. The stars are M-types with  $i < 5^\circ$ , and the circles are those with  $i > 5^\circ$ . The gray dots show the orbits of scattered test bodies started in the terrestrial planet region that entered the main-belt zone with  $i < 20^\circ$ . Some were captured on long-lived orbits within the putative locations of primordial dynamical resonances; this created the stalagmite-like features. Note that the match is interesting but imperfect, probably because the orbits of the giant planets are improperly positioned.

scenario for forming differentiated asteroids and meteorites by early accretion and disaggregation of melted planetesimals in the terrestrial planet region by hit-and-run impacts offers a new road map for explaining many of their anomalous properties and puzzling origin. In particular, it helps to explain why our collection of differentiated meteorites seems to resemble handfuls of pieces from numerous different jigsaw puzzles that cannot be reassembled into meaningful pictures. This scenario can be tested with detailed field work on differentiated asteroids by spacecraft, spectral studies of smaller asteroids, improved techniques for deriving mineral abundance and composition from spectra, better chronological constraints on the formation times of differentiated meteorites, and more detailed impact and dynamical models. We are optimistic that constraints from asteroids and meteorites can be used to discriminate between different dynamical models that have been proposed to account for the low mass of the asteroid belt and the small size of Mars (e.g., *Walsh et al.*, 2011, 2012).

We attribute much of the dunite shortage among meteorites and asteroids to preferential loss of mantle material from differentiated planetesimals by hit-and-run impacts during accretion. Mixing of molten metal and silicate by accretionary impacts may account for the formation of stony-iron meteorites, and their greater strength helps to explain the lack of complementary silicate. Silicate magma in differentiated planetesimals may also have been splashed out to form chondrules, as suggested by *Asphaug et al.* (2011) and *Sanders and Scott* (2012). Formation times of chondrules are well accounted for in this model, and chondrites, except CIIs, are substantially depleted in Fe.

We have focused on one aspect of the origin and evolution of the asteroid belt during accretion but to make more progress we require a better understanding of the effects of impacts during subsequent epochs, viz., the formation of the Moon and the late heavy bombardment. We also need a better understanding of the impact history of chondrites. Did their parent bodies escape early disruption during accretion and metamorphism, as the onion-shell model requires (*Trifeloff et al.*, 2003), or were they disrupted and disaggregated when hot like the differentiated planetesimals (*Ganguly et al.*, 2013; *Scott et al.*, 2014; *Van Niekerk et al.*, 2014)?

**Acknowledgments.** We thank numerous colleagues for helpful discussions and for sharing their insights and G. Consolmagno and D. O'Brien for helpful reviews. Micrometeorite bombardment and irradiation by solar wind and cosmic-ray ions cause variations in the optical properties of small solar system bodies surfaces, affecting efforts to draw connections between specific meteorites and asteroid types. These space weathering processes have been widely studied for the Moon and S- and V-type asteroids, and they are currently being investigated for other asteroid types. Here we review the laboratory studies performed by several groups on meteorites and asteroid surface analogs, aimed at simulating space weathering by using ion irradiation and laser ablation. Together with direct evidence of weathering of particles from asteroid Itokawa acquired by the Hayabusa mission, these results have provided a fundamental contribution to the spectral interpretation of asteroid observations, to establish a solid asteroids–meteorites link, and to understand the energetic processes affecting the surfaces of minor bodies. A general scheme for asteroid optical maturation is thus emerging. Slope trends from large surveys and in particular of young asteroid families have confirmed that solar wind is the main source of rapid ( $10^4$ – $10^6$  yr) weathering, and that a number of rejuvenating processes (impacts by small meteorites, planetary encounters, regolith shaking, etc.) efficiently counterbalance the fast weathering timescales.

## 1. INTRODUCTION

Space weathering (SW) processes affect airless bodies in the solar system. These processes include irradiation by solar ion populations (solar wind, flares, solar-energetic-particle events), galactic cosmic rays, electrons, UV and X-rays, and bombardment by micrometeorites. The surface alteration varies not only as a function of the surface composition, but also location in the solar system. Generally, SW processes have been widely studied for the Moon and S- and V-type asteroids, and they are currently being investigated for other asteroid types. Fundamental reviews on SW have been published, and the reader is invited to refer to Hapke (2001), Clark et al. (2002), and Chapman (2004) for a comprehensive view of the state of the art approximately 10 years ago. At that time, the main effects of SW and the basics of the asteroid–meteorite connection had already been settled, mainly thanks to lunar studies, asteroid remote

sensing spectroscopy, and observations by the Galileo and Near Earth Asteroid Rendezvous (NEAR) spacecraft. For a more recent review on SW, the reader is referred to Gaffey (2010) and Bennett et al. (2013).

The Moon is the most-studied airless body and best-known case where SW is observed. Lunar SW has been investigated for decades (Gold, 1955; Hapke, 2001, and references therein). Its main driver is nanophase metallic iron ( $\text{npFe}^0$ ), which is produced from solar wind bombardment (Keller and McKay, 1997), and causes the reflectance spectra to become sloped (reddened) and darken in the visible–near-infrared (VIS-NIR) (Pieters et al., 2000; Taylor et al., 2001; Hapke, 2001). Inspired by the lunar SW work, investigators have wondered to what extent the same mechanisms were operating on asteroids (Chapman, 2004). Asteroidal SW has often been regarded to be important for explaining potential matches (or mismatches) between asteroid taxonomical classes and meteorite classes [see Krot et al. (2005) for a

review on the classification of meteorites, and *DeMeo et al.* (2009) for the most recent asteroid taxonomy].

The most studied case for asteroids concerns whether S-type asteroids are the parent bodies of ordinary chondrites. Numerous works have compared the mineralogy of S-types with ordinary chondrites (OCs) and have discussed implications for possible bias in the meteorite collections (see, e.g., *Gaffey et al.*, 1993; *Meibom and Clark*, 1999; and references therein). Later studies demonstrated that a VIS-NIR reddening spectral trend can be established by comparing OCs to main-belt S-types through near-Earth asteroids (NEAs) (*Binzel et al.*, 2004). This suggested that, in general terms, lunar-style SW could also be valid for asteroids. Evidence for darkening and reddening were observed on asteroids visited by spacecraft (NEAR, Galileo), but the albedo and 1- $\mu\text{m}$  band depth dependence on the surface age/morphology for (433) Eros and (243) Ida were found to be different than that observed on the Moon (*Chapman*, 1996; *Murchie et al.*, 2002; *Gaffey*, 2010). Strong evidence for a reddening trend with respect to space exposure has been found thanks to the study of young silicate-rich asteroid families. The latter confirms the major role played by the solar wind ions and the collisional resurfacing scenario in the case of S-type objects (*Brunetto et al.*, 2006a; *Marchi et al.*, 2006a; *Willman et al.*, 2008; *Vernazza et al.*, 2009a).

Some SW processes can be simulated in the laboratory using various approaches and analytical techniques (see, e.g., *Bennett et al.*, 2013). The silicate reddening and darkening spectral trends have been measured in many SW experiments performed by different groups on terrestrial silicates and OCs for application to S-types (*Hapke*, 1965; *Moroz et al.*, 1996; *Sasaki et al.*, 2001; *Strazzulla et al.*, 2005; *Marchi et al.*, 2005; *Brunetto et al.*, 2006b; *Loeffler et al.*, 2008a, 2009; *Fu et al.*, 2012). Although some differences arise between ion irradiation and laser irradiation/ablation experiments, the general SW trend is similar. Asteroid spectral modeling has been developed using laboratory SW results; the main result is that SW does not affect band center and relative areas of VIS-NIR silicate absorptions (although the area of each silicate band decreases). Little is known about the response to SW by other classes of meteorites. For instance, SW trends become more complicated and controversial when the case of dark asteroids (C-complex) is considered. Weak reddening trends have been observed by some investigators (*Lazzarin et al.*, 2006), while other studies have found a blueing effect (*Nesvorný et al.*, 2005; *Lantz et al.*, 2013; *Vernazza et al.*, 2013).

The common view of asteroid SW given in the *Asteroids III* volume (*Clark et al.*, 2002) was that studies of lunar rocks and soils were the most important basis on which to build an understanding of asteroidal SW. At that time it was not possible to directly measure asteroid surfaces in the laboratory. But in the recent years, extraordinary results have been obtained by the Japan Aerospace Exploration Agency (JAXA) Hayabusa mission, which visited and returned samples from asteroid (25143) Itokawa. Hayabusa spectrometers showed that SW effects develop on different regions (*Hiroi*

*et al.*, 2006), and returned Itokawa grains, later analyzed in the laboratory, showed multi-layered structures related to SW effects, including amorphized silicates and npFe<sup>0</sup> and iron sulfide inclusions (*Noguchi et al.*, 2011, 2014). Thus, although many questions are still open, Hayabusa results seem to confirm the general scenario of reddening and darkening first observed on the Moon and later on asteroid families.

In this chapter we will review the laboratory studies performed in the last decade on meteorites and asteroid surface analogs that were aimed at simulating SW (Table 1). We will also discuss the direct evidence of weathering observed on Itokawa samples and the spectral slope trends determined from observational surveys taken in the last decade. Open points for future investigations will be identified and discussed.

## 2. LABORATORY STUDIES ON SPACE WEATHERING

### 2.1. Overview of Laboratory Techniques

**2.1.1. Conditions and limitations considered for laboratory studies.** A complete simulation of an asteroid surface environment (including relevant pressures, temperatures, textures, and compositions) is not feasible, and thus much of the focus in laboratory studies is on trying to simulate the most important factors that are believed to contribute to SW. Three of the main characteristics regarding an asteroid's surface are its composition, temperature, and pressure.

The composition will vary from asteroid to asteroid, so laboratory experiments utilize data taken from remote sensing to try and pick a suitable sample material. Laboratory studies often focus on a single component (e.g., olivine, pyroxene, etc.) among the many associated with the asteroid to test its affinity to weathering. From a practical point of view, this will give insight into whether some of the minerals present may be more susceptible to weathering than others. The mineral is usually crushed down to a grain size relevant to the regolith, which is typically <100  $\mu\text{m}$ . The crushed grains are then pressed into a pellet (e.g., *Sasaki et al.*, 2001; *Brunetto et al.*, 2006b), so that it can be mounted at any geometry to be irradiated and analyzed.

To simulate the low-pressure environment that exists on most asteroids ( $10^{-15}$  Torr), the prepared sample is placed into a contaminant-free vacuum system, which typically ranges between  $10^{-5}$  and  $10^{-10}$  Torr (e.g., *Sasaki et al.*, 2001; *Loeffler et al.*, 2009). Finally, laboratory experiments on SW are typically performed at room temperature, even though the surfaces of asteroids can be at significantly lower temperatures and there is the potential that the irradiation effects produced in the minerals could depend on temperature. The lack of attention to this aspect is likely a result of the increased complexity involved with cooling of the sample. However, as one spectral study found that relevant mineral (olivine) reflectance spectra did vary with temperature (*Lucey et al.*, 1998), it is important to at least consider performing some of these SW studies at more relevant temperatures in the future.

TABLE 1. Summary of SW experiments performed on terrestrial and extraterrestrial materials.

Material	Ion Irradiation		Laser Irradiation	VIS-NIR Spectral Effects	Physical Mechanisms
<i>High albedo</i>					
Terrestrial olivine	Species: H, He, N, Ar; Energies = 1–400 keV	$\lambda = 193, 248, 1064 \text{ nm}$ ; Dose $\leq 800 \text{ J cm}^{-2}$ *	"	Strong spectral reddening and darkening	Formation of npFe <sup>0</sup> , structural modifications
Terrestrial pyroxene	"	"	"	Same as olivine but weaker	"
Ordinary chondrites	"	"	"	"	"
Enstatite chondrites	Ar 200 keV	Not performed		Very weak darkening	Structural modifications?
HED meteorites	C, Ar; 60, 200, 400 keV	$\lambda = 1064 \text{ nm}$		Same as OCs	Same as OCs
<i>Low albedo</i>					
Terrestrial bitumens	Same as olivine	Not performed		Very strong spectral flattening, weak brightening	H/C and gap decrease, aromaticity increase
Organic residues from C-rich ices	"	"	"	Reddening and darkening	Formation of refractory molecular solid
Organics covering silicates	H 200 keV, Ar 400 keV	"	"	"	Same as bitumens
"Bright" CC (Allende)	He, Ar 40 keV; Ar 400 keV	$\lambda = 1064 \text{ nm}$ ; pulse 0.5–1 $\mu\text{s}$		Weak reddening-darkening	OC-like?
"Dark" CC (Tagish Lake)	He, Ar 4 keV; He 200 keV	$\lambda = 1064 \text{ nm}$ ; D $\leq 10 \text{ J/}$ $\text{cm}^2$	Flattening		Bitumen-like?

\*The dose is usually provided as  $0.05\text{--}2 \text{ J cm}^{-2}$  per pulse (duration 5–10 ns or 0.5–1  $\mu\text{s}$ ) and then repeated on several shots.

References for high- and low-albedo materials are given in sections 2.2 and 2.3 respectively.

**2.1.2. Radiation processing.** An equally important characteristic to consider is the type of radiation that is going to be driving SW. For asteroids, one of the main drivers is believed to be ions (solar wind and cosmic rays). The solar wind consists of mostly hydrogen and helium ions (>99%), which have a mean energy of 1 keV per atomic mass unit (Gosling, 2007), and thus most studies have focused on using either of these ions. The other ion components of the solar wind could also potentially contribute to SW, but these are typically neglected as their flux is so low. Cosmic rays, mainly consisting of hydrogen ions, also impact the surface, albeit at a much lower flux than the solar wind ions. However, since they are more energetic, they can penetrate much deeper than the solar wind ions, and thus even though their flux may be lower, there is the potential that they may also contribute to SW. When considering ions and their interaction with the mineral samples, they can alter the surface by depositing energy as they pass through the grain, which may induce sputtering or structural and chemical changes. To first order, the degree to which these changes occur is going to depend on the stopping power of the ion, which is typically described as energy transfer through elastic (nuclear) and inelastic (electronic) collisions with the atoms in the solid. Although the two forms of energy transfer are different, both produce alteration in the target material and thus are relevant for SW.

In addition to ion irradiation, the surfaces of asteroids are also bombarded with micrometeorites, which can alter the regolith significantly. The fast ones (approximately kilometers per second) are believed to be able to slow down so quickly

that they can partially or even completely vaporize some of the surface grains. Interestingly, nanosecond-pulsed lasers at fluences higher than the ablation threshold have been used as an analog for micrometeorite impacts (Sasaki et al., 2001; Brunetto et al., 2006b; Loeffler et al., 2008a), as they are effective for depositing large amounts of energy over short amounts of time and can yield power densities similar to those estimated for micrometeorite impacts (Kissel and Krueger, 1987). Using a pulsed laser is appealing, because it can be purchased commercially, is typically small, can easily produce many pulses in a very short amount of time, and has pulses that can be rastered uniformly over a large sample area. The other more direct simulation of micrometeorite impacts is using a dust accelerator (e.g., Cintala and Hötz, 2008), yet the instrument's large size and low particle flux have made it less appealing for these types of studies; however, we note that a new facility capable of producing dust at much higher fluences is now in operation (Shu et al., 2012) that could potentially be useful for SW studies.

As an asteroid is exposed to radiation processing over timescales that are orders of magnitude longer than what is attainable in the laboratory, a critical step for the ions is that the effects depend on the total fluence ( $\text{ions cm}^{-2}$ ) and not on the actual flux ( $\text{ions cm}^{-2} \text{ s}^{-1}$ ) used in experiments. This is obtained by using ion currents [typically 1–2  $\mu\text{A}$  (microamperes)] that do not cause macroscopic heating of the sample. For laser irradiation experiments, the total energy deposited by the impacts that are fast enough to cause vaporization are compared with the total energy deposited by the laser

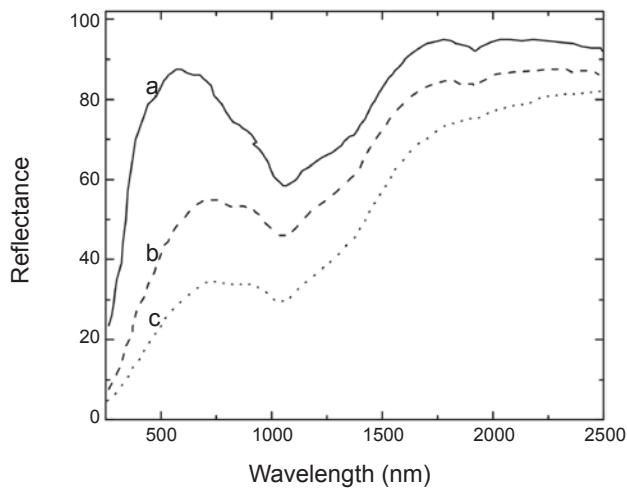

(e.g., Sasaki *et al.*, 2001; Loeffler *et al.*, 2009). However, this ends up being more of a qualitative comparison, as the vaporization of the surface minerals will be nonlinear and therefore how the energy is deposited (in one impact vs. many impacts) is critical.

**2.1.3. Analytical methods.** The main technique used for analysis of space-weathered samples in the laboratory has been VIS-NIR reflectance spectroscopy (Moroz *et al.*, 1996; Hapke, 2001, and references therein; Sasaki *et al.*, 2001; Brunetto and Strazzulla, 2005; Loeffler *et al.*, 2009), which have been performed both *in situ* and *ex situ* (i.e., in the same vacuum chamber where the alteration is performed, or outside of it). Other complementary *in situ* measurements have been used to probe the structure [Raman spectroscopy (Vernazza *et al.*, 2009b)] and surface composition [X-ray photoelectron spectroscopy (Dukes *et al.*, 1999; Davoisne *et al.*, 2008; Loeffler *et al.*, 2009)], while a number of *ex situ* techniques have been employed to look for structural and chemical changes in the grains: scanning electron microscopy SEM (Yamada *et al.*, 1999; Moroz *et al.*, 1996), transmission electron microscopy (TEM) (Sasaki *et al.*, 2001, 2003; Loeffler *et al.*, 2008a; Noble *et al.*, 2011), energy dispersive spectroscopy (EDS) (Sasaki *et al.*, 2001), and electron spin resonance (ESR) (Kurahashi *et al.*, 2002). These techniques can provide insight into the identifying characteristics of SW and when combined can provide complementary information that can help to unravel the underlying mechanisms driving SW.

## 2.2. Bright Objects

**2.2.1. Experiments on high-albedo meteorites and silicate analogs.** Many laboratory studies investigating SW relevant to asteroids have focused on the alterations produced in silicates, namely pyroxene and olivine. Most of the studies have been performed on single-component terrestrial minerals (e.g., Sasaki *et al.*, 2001; Brunetto *et al.*, 2006b; Loeffler *et al.*, 2009; Fu *et al.*, 2012), yet there have also been a number of experiments on meteorites (OCs and HEDs) that contain varying amounts of these silicates as well (e.g., Strazzulla *et al.*, 2005; Fulvio *et al.*, 2012). These silicates are of particular interest in that they can easily be identified by remote sensing spectra from their diagnostic absorption bands near 1  $\mu\text{m}$  and 2  $\mu\text{m}$  (pyroxene only). Laboratory studies show that irradiation by ions and pulsed lasers can darken (lower reflectance) and redden (cause a slope change) their spectra, as shown in Fig. 1; these findings are similar to what has been observed on lunar samples and lunar analogs and are consistent with the explanation that the spectral mismatch between OCs and their presumed parent bodies, S-type asteroids, may be explained by SW processes.

The mechanism behind the SW trends observed in these silicates has been proposed to be either due to the formation of metallic iron, e.g., iron nanoparticles, as is observed on lunar analogs (Hapke, 2001), and/or due to structural modifications/damage (Brunetto and Strazzulla, 2005). It is important to note that in all experiments the spectral changes observed for silicates and meteorites are similar and are consistent with

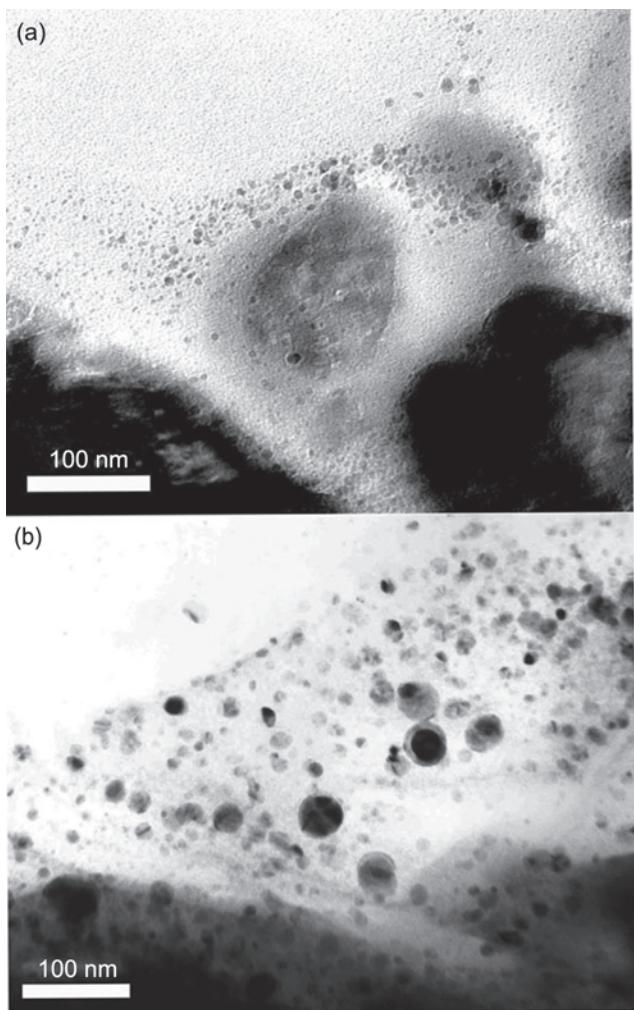

**Fig. 1.** Reflectance spectra of a <75- $\mu\text{m}$  San Carlos olivine pellet sample before (line marked "a") and after (line marked "b") one and five laser pulses from a 1064-nm laser with a fluence of 24  $\text{J cm}^{-2}$ . Spectra are adapted from Sasaki *et al.* (2001). The overall drop in reflectance is referred to as darkening, while the increase in slope, e.g., more drastic drop in reflectance at lower wavelengths, is referred to as reddening. From Sasaki *et al.* (2001), reprinted with permission of Macmillan Publishers Ltd.

the darkening and reddening mentioned previously. The presence of  $\text{npFe}^0$  (formed from oxide bound to iron) is evident through a number of studies on silicates. Sasaki *et al.* (2001) was the first to show the correlation in olivine using TEM (see Fig. 2) and he and other groups confirmed these findings using ESR (Kurahashi *et al.*, 2002). Later studies focusing on evaporated deposits produced from a pulsed laser showed that the deposits also contain metallic iron and can darken and redden the spectral reflectance (Loeffler *et al.*, 2008a). Interestingly, evaporated deposits made from iron-free forsterite ( $\text{Mg}_2\text{SiO}_4$ ) showed little spectral modification. In addition, studies using 4-keV He ions to irradiate San Carlos olivine used *in situ* XPS to correlate the formation of metallic iron with spectral reddening (Loeffler *et al.*, 2009).

Structural modification induced by bombardment has the potential to contribute to SW as well, as previous studies have shown that both olivine (Brucato *et al.*, 2004; Carrez *et al.*, 2002) and pyroxene (Demyk *et al.*, 2004; Jager *et al.*, 2003) samples are amorphized under ion bombardment. Furthermore, more recent experiments on olivine show that different crystal planes amorphize at different rates (Li *et al.*, 2013). However, in comparing experiments that used the same ion (He), the fluences needed for amorphization (Carrez *et al.*, 2002) are much lower than what was needed to observe reddening for San Carlos olivine (Loeffler *et al.*, 2009). In addition, when iron-free forsterite was irradiated well past the fluence needed for amorphization, no changes were observed in the near-infrared reflectance spectrum (Loeffler *et al.*, 2009).

The contribution of structural modification to SW for silicates may be more important in samples that have been

**Fig. 2.** Transmission electron microscope images of San Carlos olivine after irradiation with a 1064- $\mu\text{m}$  pulsed laser. The presence of npFe<sup>0</sup> are easily seen after 5 pulses (top), and are more evident and slightly larger after 20 pulses (bottom). In both cases, the laser fluence was 24 J cm<sup>-2</sup>. From Sasaki et al. (2001), reprinted with permission of Macmillan Publishers Ltd.

directly irradiated with a pulsed laser (Brunetto et al., 2006b), as the rapid melting of the sample may not only change the phase of the silicates but could also induce irregular structures that may contribute to changes in the scattering properties of the minerals. Regardless of whether alteration of the physical structure/morphology of the sample contributes to SW, it is possible that the mineral chemical structure (olivine vs. pyroxene), not simply the presence of iron bound to an oxide, may matter as laser irradiation experiments (1064 nm wavelength) showed that olivine was more easily altered by the laser than was pyroxene that contained a similar amount of iron bound to oxide (Yamada et al., 1999). However, comparing the susceptibility of different minerals to laser irradiation is complicated, as a small difference in the absorption coefficient at a given wavelength between two minerals may translate into larger

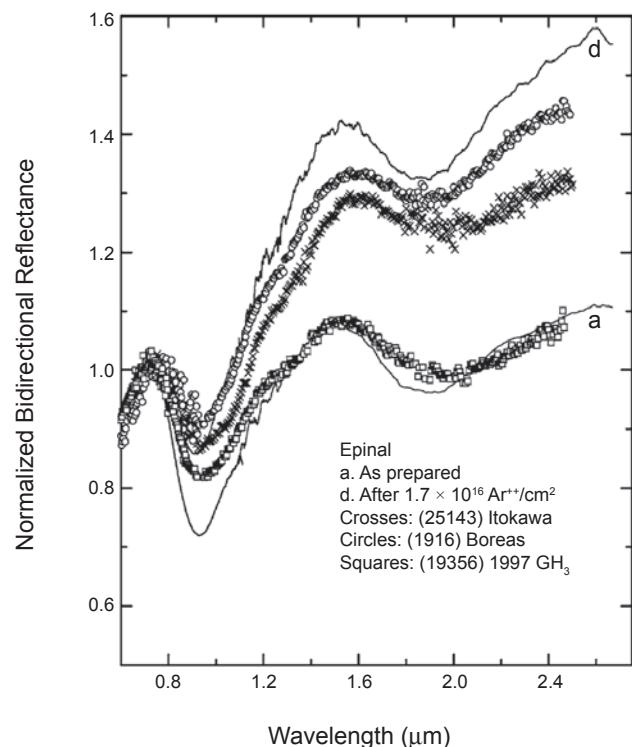

differences in the ablation, since it is a nonlinear process. For instance, a similar study using a UV laser (Brunetto et al., 2006b) showed that the reddening (slope change) induced in clinopyroxene was only 15% less than that for olivine. Thus, the importance of chemical structure on SW needs to be studied in more detail to determine whether it is a real effect or whether it is simply a consequence of the laser wavelength.

Finding evidence of weathering in samples either taken directly from extraterrestrial bodies (the Moon, asteroids) or believed to originate from them (meteorites) is a great way to substantiate that SW is an important process active on asteroid surfaces. Space weathering is clearly active on the Moon (Hapke, 2001) and on Itokawa (section 3). However, microscopy studies on meteorites have also shown characteristics expected from SW. For instance, Noble et al. (2011) used SEM and TEM to examine two meteorites (Kapoeta and Fayetteville) and found that both exhibit some glass characteristics indicative of SW products. Furthermore, Kapoeta also had an amorphous rim similar to those found on lunar grains and another region that contained npFe<sup>0</sup>, both of which are consistent with SW processing.

**2.2.2. Connection to bright asteroids (*A, Q, S, E, V*) and timescales.** Laboratory results have been applied to spectral modeling and used to interpret observations from large surveys and space missions with the high-albedo classes of asteroids [see Bus and Binzel (2002) and DeMeo et al. (2009) for a complete discussion of differences among taxonomic classes] receiving the most attention. The large number of observations obtained in the past decades combined with laboratory experiments allow the identification of a few general SW spectral trends for asteroids:

1. It had been suggested for decades that SW can be responsible for the puzzling and significant mismatch between the VIS-NIR spectra of the most populous class of meteorites (OCs) and the surface spectra of S-type near-Earth objects (NEOs) and main-belt asteroids (MBAs), their presumed asteroidal parent bodies (see Chapman, 1979, 2004; Clark et al., 2002). The reason for this mismatch has become clearer thanks to several SW experiments and to the Itokawa sample return (see section 3). For example, reflectance spectra measured after irradiating an OC meteorite with increasing ion fluence exhibit a progressive reddening that is similar to the spread of spectra observed for S-type NEAs (Fig. 3).

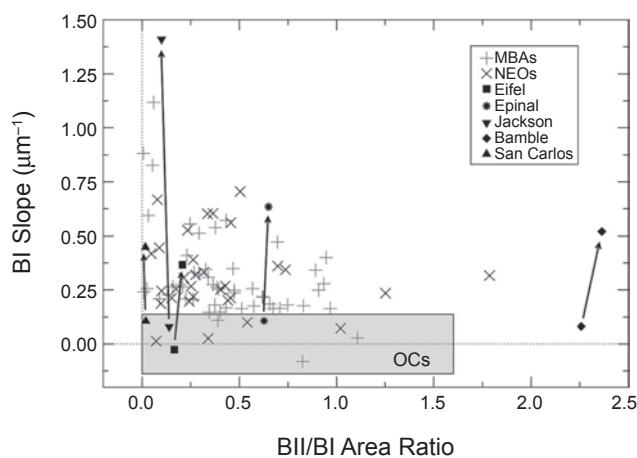

2. Analysis of the VIS-NIR spectra of a large sampling of OCs, MBAs, and NEOs showed a similar mineralogy between most asteroids and meteorites, but different distributions of spectral slopes (Marchi et al., 2005), as shown in Fig. 4. This was interpreted as a SW effect induced by solar wind ion irradiation. Experimental results can explain the shift of the OC distribution toward asteroid distributions. Spectra of unaltered and irradiated silicates have slopes that span a wider range than that observed in NEOs and MBAs. Asteroids exhibit an asymmetrical slope distribution, possibly due to a different rate of weathering between olivine-rich and pyroxene-rich asteroids, a behavior that needs to be tested by laboratory experiments.

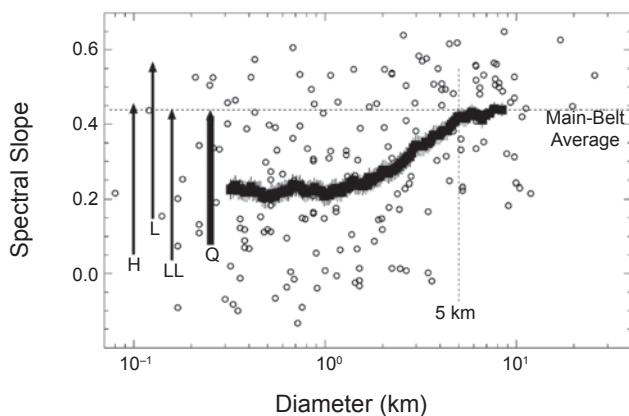

**Fig. 3.** The initial reflectance spectrum of OC Epinal and that obtained after ion irradiation (with 60 keV Ar<sup>++</sup>; only the maximum dose is shown) are shown normalized to 1 at 0.7 μm. The normalized observed spectra of three NEOs are also shown for comparison. From Strazzulla *et al.* (2005), reprinted with permission of Elsevier.

3. Studying the slope-diameter correlation for NEOs, a size-dependent transition from OC-like (Q-type) objects to S-type asteroids over the size range of 0.1–5 km (Binzel *et al.*, 2004) was observed, as reported in Fig. 5. A VIS-NIR reddening spectral trend can thus be established comparing OCs to main-belt S-types through NEAs [although an important fraction of unweathered OC-like objects may also be found among MBAs (e.g., Mothé-Diniz *et al.*, 2010; Rivkin *et al.*, 2011; Thomas *et al.*, 2012)]. The 0.1–5-km size range appears to be critical for understanding the processes, timescales, and conditions under which a regolith conducive to SW is generated, retained, and refreshed.

4. As discussed by Marchi *et al.* (2012), “the spectral reddening of an individual object can be considered as the sum of three terms, one (which is relevant for statistical analyses) depending on the exposure of the object to SW during its lifetime, a second one due to the original surface composition, and a third one (a noise term) due to the combination of poorly constrained effects (e.g. structure and texture of the surface)”. In addition, the spectral reddening induced by SW can be confused with other effects, such as surface texture or phase reddening (see, e.g., Sanchez *et al.*, 2012; Beck *et al.*, 2012). Nevertheless, it was possible to find a general correlation between the visible spectral slope of asteroids and the exposure to solar wind (Marchi *et al.*,

**Fig. 4.** Spectral slope around BI (broadband at about 1 μm due to the presence of ferrous iron Fe<sup>2+</sup> in olivine crystals but is also present in pyroxene) as a function of the BII/BII area ratio (where BII is the broad 2-μm band that is characteristic of pyroxene but not olivine) for main-belt asteroids (MBAs) and near-Earth objects (NEOs). Vertical arrows show the trend from unirradiated to irradiated silicates determined by laboratory experiments. The shaded box contains 95% of OCs; symbol dimensions correspond to error bars. From Marchi *et al.* (2005), reprinted with permission of ESO.

**Fig. 5.** VIS-NIR spectral slopes vs. diameter (open circles) for near-Earth and Mars-crossing objects residing within the S, Sq, and Q classes. A running box mean is shown by filled squares (box size = 50, with error bars depicting the standard deviation of the mean). The running box trend asymptotically approaches the mean slope (dashed line) for SMASSII main-belt S-type asteroids, reaching this limit at a size of 5 km. The evolution from typical OC-like (Q-type) to S-type surfaces is depicted by the Q-S vector. The vectors labeled “H,” “L,” and “LL” show the effects of a reddening model for OC meteorites resulting from the addition of 0.05% submicroscopic iron. The magnitude of the transition for the meteorites is comparable to the magnitude of the Q-S vector for the asteroids; see Binzel *et al.* (2004) for more details. Consistent results were obtained by Thomas *et al.* (2012) for the Koronis family. From Binzel *et al.* (2004), reprinted with permission of Elsevier.

2006a,b; Paolicchi et al., 2007), defined as the age times the inverse squared mean distance from the Sun (function of the semimajor axis and of the eccentricity). The relevance of the exposure parameter requires the dominance, at least for distances smaller than about 3–4 AU, of SW effects connected to the Sun. In other words, this suggests that solar ion flux is the main source of the asteroidal SW.

5. Finally, the color of asteroid families becomes redder with increasing dynamical age. This will be largely discussed in section 4, together with the estimation of the observational and experimental timescales for SW processes.

Inspired by the OC meteorites vs. Q-type and S-type paradigm, a few studies have been conducted to explore SW of other asteroid classes, such as A-types (Sasaki et al., 2001; Brunetto et al., 2007a; Fu et al., 2012), E-types (Vernazza et al., 2009b), and V-types (Fulvio et al., 2012). Strong reddening and darkening have been reported for A-type analogs, whereas little effects are observed on E-type analogs. The presence of iron and the nature of the target silicate seem to play a major role in determining the spectral effects. Unfortunately, there is still a lack of laboratory SW simulations on meteorites relevant to these asteroids, and many issues are open for future studies. The case of V-types seems particularly intriguing: Although SW effects (reddening and darkening) have been reported both in laboratory and observational studies (see, e.g., Marchi et al., 2010, and references therein), asteroid (4) Vesta (the parent body of vestoids and HED meteorites) is not reddened and shows peculiar signs of SW, as revealed by groundbased observations and by the recent Dawn mission (see, e.g., Pieters et al., 2012, and references therein).

### 2.3. Dark Objects

**2.3.1. Experiments on low-albedo meteorites and organic analogs and connection to dark asteroids.** Recent investigations have shown that primitive dark material (C-, P-types) accounts for more than half of the main-belt and Trojan asteroids by mass (DeMeo and Carry, 2013). From the astronomical point of view, SW trends become more complicated and controversial when we consider the case of dark asteroids. Weak reddening trends have been observed by some investigators (Lazzarin et al., 2006) while other authors have found a blueing effect (Nesvorný et al., 2005). Lantz et al. (2013) assumed that CM meteorites and Ch/Cgh asteroids are the same material (fresh subsurface and weathered surface materials respectively). They found a neutralization of the spectral slopes possibly due to SW, with few albedo and band modifications. It has been suggested many times that carbonaceous chondrites (CCs) are connected with specific classes of dark asteroids (C, D, P, B), although an unambiguous correspondence between single CC and asteroid classes has proven to be arduous.

The few irradiation experiments of dark CCs have shown what appear to be contradictory trends. Spectral reddening (and the presence of abundant silicates causing the band at about 1 μm) was observed in ion and/or laser irradiation ex-

periments of the Allende (CV3) meteorite, a CO3 meteorite, and CM Mighei (Moroz et al., 1996, 2004a; Lazzarin et al., 2006; Brunetto et al., 2014), while a flattening effect was observed in the case of the ion- or laser-irradiated Tagish Lake meteorite (Hiroi et al., 2004, 2013; Vernazza et al., 2013). In both cases, the spectral variations of irradiated CCs are much smaller than those observed on H-rich organics (see below) and also smaller than variations associated with the heterogeneity of the original composition. However, these differences may simply imply that these meteorites are at a different stage in the weathering process. To test the validity of these and other hypothesis, it is critical to perform laboratory studies on materials that are considered “analogs” of those present in astrophysical environments during different evolution phases of the solid matter.

Numerous SW experiments have been performed on different classes of carbon-bearing materials:

1. Carbon-bearing frozen gases ( $\text{CH}_4$ ,  $\text{CH}_3\text{OH}$ ,  $\text{C}_6\text{H}_6$ ) (Brunetto et al., 2006c), a reasonable analog for the icy surfaces of small objects in the outer solar system [e.g., (5145) Pholus)], have been irradiated, and it is found that the initially transparent layers exhibit a strong reddening of the spectra due to the formation of a “red” molecular solid similar to some terrestrial materials (e.g., bitumen). Further prolonged irradiation drives the material toward a spectrally flat and dark organic (C-rich) refractory residue. The color is preserved during annealing and sublimation of the residual volatiles produces a refractory material that has been called ion-produced hydrogenated amorphous carbon (IPHAC). Such a polymer-like cross-linked solid has a flat and dark spectrum, is mostly insoluble, and represents a “fully weathered material.” The experiments on ices are directly related to the icy objects in the outer solar system (Trojans, transneptunian objects, Oort cloud comets). However, they are also connected to asteroids, as some asteroids are likely remnants of icy objects and because asteroids are being continuously bombarded with interplanetary dust and micrometeorites, which may have come from icy objects. This latter hypothesis has been recently supported by the finding of dark material on Vesta (McCord et al., 2012) (see section 4.3).

2. Natural bitumens (asphaltite, kerite) (Moroz et al., 2004b) have very red spectra that resemble those obtained after moderate irradiation of the C-rich ices. Also, irradiation of these bitumens causes their spectra to become flatter and darker. Such spectral flattening is attributed to a specific modification of the carbonaceous component: a loss of hydrogen from the carbonaceous structure, an increase in aromaticity, and a consequent variation of the optical gap. These imply that the absorption coefficient increases so much that the molecules become optically thick and their spectral behavior changes from a volume-scattering regime into a surface-scattering regime. This may even induce an increase in the UV-VIS albedo.

The role of the optical gap change and hydrogen loss has been discussed in the context of SW of transneptunian objects, where dark inclusions in a transparent matrix (ice) play a major role (see, e.g., Dalle Ore et al., 2011, and

references therein). In the case of dark meteorites, silicates may play the role of semitransparent matrix for both carbon and npFe<sup>0</sup> inclusions. The chemical effects dominate the processing of carbon-based materials. The C/H (as well C/O or C/N) ratios all increase, producing a carbonization of the target. Carbon skeleton structural modifications after ion irradiation have also been observed, and they correlate with the elastic energy loss in the sample (Brunetto *et al.*, 2009). The spectral modifications observed by Moroz *et al.* (2004b) also scaled with the elastic energy loss. Figure 6a compares the spectrum of asphaltite, scaled at 0.55 μm, as deposited (the reddest spectrum) and after different ion fluences (for details, see Moroz *et al.*, 2004b). For comparison, the spectra of two asteroids, (1542) Schalen (D-type) and (5145) Pholus (Centaur), are also shown. The colors of both asteroids are similar to an initially red material (asphaltite) that has been ion irradiated.

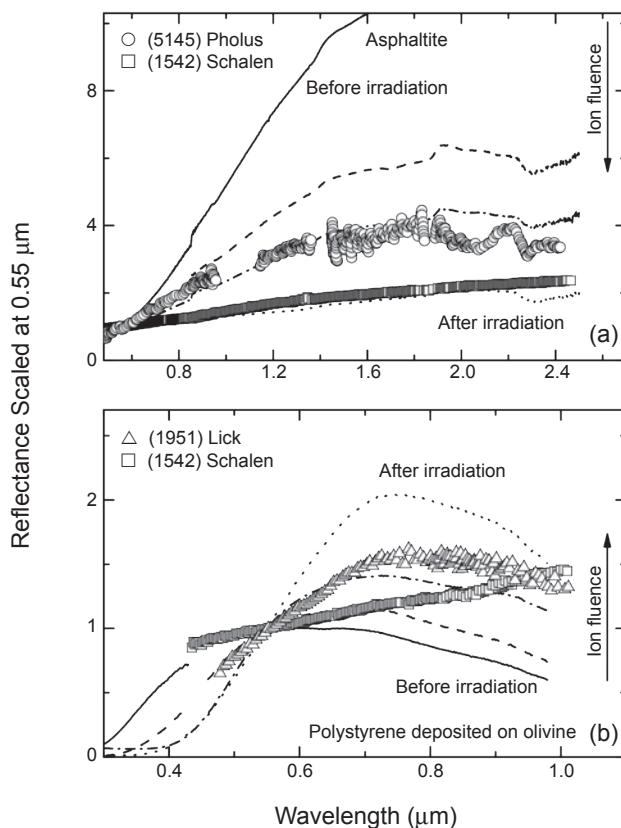

3. Recently, polystyrene, deposited on a silicate (olivine), has been studied as an analog for “fresh” organics (Kaňuchová *et al.*, 2010). The spectra of the unirradiated and irradiated samples are shown and compared to asteroids (1542) Schalen (D-type) and (1951) Lick (A-type) in Fig. 6. Deposited polystyrene is a transparent polymer, unlike asphaltite, which is initially red. Polystyrene exhibits a progressive spectral reddening and darkening during irradiation. At high irradiation doses, the reddening reaches a maximum, while the sample continues to darken and starts to flatten. Interestingly, the spectral shape of the irradiated material at different doses can reproduce some asteroid spectra. It is also noted that the material is insoluble after irradiation. On the basis of these experimental results, a reddening-blueing loop has been proposed by Kaňuchová *et al.* (2012): Irradiated organics, initially exhibiting a flat spectrum and a high albedo, are progressively reddened while the albedo decreases. At very high doses, the spectra are flattened (blueing) while the albedo continues to decrease. A fully weathered organic will then have a flat and dark spectrum.

The results from irradiation experiments and the diversity of spectral slopes among carbon-rich asteroids suggest that many asteroids may contain organic materials that are not fully weathered. This material could have been produced by ion bombardment of more complex organic material originally present on the asteroid surface, such as organic ices (e.g., benzene, methane, methanol), very red materials (e.g., bitumens), or other organic molecular solids. Alternatively, this material could also be the relic of presolar material processed in the placental molecular cloud.

In summary, experiments indicate that ion bombardment of H-rich organic materials can explain the large color differences observed among dark asteroids. However, it is more difficult to determine trends in the small color differences that are observed for the high weathered asteroids with dark and flat spectra, as the observed spectral variations are comparable to variations due to sample preparation and other effects (grain size, etc.). Also, opposition effects (relative) are stronger for dark meteorites (Beck *et al.*, 2012), and these can be comparable to albedo variations induced by

irradiation. All this may explain why a clear and general SW trend for dark asteroids has not yet been found and why SW is neither necessary nor ruled out as an explanation of spectral differences between primitive asteroid families (Ziffer *et al.*, 2011).

**2.3.2. Synthesis and survival of C-H and O-H on space-weathered asteroids.** In the ion implantation process, reactive ions, such as H, C, N, O, and S, have the potential to directly

**Fig. 6.** The observed spectra of asteroids (1951) Lick [triangles, A-type, albedo 0.09 (Brunetto *et al.*, 2007a)], (1542) Schalen [squares, D-type (Bus and Binzel, 2002)], and (5145) Pholus [circles, Centaur, albedo 0.05 (Cruikshank *et al.*, 1998)] are compared with the reflectance spectra of laboratory materials before and after ion irradiation: (a) asphaltite [bitumen, for details see Moroz *et al.* (2004b)] and (b) olivine pellet with 34.4 μm of polystyrene deposited (for details, see Kaňuchová *et al.*, 2010). Schalen is chosen as an example of a primitive and possibly organic-rich surface. Pholus has one of the reddest slopes among solar system small bodies. Lick exhibits a strong silicate absorption, which suggests that the slope may be a result of SW of silicates (Brunetto *et al.*, 2007a), although the presence on the surface of a coloring organic material cannot be ruled out. A comparison between the red asteroids and irradiated asphaltite shown in (a) shows that SW of an extremely red material causes a decrease of the spectral slope that can reproduce the observed slopes. Irradiation of an olivine sample covered by an organic transparent material (polystyrene) causes a progressive reddening shown in (b) that can also reproduce some observed asteroidal slopes.

alter the target material, but they also can react with the target to produce new molecules. This phenomenon has been well studied for implantation of reactive ions in different ices (e.g., Strazzulla, 2011). As an example, the presence of sulfuric acid on Jupiter's moon Europa has been explained as due to magnetospheric sulfur ion implantation (Strazzulla et al., 2007).

The presence of organic materials on solar system objects has been inferred by the observation of C-H bonds in the reflectance spectra. However, laboratory experiments have demonstrated that C-H bonds can both be created and destroyed by radiation processes: keV-MeV ion bombardment of hydrogenated amorphous carbons causes a loss of hydrogen (Mennella et al., 2003; Godard et al., 2011), while exposing carbonaceous material to a flux of very low energy (thermal) protons produces new C-H bonds (Muñoz Caro et al., 2001). These experimental results have been applied to the dust life cycle in the interstellar medium, yet it has not been possible to apply this to asteroids, mainly because the flux of thermal protons impinging on their surface is not known. At present, the observation of surface C-H bonds suggests that the organic material on the surface is not fully weathered.

Irradiation experiments on relevant meteorites would determine the stability of organics (probed by CH stretching bands) on asteroid surfaces: Cross sections for CH destruction have been measured for ion irradiation in electronic energy loss regime [cosmic rays (Godard et al., 2011, and references therein)], but constraining CH survival timescale on inner solar system small bodies requires solar wind simulations and diffuse reflectance probes. These studies will help us to understand whether the CHs observed on asteroids (e.g., Campins et al., 2010b) correspond to a young or an old terrain.

Less numerous and more controversial are the experiments of implantation of reactive ions in silicates. In particular, it has been suggested that the bands attributed to water ice (or to hydrated silicates) observed on the Moon (Pieters et al., 2009; Basilevsky et al., 2012) and on some asteroids (Campins et al., 2010b; Rivkin et al., 2010) are produced by implantation of energetic solar protons. However, laboratory experiments have provided controversial results. While some authors have found that hydroxyl radicals are induced by proton implantation in silicates (Djouadi et al., 2011; Ichimura et al., 2012), others have found the contrary (Burke et al., 2011). In the future, experiments focusing on the implantation of reactive ions in silicates and solid carbonaceous material are necessary to obtain a more complete understanding of their potential relevance for the evolution of asteroid surfaces.

### 3. EVIDENCE FOR SPACE WEATHERING FROM SAMPLE RETURN

#### 3.1. Asteroid (25143) Itokawa: Evidence from Remote Sensing and *In Situ* Observations

Prior to observation by the Hayabusa mission (2003–2010), groundbased visible and infrared spectroscopic observations showed that (25143) Itokawa was an S (IV)-type asteroid mainly composed of olivine and pyroxene with

apparent 1- and 2- $\mu\text{m}$  absorption bands (Binzel et al., 2001). Disk-integrated visible-infrared spectra compared best with lightly reddened LL5/6 chondrites. In addition, a fairly large thermal inertia of  $750 \text{ J m}^{-2} \text{ s}^{-0.5} \text{ K}^{-1}$  was estimated, suggesting a paucity of fine regolith particles (Müller et al., 2005). In the following, we focus on the Hayabusa results that are most relevant for SW. For a complete review of the Hayabusa results, see the chapter by Yoshikawa et al. in this volume.

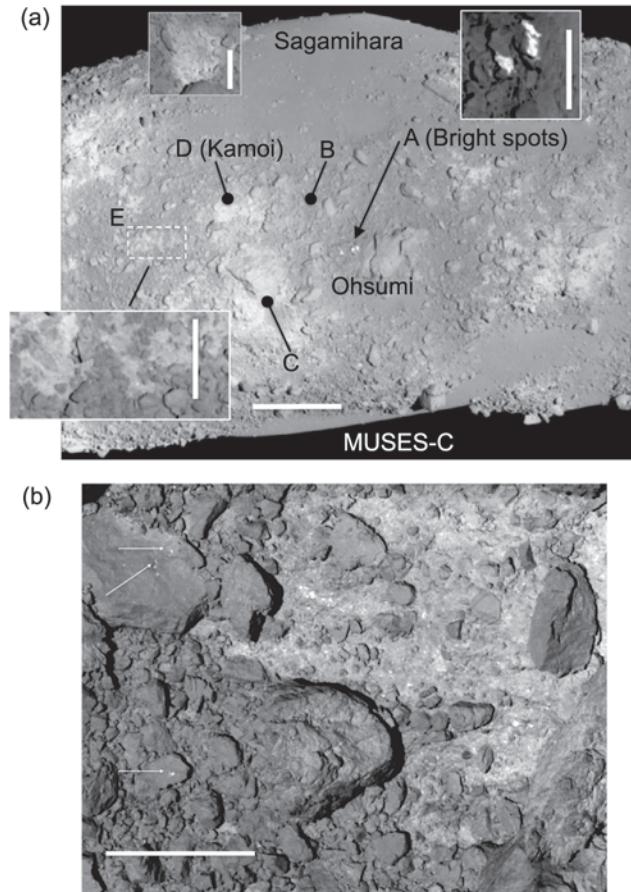

As shown in Fig. 7a, the surface of Itokawa is divided into rough terrain (about 80% of the surface), mostly consisting of numerous boulders, and smooth terrain, which is composed of millimeter- to centimeter-sized grains (Yano et al., 2006). Even though Itokawa's surface is deficient in fine (less than millimeter-sized) regolith particles, the observed strong opposition effect suggests that Hapke's scattering model can be applied (Hapke, 1993). Itokawa also has surface heterogeneity in both visible brightness and color. The brightness difference is approximately 10–20% on distant images and as high as 30% (up to 40%) on close-up images in the v-band (553 nm). This difference is too large to be explained by photometric effects. In the rough terrain, brighter areas are observed at some of the elevated zones, gravitationally steep zones, and structures that are presumably of impact origin (Saito et al., 2006; Hirata et al., 2009). Asteroid Multiband Imaging Camera (AMICA) observations show significant variations in brightness and color in the visible bands: ul (381 nm), b (429 nm), v (553 nm), and w (700 nm) (Ishiguro et al., 2007) and are correlated with each other: Brighter areas are bluer in color and darker areas are redder.

The near-infrared spectrometer (NIRS) confirmed previous disk-integrated results that suggested Itokawa's spectrum closely matched a weakly weathered LL5/6 chondrite (Binzel et al., 2001; Hiroi et al., 2006). Spectral variations were observed that can be explained by Hapke's SW model (Hapke, 2001), where the amount of npFe<sup>0</sup> controls spectral reddening (Fig. 8a; see section 3.3 for more details). Recent analysis of the AMICA NIR wavelengths (Ishiguro et al., 2014) shows that Itokawa's surface exhibits a good correlation between R<sub>w</sub>/R<sub>b</sub> (700 nm/429 nm reflectance ratio) and R<sub>p</sub>/R<sub>w</sub> (980 nm/700 nm reflectance ratio) (Fig. 8b). In other words, bluer and more immature regions (with moderate slope between 0.43  $\mu\text{m}$  and 0.70  $\mu\text{m}$ ) show the apparent deeper 1- $\mu\text{m}$  bands, which is consistent with NIRS results. The spectra of the rough terrains vary considerably in its degree of SW, while the smooth terrains have, on average, spectra that are lightly weathered.

It should be noted that disk-integrated reflectance between the ul-band (381 nm) and p-band (980 nm) at different rotational phases of Itokawa agree well with continuous reflectance spectra by groundbased observations (Binzel et al., 2001; Lowry et al., 2005).

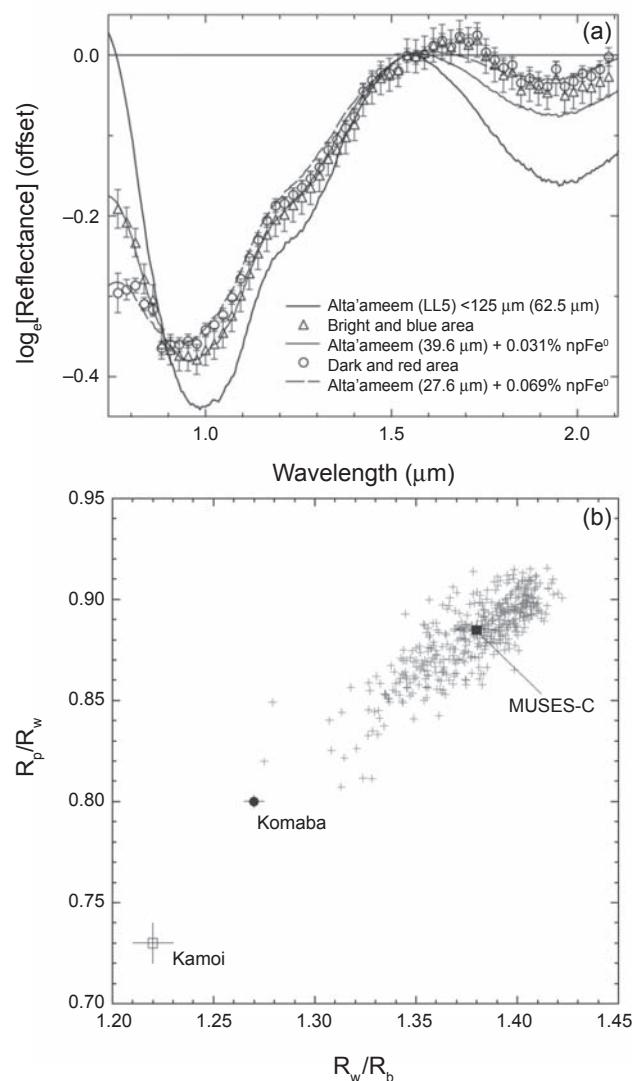

The rough terrain on Itokawa contains both dark (and red) and bright (and blue) areas (Ishiguro et al., 2007, 2014). The darker areas are more abundant in boulders, while the larger (a few tens of meters) angular blocks, such as Yoshinodai, appear brighter than the smaller boulders. Figure 7a is a v-band (553 nm) image of rough terrain on the western side

of Itokawa, centered at Ohsumi Regio. The inset shows detailed images obtained in the b-band (430 nm). The bright spot (“A”) is one of the brightest points on Itokawa; it is likely that a very recent impact removed parts of the rocks’ weathered surface. Exposed bedrock zones are situated west of Ohsumi (“C”); the slope of the NIRS spectra taken in this region was blue. On the lefthand side of Fig. 7a, the area labeled “E” shows a patched dark thin layer ( $\leq 1$  m) covering the underlying brighter zone. Some boulders may have moved here after the bedrock was exposed. Kamoi (“D”) is a distinct bright circular and slightly depressed

**Fig. 7.** (a) A v-band AMICA image around Ohsumi (Tsukuba) Regio in the western hemisphere of Itokawa image ST\_2494991986. Scale bar (white line) is 50 m. The dark boulder-rich zone is centered between brighter or patched areas. The arrow labeled “A” indicates “bright spots,” one of the brightest surfaces on Itokawa. Labels “B” and “C” correspond to the positions of redder and bluer NIRS spectra, which were obtained and discussed in Hiroi *et al.* (2006) (courtesy of H. Kitazato and N. Hirata). Kamoi (“D”) is a possible impact structure, where a relatively fresh surface was exposed. Inset figures (scale bars 10 m) are from a detailed b-band (429-nm) strip image ST\_2572086065. (b) ST\_2539451609 (v-band) after filtering. The original brightness difference between the basement brecciated rock and darker boulders is about 10%. Scale bar is 2 m. Small bright spots on dark boulders are shown by arrows.

area, suggesting it has an impact origin (Hirata *et al.*, 2009). Furthermore, Kamoi also looks relatively dark in the p-band (Fig. 8b), which suggests the surface is relatively fresh and unweathered (Ishiguro *et al.*, 2007, 2014). The difference in the average brightness (A, D, C, and E in order of brightness) observed in the surface features shown in Fig. 7a is consistent with each surface region having different SW exposure times. However, within bright zones of each inset image (A, D, E), finer ( $< 1$  m) brightness variations are recognized.

**Fig. 8.** (a) Estimation of the degree of space weathering for two areas on Itokawa. Reflectance spectra of a dark and red area (“B” in Fig. 7a) and a bright and blue area (“C” in Fig. 7a) of Ohsumi Regio are fitted with the spectrum of Alta'ameem (LL5, 125-mm sample), by optimizing the mean optical path length (MOPL) and volume percentage of npFe<sup>0</sup> particles. From Hiroi *et al.* (2006), reprinted with permission of Macmillan Publishers Ltd. (b) Correlation between  $R_p/R_w$  and  $R_b/R_w$  (courtesy of M. Ishiguro). The overall trend from the lower left to upper right can be explained by SW (Chapman, 2004). In addition to values at the Komaba crater and Hayabusa sampling site (MUSES-C Regio), the value at Kamoi is shown.

Close-up images of boulders and pebbles were obtained in the eastern hemisphere of Itokawa. Figure 7b shows the boundary area between the dark boulder-rich zone and the bedrock zone. The heterogeneous features observed in the brighter zone can be explained if the bedrock of Itokawa is breccia that was lithified on the parent body, as lithified breccias have mineralogical and petrological heterogeneity for various scales, which would affect the degree of SW. Brightness variations in the inset images (A, D, and E in Fig. 7a) can also be explained in the same manner. The two types of boulders observed on Itokawa are shown in Fig. 7b: rounded boulders with rounded edges and angular boulders with sharp edges and relatively flat surfaces (Noguchi et al., 2010). The features of the rounded boulders with undulated surfaces (10-cm-scale protrusions and patches being observed) are compatible with breccia with hardness heterogeneity. The fraction of angular rocks increases for the submeter-sized rocks. As seen in Fig. 7b, both type of boulders have weathered surfaces and may have experienced movement. It is likely that the hidden sides of boulders have experienced weathering as well. There are no significant color variations between the large rounded and angular boulders, but the smaller angular boulders do show some albedo variations. No fine (less than centimeter-sized) regolith is observed in this image of the rough terrain. Furthermore, centimeter-sized pebbles appear to have been moved out of this area into the low-lying smooth region (see the chapter by Murdoch et al. in this volume).

Distinct bright speckles are observed on some of the boulders (Miyamoto et al., 2007). In Fig. 7b, white arrows highlight the bright spots on the dark boulders. These speckles are mainly formed by high-velocity impact of small meteoroids, because 90% of bright speckles are quasicircular and the size-frequency distribution can be compared with that of craters (Takeuchi et al., 2010). The weathered surface layer is thin but appears to be resistant to alteration by rock-regolith movements.

### 3.2. Returned Itokawa Samples

**3.2.1. Laboratory analyses.** After orbiting Itokawa for two months, Hayabusa touched down onto the surface (MUSES-C Regio) for two sample collections on November 20 and 26, 2005, and then returned to the Earth on June 13, 2010. More than 2000 particles have been recovered from the returned capsule of Hayabusa. Detailed analyses of many of those particles were first described in a series of papers that appeared in *Science* in 2011 (vol. 333, issue 6046) (e.g., Nakamura et al., 2011; Noguchi et al., 2011; Tsuchiyama et al., 2011) and more recently in *Meteoritics & Planetary Science* (vol. 49, issue 2) (e.g., Noguchi et al., 2014). See also the chapter by Yoshikawa et al. in this volume for a more detailed discussion.

Analysis of mineral assemblies and the composition of Itokawa particles supports Itokawa having an LL-chondrite composition. The olivine, low-Ca pyroxene, and kamacite composition of most Itokawa particles fall within the nar-

row range that matches LL chondrites (Nakamura et al., 2011); compositional homogeneities would suggest early thermal metamorphism. The triaxial shape distribution of Itokawa particles suggests mechanical disruption as a primary source. In addition, while most Itokawa particles have angular edges compatible with their disruption origin, some have rounded edges, suggesting mechanical abrasion after particle formation (Tsuchiyama et al., 2011) (see also the chapter by Yoshikawa et al. in this volume). It should be noted that none of the textures of Itokawa particles is consistent with lunar agglutinates, caused by high-velocity meteoroid impacts.

**3.2.2. Space weathering rims and nanophase iron and iron sulfide.** Some pebbles and rocks located in the MUSES-C area have bright surfaces and may have come from the nearby bright steep area of Shirakami and Yatsugatake. It is also possible that mechanical abrasion and/or thermal fatigue may have removed some of the weathered surface. Regardless, the brightness variation in this region led to the correct hypothesis that samples taken from this region would have varying degrees of SW (Noguchi et al., 2014; Bonal et al., 2015).

The first detailed microscopic analysis of Itokawa particles found that half the particles analyzed showed surface modification (Noguchi et al., 2011). Later studies found that even the particles that appeared to be unaltered did contain very thin (~5 nm) rims (Noguchi et al., 2014). These rims lack npFe<sup>0</sup> but contain elements that were not found in the underlying bulk grain, suggesting that they were formed from vapor redeposition (Noguchi et al., 2014). The most telling indicator of surface modification for the weathered grains is the presence of an amorphous rim that contains npFe<sup>0</sup> (Noguchi et al., 2011, 2014; Matsumoto, 2014). This rim, categorized as Zone II by Noguchi et al. (2014), is relatively thick (30–60 nm), partially amorphous, and contains 2–3 nm npFe<sup>0</sup> (Fig. 9a). Given that the thickness of the rim is comparable to the penetration depth of the He solar wind ions, it seems likely that this rim was formed by solar wind irradiation.

In some of the analyzed particles, Zone II contains vesicles, which is probably due to trapping of implanted He [composite vesicular rim (Noguchi et al., 2014)]. In fact, larger vesicles were identified in 11 out of 20 Itokawa regolith particles analyzed by Matsumoto (2014). It was confirmed that a blister corresponds to a vesicle in the npFe<sup>0</sup>-bearing amorphous layer (Fig. 9b). These vesicles are heterogeneously distributed even in one particle. Sometimes they are observed in opposite surfaces of the same particle, which is strong evidence of regolith mixing. So far, there is no correlation between the vesicle distribution and surface morphologies such as the roundness of particles.

Like the unaltered particles, the outermost surface of the weathered grains contains a region distinct from the partially amorphized Zone II region. This thin amorphous (~5–15 nm) surface layer, characterized as Zone I (Fig. 9a) by Noguchi et al. (2014), contains npFe<sup>0</sup>, nanophase FeS (and MgS), and elements not present in the underlying minerals. The

presence of npFeS in asteroidal regolith is compatible with the observation of regolith breccia meteorites (*Noble et al.*, 2011). Furthermore, the difference in composition between the Zone I and II layers, which has also been confirmed in studies of other Itokawa particles (*Thompson et al.*, 2014), suggests that Zone I is formed by redeposition of impact-generated vapors or sputter deposits (*Keller and Berger*, 2014).

Based on solar flare densities, it has been estimated that the Zone II regions could have formed in less than  $10^3$  yr, while the npFe<sup>0</sup> may have formed on even shorter timescales (*Noguchi et al.*, 2014). Regolith mixing processes (discussed

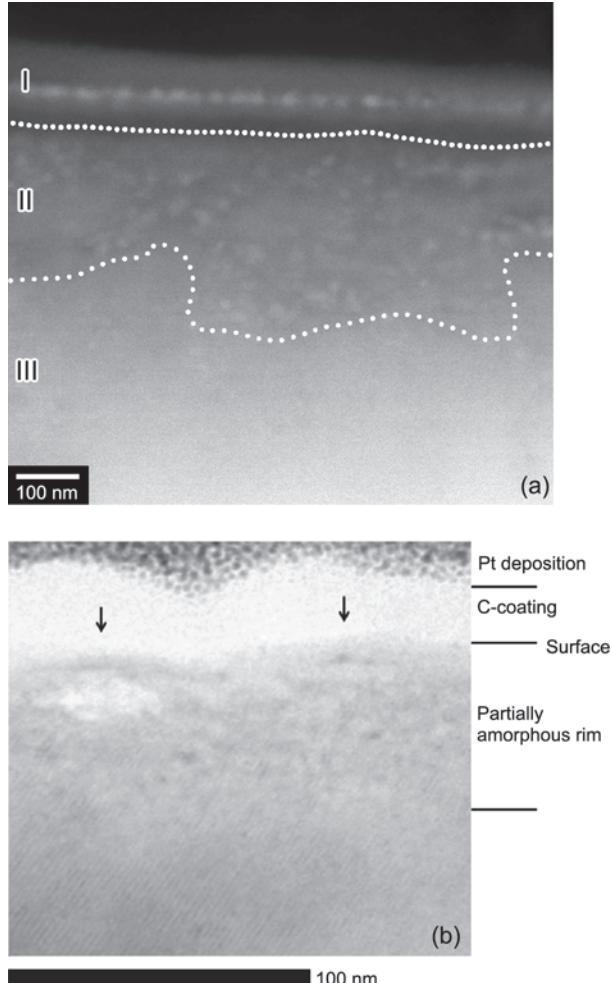

in the following section) may prolong the timescale of optical maturation on smooth regions of Itokawa. Another estimate of the cosmic-ray (galactic and solar) exposure age using <sup>21</sup>Ne was obtained for an olivine-rich grain (RA-QD02-0035),  $1.5 \pm 0.4$  Ma (*Meier et al.*, 2014), which is compatible with the upper limit of 8 Ma estimated by *Nagao et al.* (2011). The timescale for the formation of the thin surface redeposition region (Zone I) must be significantly shorter than that of Zone II, as Zone I deposits are found on both the altered partially amorphous grains and the pristine crystalline surfaces. However, as there is much less npFe<sup>0</sup> found in Zone I compared with Zone II, this thin region should have little contribution to the optical properties of the weathered surface.

Finally, analysis of Itokawa samples suggests that the composition of the grain may affect the degree of weathering that occurs. This hypothesis is not new, as previous laser irradiation studies on pyroxene and olivine also suggested this (*Sasaki et al.*, 2002; *Brunetto et al.*, 2006b). However, the pyroxene grains found in the Itokawa samples appeared to be more weathered than the olivine (T. Matsumoto, personal communication), which is in contrast to previous laser irradiation studies. This apparent discrepancy is interesting and may suggest that laser irradiation produces different compositional effects than found on Itokawa, and that young asteroids are likely dominated by solar wind processing. However, more laboratory studies that focus on how the SW rates of pyroxenes and olivines induced by ion irradiation compare are needed to determine whether this is a viable explanation. In addition, it is possible that compositional differences may also explain why plagioclase grains found in Itokawa particles lack the vesicles that were easily identified on adjacent pyroxene particles (T. Matsumoto, personal communication). More experiments are also necessary to elucidate the role of FeS in SW (see, e.g., *Okazaki et al.*, 2014).

### 3.2.3. Spectral models: Lessons learned from Itokawa.

Several experimental studies (see section 2) have shown that while SW alters the reflectance spectra of minerals, the changes mainly involve alteration of the spectral continuum, as the absorption band positions and relative areas of VIS-NIR silicate absorptions are not significantly changed (see, e.g., *Gaffey*, 2010, and references therein). Thus, by computing the ratio between laboratory spectra of weathered and unweathered materials, the silicate absorption bands can essentially be removed, leaving only the continuum curve (e.g., *Brunetto et al.*, 2006a). This curve can be parameterized by a coefficient and related to the SW exposure time. This approach has also been used to remove SW effects from S-type asteroid reflectance spectra, so that the surface composition could be extracted in a more straightforward manner (*Popescu et al.*, 2012).

Modeling described in *Hapke* (2001) and *Ueda et al.* (2002) clearly shows that optical alteration depends on wavelength, thus changing the 1- and 2-μm bands in different ways. More precisely, the “weathered” spectral continuum is a nonlinear function of the optical constants of the silicate host matrix and the inclusions produced by the energetic alteration (*Hapke*, 2001; *Hiroi and Sasaki*, 2001;

**Fig. 9.** (a) High-angle-annular-dark-field (HAADF) STEM image of the surface zone of a low-Ca pyroxene in particle RA-QD02-0042. The partially amorphous zone (I) is a vapor-deposited layer containing npFe, npFeS, and npMgS (appearing as brighter spots), depleted in Si. Zone (II) is an amorphous layer containing abundant npFe. Zone (III) retains the crystal characteristics. Figure courtesy of T. Noguchi. (b) A TEM image of a blistered surface on low-Ca pyroxene particle (QD-RB-0043) shows the npFe<sup>0</sup>-bearing rim layer associated with voids (arrows). The FIB-TEM sample was prepared to allow observation of the cross section and the structure underneath blisters. Figure courtesy of T. Matsumoto.

*Hiroi et al.*, 2006; *Brunetto et al.*, 2006b, 2007b; *Noble et al.*, 2007). Considering the inclusions to be metallic iron particles (smaller than the wavelength) in vapor-deposited coatings on soil particle surfaces and inside agglutinates, *Hapke* (2001) used the Maxwell-Garnett effective medium theory to calculate the absorption coefficient of a silicate host medium containing inclusions of small metallic iron spheres. This model can thus be used to estimate the surface abundance of nanophase iron.

*Hiroi et al.* (2006) used Hapke's SW model to estimate the abundance of npFe<sup>0</sup> for different regions on Itokawa, confirming that the asteroid is subject to SW. Now that Itokawa's samples can be studied directly in the laboratory, future studies should be able to improve these estimates as well as increase the general understanding of how SW alters asteroids. This improvement has already been realized with the recent discovery of the multilayer structure on Itokawa particles that appears to be associated with SW (*Noguchi et al.*, 2014). Furthermore, *Bonal et al.* (2015) explored the possibility of performing VIS-NIR diffuse reflectance studies on isolated Itokawa particles, which could be compared directly with remote sensing spectral data. Finally, in addition to direct laboratory measurements, improvements to the existing Hapke model, such as that developed by *Nimura et al.* (2008), and additions to take into account other possible alterations caused by SW, such as textural changes (*Moroz et al.*, 2014), will also be critical for analyzing SW effects in the near future.

#### 4. ESTIMATES FOR SPACE WEATHERING RATES ON ASTEROIDS

One of the main advantages of laboratory studies is that they can establish what spectral trends are a result of SW. These results can be used to determine whether SW could cause the variations observed between terrestrial analogs and asteroids or simply the variations between asteroids of similar composition. The spectral changes observed in the laboratory have also been used to estimate the timescale for which these spectral alterations may occur in the space environment. For example, timescales in the inner solar system have been estimated previously by comparing laboratory spectra of irradiated silicates and meteorites with remotely acquired spectra of silicate-rich asteroids, and scaling the fluences used in the laboratory to the fluxes of the solar wind ions. These estimates suggest that the effects caused by ion bombardment will saturate between 10<sup>4</sup> and 10<sup>6</sup> yr (*Hapke*, 2001; *Strazzulla et al.*, 2005; *Loeffler et al.*, 2009), while for micrometeorite bombardment, estimates are on the order of 10<sup>8</sup> yr (*Sasaki et al.*, 2001; *Brunetto et al.*, 2006b). In some cases [e.g., asteroid (832) Karin (*Brunetto et al.*, 2006a)], the irradiation timescales are in agreement with the dynamical timescales [in the case of (832) Karin, this is the age of the catastrophic impact that rejuvenated the surface about 5.8 × 10<sup>6</sup> yr ago].

However, even though the SW induced by ions is a relatively efficient process, there are many asteroids that are

not fully weathered, even though they are likely older than the above estimated timescale. This apparent discrepancy likely indicates that some rejuvenating process is able to partially resurface the asteroid, which effectively lowers the SW rate. As the average collisional lifetime of asteroids larger than several kilometers is much longer than these estimated weathering timescales, other processes such as small (nondestructive) impacts (e.g., *Shestopalov et al.*, 2013) or planetary encounters (section 4.2) are likely responsible for rejuvenating the surfaces. In the following sections, we will discuss another approach to estimate SW rates (section 4.1), as well as a few other processes that may be important to consider when estimating SW rates for asteroid surfaces.

Finally, we point out that nearly all the laboratory data used to determine SW rates focused on the reflectance spectra taken in the VIS-NIR regions. However, since the thickness probed by reflected solar photons is a function of wavelength, it is desirable to have an estimate of SW effects in another wavelength region. In this respect, it is interesting to observe that SW produces a blueing of the spectrum at near-UV wavelengths, in contrast to the reddening in the VIS-NIR. Such UV blueing occurs with a lower amount of weathering than the VIS-NIR reddening (*Hendrix and Vilas*, 2006). This implies that the UV range is highly promising to better constrain the SW timescale in future studies.

#### 4.1. Space Weathering Rates Inferred from Studies of Dynamical Families

An asteroid family is a group of fragments (the so-called family "members") produced by collisional disruption of a larger parent body. Several dozens of asteroid families have been identified in the main belt (see the chapter by Nesvorný et al. in this volume; physical properties of asteroid families are discussed by Masiero et al. in this volume). The disruption itself is a violent process that should erase the preexisting surface of a parent body (weathered or not) and expose new material, mainly from the parent body interior, on the newly created surfaces. Initially, this material should be predominantly unweathered, but it will be altered by SW processes over subsequent time.

Ideally, the asteroid families could therefore be used to empirically measure the rate of SW. The basic method consists of characterizing the surface properties of members of a single family, and then correlating them with the family age ( $t_{age}$ ), defined as the time elapsed since the family formation, and across a dataset of at least several families with different  $t_{age}$ . In practice, it is challenging to distinguish between the effects of age and composition, which is obviously significant, because the composition influences the optical properties of a surface, and because SW effects depend on composition. Also, the empirically measured rates will include the counterbalancing effects of the regolith gardening by impacts (e.g., *Willman et al.*, 2010).

The first prerequisite for this method is to have an independent estimate of  $t_{age}$ . In the past decade, several different approaches have been used: a direct integration of orbits

back in time (*Nesvorný et al.*, 2002), modeling the Yarkovsky effect on the dynamical structure of a family (*Vokrouhlický et al.*, 2006), and modeling the size distribution of small family members as it evolves by collisions (*Marzari et al.*, 1999). The dynamical methods generate credible results for the youngest families ( $t_{\text{age}} \leq 10$  Ma), while their precision degrades with increasing  $t_{\text{age}}$ , mainly because various processes acting on the longest timescales are poorly understood. The estimates for  $t_{\text{age}} > 1$  Ga are only tentative at best.

To properly characterize the average surface properties of each family and their uncertainties, several members of each family need to be observed. This first became possible with a large dataset of asteroid colors obtained by the Sloan Digital Sky Survey (SDSS) (*Ivezić et al.*, 2001). More recently, the spectroscopic surveys of young and old families generated enough data that the spectroscopic properties of families can be reasonably well established (e.g., slope, depth of the absorption bands). This is an important improvement because the SDSS colors are known to be somewhat unreliable for a precise physical characterization in specific cases. Furthermore, we now also have a large dataset of the asteroid albedo measurements from the WISE telescope (*Masiero et al.*, 2013).

The interpretation of the results obtained by correlating colors/spectroscopy with  $t_{\text{age}}$  has been subject to controversy. The initial results indicated that the characteristic timescale of SW was long (*Jedicke et al.*, 2004; *Nesvorný et al.*, 2005; see also *Willman et al.*, 2008, 2010). Specifically, *Nesvorný et al.* (2005) found that the spectral slope (at 0.35–0.9 μm) of aging surfaces of the S-type asteroids increases with time  $t$  as  $0.1 \mu\text{m}^{-1} \times \log_{10}(t/1 \text{ Ma})$ . This fit is valid only for  $2.5 \leq t \leq 3000$  Ma, because no families younger than  $\approx 2.5$  Ma were known at the time.

Correcting the spectral slopes for differential effects presumably caused by compositional differences, *Vernazza et al.* (2009a) found that the slope-time profile is essentially flat for  $t > 1$  Ma (see Fig. 10). From Fig. 3 of *Vernazza et al.*, we estimate the SW rate of  $\sim 0.3 \mu\text{m}^{-1} \times \log_{10}(t/1 \text{ Ma})$  for  $t > 1$  Ma, which is about 3× faster than the previous estimate. Comparing the spectral slope at  $t \sim 1$  Ma with that of the OC meteorites, whose spectral properties were measured in the laboratory, *Vernazza et al.* pointed out that asteroid surfaces should evolve from unweathered (as represented by OCs and Q-type NEAs; see section 4.2) to nearly completely weathered in  $\sim 1$  m.y.

However, this result is largely dependent on the differential correction that *Vernazza et al.* applied to the spectral slopes. With this correction, the Karin family, with  $t_{\text{age}} = 5.8 \pm 0.2$  Ma, appears to be  $\sim 80\%$  space-weathered but without the correction, it appears only  $\sim 40\%$  space-weathered. To apply the differential correction, *Vernazza et al.* (2009a) opted to use the Flora family as a reference composition, but showed earlier (*Vernazza et al.*, 2008) that the Flora family is incompatible in composition with the L- and H-chondrites, which together represent  $\approx 80\%$  of meteorite falls. If, instead, the Gefion family, which is thought to be the source of L-chondrites (*Nesvorný et al.*, 2009), were

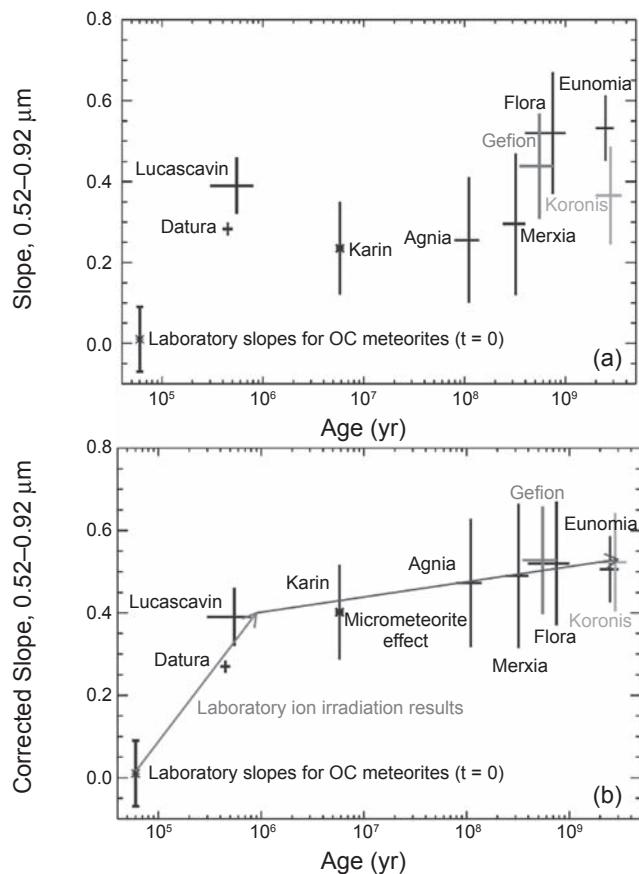

chosen for a reference composition, the differential correction would have been less dramatic.

Regardless, these estimates using asteroid families suggest that the reddening trend of the visible spectral slope of an average OC-like surface in the main belt probably proceeds to reach a 50% completion in  $\sim 1$ –10 m.y., and that the following stage to reach a fully weathered surface lasts much longer. The transition between the first and second stages can be sharp or more gradual. More work will be needed to understand whether the transition really represents a switch from faster, solar-wind-induced reddening (*Vernazza et al.*, 2009a), to slower reddening at later times where other effects become important as well [e.g., regolith gardening (*Willman et al.*, 2010)]. In this respect, young families are very important because they should show the most obvious SW effects. Interestingly, some young families (Karin, Datura) seem to indicate that the  $\sim 1\text{-}\mu\text{m}$  band suppression could proceed faster than the slope reddening (*Nesvorný et al.*, 2006; *Takato*, 2008). With that much said, it has to be pointed out that the existing observational record for young families is mixed (e.g., *Mothé-Diniz and Nesvorný*, 2008) and more observations will be needed to gain some confidence in these results and separate them from other effects (i.e., grain size, etc.). In the future, additional input shall also be obtained from spectroscopic observations of the asteroid pairs (e.g., *Polishook et al.*, 2014).

#### 4.2. Unweathered Small Near-Earth Asteroids and Effects of Planetary Encounters

While only a few unweathered OC-like spectra were detected in the main belt (e.g., *Mothé-Diniz and Nesvorný*, 2008; *Polishook et al.*, 2014), they are relatively common among the small NEAs (*Binzel et al.*, 1996, 2004). While this may simply be a consequence of the difficulty of obtaining a reliable reflectance spectrum for a small faint main-belt asteroid, this may also be attributed to some special process affecting the NEAs. Using the standard asteroid taxonomy, where the unweathered OC-like spectrum is denoted by the letter Q, *Binzel et al.* (2004) showed that the number ratio of Q- to S-type NEAs is  $\sim 20\%$  for  $D \sim 1$  km. The fraction of Q-types drops with increasing diameter, and there is no known Q-type among about two dozen NEAs with  $D > 5$  km (see Fig. 5).

Previously, the appearance of Q-types among the small NEAs has been attributed to short collisional lifetimes of small asteroids, but this appears to be unlikely because the collisional lifetimes of kilometer-sized asteroids are presumably  $> 10$  m.y. (*Bottke et al.*, 2005), while the SW timescales are probably shorter. It appears, instead, that this issue can be related to the regolith retention, because small asteroids have weaker gravity and weathered regolith layers can be more efficiently stripped from them by small impacts. In addition, small asteroids undergo the so-called YORP cycles (see the chapter by Vokrouhlický et al. in this volume), which can remove or redistribute surface regolith when the asteroid is spun up beyond the critical spin rate, and the centrifugal

**Fig. 10.** The mean spectral slopes for both OC meteorites and S-type asteroid families vs. the age of the family. Laboratory spectra for OCs form the baseline assumption for fresh ( $t = 0$  yr) “unweathered” asteroid surfaces. The slope domain for OCs is placed at  $t = 4.6 \times 10^4$  yr. (a) Uncorrected data. (b) Data corrected for different composition. As explained by Vernazza et al. (2009a), composition can vary the outcome of a SW slope value by almost a factor of 2. Thus a comparison between weathered spectral slope and surface age requires a correction for composition. To perform this correction, Vernazza et al. (2009a) chose the composition of the Flora family as a reference. To estimate the slope deficit or excess for each family vs. the slope of the Flora family, they fitted the slopes of the S-type sample (0.52–0.92 μm range) by a straight line, providing the mean slope for a given composition. To correct the slope distribution for composition, they calculated the slope deficit or excess for all families and shifted (up or down) their mean slope values by the calculated amount. The two arrows in (b) stress two different regimes. First, the slope of an unweathered surface (at exposure time  $t = 0$ ) starts in the middle of the slope domain of OCs and reaches the 0.4 slope value of the Lucascavin family in less than 0.5 m.y. This represents a slope variation of ~0.4 in just ~0.5 m.y., which is consistent with the very rapid reddening trend observed during laboratory ion irradiation experiments. Such a rapid trend appears to be required within the first  $\sim 10^6$  yr for newly formed asteroid families. Second, the slope evolution over the interval  $t = 0.5$ –5 Ma to  $t = 2500$  Ma appears more gradual (gray line). Gradual weathering processes such as micrometeorite impacts may account for the continuing slope increase throughout the following  $2 \times 10^9$  yr. From Vernazza et al. (2009a), reprinted with permission of Macmillan Publishers Ltd.

force on the surface exceeds gravity (see the chapter by Walsh and Jacobson in this volume).

Recently, Binzel et al. (2010) found evidence that planetary encounters of NEAs with the Earth can refresh surfaces. The evidence is based on the orbital distribution of Q-type NEAs, which shows, according to Binzel et al. (2010), a sharp transition beyond the Earth-crossing limit, where Q-types cease to be found. Adopting the short, 0.5-m.y. SW timescale from Vernazza et al. (2009a), they estimated that for the planetary encounters to be significant, the optical properties of an average NEA’s surface may be refreshed for an encounter distance of up to 16 planetary radii ( $R_{pl}$ ). DeMeo et al. (2014), using a larger database of spectroscopic observations, found that Q-type NEAs also exist on orbits beyond the Earth-crossing limit.

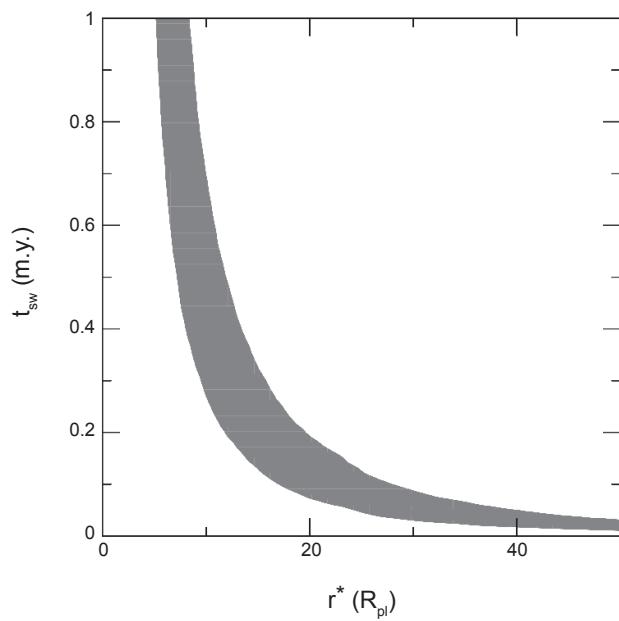

The effect of encounters of NEAs with all terrestrial planets has been considered in Nesvorný et al. (2010), who used the SW timescale,  $\tau_{sw}$ , and the encounter radius below which the refreshing effect occurs,  $r^*$ , as free parameters (see Fig. 11). Here  $\tau_{sw}$  is defined as the timescale to bring an initially unweathered, average Q-type spectrum to appear as average S. They found that  $\tau_{sw} \sim 10^6$  yr (at 1 AU) and  $r^* \sim 5 R_{pl}$  best fit the data. Values  $\tau_{sw} < 10^5$  yr would require that  $r^* > 20 R_{pl}$ , which seems implausible because

these very distant encounters should be irrelevant. Also, the fraction of Q-type NEAs would be much larger than observed if  $\tau_{sw} > 10^7$  yr. While these results are broadly consistent with those discussed in section 4.1, they need to be validated by direct detection of the hypothesized effects. Some very close encounters of NEAs to Earth, such the encounter of 99942 Apophis at  $\approx 6 R_{pl}$  in 2029, may offer such an opportunity, i.e., to have an independent estimate of  $r^*$ .

Finally, a recent experimental work has suggested that thermal fatigue fragmentation (and the consequent production of regolith) may be an important process for the rejuvenation of the surfaces of NEAs (Delbó et al., 2014). This result deserves further investigation.

#### 4.3. Mass Accretion and Loss by Micrometeorite Impacts and Solar Wind Ion Implantation

Resurfacing agents can excavate “fresh layers” and/or add exogenous material. The exogenous material could have been processed in different environments, such as in the presolar nebula, in the solar nebula during the early phases of the solar system formation, or after prolonged permanence in the outer solar system, e.g., comets. In fact, objects in the solar system, including asteroids, receive a continuous flux

**Fig. 11.** The observed fraction of Q-type NEAs can be used to constrain parameters  $r^*$  and  $t_{sw}$  discussed in the main text (Nesvorný *et al.*, 2010). The best-fit solutions are located along a hyperbola-shaped region in  $(r^*, t_{sw})$  space. This relationship can be qualitatively explained as follows: If the distance from the planet  $r^*$  necessary to rejuvenate the asteroid is small, then the resurfacing efficiency of planetary encounters must be small as well, which implies that the weathering timescale  $t_{sw}$  must be higher, in order to account for the observed fraction of Q-type NEAs. Since planetary tides during encounters with  $r > r^* = 20 R_{pl}$  should be negligible, this implies that  $t_{sw} > 0.1$  m.y. This result holds unless Earth's magnetospheric effects are important at  $r > 35 R_{\oplus}$ , which is unlikely. From Nesvorný *et al.* (2010), reprinted with permission of Elsevier.

of mass from the interplanetary medium. There are two main sources of mass accretion: (1) dust and meteoroids and (2) solar energetic particles (solar wind and energetic events).

The flux of dust is not well known. Values consistent with that estimated for the Moon, Mars, and outer objects would be on the order of  $2 \times 10^{-17}$ – $2 \times 10^{-16}$  g cm $^{-2}$  s $^{-1}$  (see Table 3 in Bennett *et al.*, 2013). Estimates for the micrometeorite impact flux on asteroidal surfaces can be obtained from dynamical models of the zodiacal cloud (ZC). These models calibrate the populations of small particles in interplanetary space based on infrared observations of the ZC, performed by space telescopes such as the Infrared Astronomical Satellite (IRAS) and Cosmic Background Explorer (COBE), on the measurements of the impact detectors, such as the Long Duration Exposure Facility (LDEF), and on meteor observations from the ground. The main result obtained from these studies is that the ZC has a predominantly cometary origin, with perhaps as much as 90% of grains in space sampling disrupted Jupiter-family comets (Nesvorný *et al.*, 2010).

The estimated mass influx of micrometeoroids on (1) Ceres, which has a rather typical orbit in the middle of the main belt,

is  $\sim 3.5$  tons/yr. This is only a small fraction of the terrestrial impact flux [ $\sim 30,000$  tons/yr from LDEF (Love and Brownlee, 1995)], which is mainly due to a relatively small collisional cross-section of Ceres. Using these fluxes, we estimate that a square meter in the asteroid belt should be exposed to an average mass flux of  $\sim 5$  g m.y. $^{-1}$ , mainly in  $\sim 100$ - $\mu$ m cometary particles. The typical impact speeds inferred from the model are  $\sim 10$  km s $^{-1}$  (Nesvorný *et al.*, 2010).

However, this material is itself a weathering agent that influences the properties of the local regolith and the reflectance spectra of the regions where it is deposited. A recent example comes from the localized dark materials found on Vesta's surface that have been attributed to the infall of carbonaceous volatile-rich material (McCord *et al.*, 2012; Pieters *et al.*, 2012). Such a material would be similar to that present in interplanetary dust particles. These materials can be lost from comets and weathered in the interplanetary medium as simulated in the laboratory (e.g., Baratta *et al.*, 2004) and then are delivered to the surfaces of different objects, including Earth (e.g., Dartois *et al.*, 2013).

The amount of material due to energetic solar particles that impinge the surface of an airless body scales with the inverse of the squared distance from the Sun. At 1 AU the total flux of solar protons (that obviously dominate) is about  $4\text{--}6 \times 10^8$  cm $^{-2}$  s $^{-1}$  depending on the phase of the solar cycle. This corresponds to a mass infall (at 2.5 AU) of  $1\text{--}1.6 \times 10^{-16}$  g cm $^{-2}$  s $^{-1}$  ( $\sim 40$  g m $^{-2}$  m.y. $^{-1}$ ) that is competitive with the mass delivered by dust. In addition, the energy range (keV-MeV) is such that solar ions penetrate the surface and then release their energy by elastic and inelastic interactions, and most of them (those that are not backscattered) remain implanted in the object at a depth that depends on the energy and mass of the ion. As an example, the flux of C ions (average energy of about 12 keV) that hits an asteroid at 2.5 AU is on the order of  $9 \times 10^3$  cm $^{-2}$  s $^{-1}$ . Thus the time necessary to accumulate a fluence of  $10^{17}$  carbon ions cm $^{-2}$  is on the order of  $3.5 \times 10^5$  yr. It has been demonstrated that after that fluence, the wide range of colors of most of the asteroids can be reproduced by the C-ion-induced weathering of HED meteorites (Fulvio *et al.*, 2012).

Finally, a last point to mention is the possibility of surface mass loss induced by ion sputtering and meteorite bombardment. This subject can be linked to the search for exospheres around asteroids [e.g., the case of asteroid Eros (Loeffler *et al.*, 2008b)]. More experimental and observational studies will be necessary in the future. Information about surface ion sputtering can be found in Bennett *et al.* (2013) and references therein.

## 5. SUMMARY

In the past decade, new ion irradiation and laser ablation experiments on meteorites and asteroid surface analogs, together with unambiguous proofs of SW effects on particles from asteroid Itokawa, have provided a fundamental contribution to the spectral interpretation of asteroid observations, to establish a solid asteroids–meteorites link, and

to understand the energetic processes affecting the surfaces of minor bodies. Laboratory analyses of Itokawa samples in particular have revealed for the first time direct evidence and a multiplicity of new details on asteroidal SW. Returned samples contained silicate particles compatible with an LL origin, half of which revealed the presence of two types of SW rims on their surfaces: a vapor-deposited rim (~10 nm) containing nanophase Fe, FeS, and MgS particles, and a 30–60-nm-thick radiation-damaged amorphous rim containing nanophase Fe. The fundamental role played by solar wind irradiation has been established. A general scheme for asteroid optical maturation is thus emerging.

From the observational point of view, slope trends from large surveys and in particular of young asteroid families have confirmed that solar wind is the main source of rapid ( $10^4$ – $10^6$  yr) weathering, and that a number of rejuvenating processes efficiently counterbalance the fast weathering timescales. This implies that the spectral properties of asteroids depend on the relative efficiencies of resurfacing and SW agents.

The diversity and mechanisms of asteroid SW need to be investigated further. For many asteroid classes we still do not know precisely how SW acts and what effects are produced, which hampers efforts to draw connections between specific meteorites and asteroid types. In particular, VIS-NIR slope variations are still controversial for dark asteroids and contradictory trends have been observed, making future experiments that simulate micrometeorite bombardment and irradiation by solar wind and cosmic ray ions critical. In addition, establishing a solid SW trend on dark objects can provide valuable support to the selection of sampling/landing sites for future sample return missions [e.g., the Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) (Campins et al., 2010a) or Hayabusa 2 (Takagi et al., 2011)], and will also help interpret mission results. Inspired by the extraordinary results obtained by Hayabusa, we anticipate that these new sample return missions will enhance our knowledge about the microphysical and chemical processes affecting weathered extraterrestrial materials, and help us to solve some of the open questions about SW, similar to what has previously been achieved for the Moon and S-type asteroids.

New important information on asteroid SW will be available soon from the observations of instruments onboard Gaia, a space mission of the European Space Agency (ESA) that will survey the entire sky. In particular, Gaia is expected to observe about 400,000 asteroids, for which high-precision astrometry and photometry will be obtained (Cellino and Dell’Oro, 2012). It has been estimated that spectral characterization will be obtained for at least 100,000 asteroids from the low-resolution spectra (0.35–0.95  $\mu\text{m}$ ) obtained by Gaia (Delbó et al., 2012). These observations will provide the possibility of a new taxonomy [present taxonomy is based on the observation of a few hundred objects in the NIR (DeMeo et al., 2009) or a few 10,000 in the visible (DeMeo and Carry, 2013)], and a larger and statistically stronger view of asteroid SW.

Ordinary chondrites (OCs) are by far the most abundant meteorites (80% of all falls). Their origin has long been the matter of a heated debate. About 30 years ago (e.g., *Pellas*, 1988), it was proposed that OCs should originate from S-type bodies (the most abundant asteroid spectral types in the inner part of the asteroid belt), but the apparent discrepancy between S-type asteroid and OC reflectance spectra generated what was known as the S-type/OC conundrum. This paradox has gradually been resolved over the years. It is now understood that space weathering processes are responsible for the spectral mismatch between S-type bodies and OCs. Furthermore, both telescopic observations and the first asteroid sample return mission (*Hayabusa*) indicate that most S-type bodies have mineralogies similar to those of OCs. Importantly, the S-type/OC link, which has remained sterile for more than 30 years, has been delivering fundamental constraints on the formation and evolution of planetesimals over the recent years.

## 1. INTRODUCTION

Observations of main-belt asteroids (MBAs) performed between the early 1970s and the late 1990s, along with meteorite measurements, led to the determination of a preliminary version of the compositional distribution in the asteroid belt (see the chapter by DeMeo et al. in this volume; *Gradie and Tedesco*, 1982; *Mothé-Diniz et al.*, 2003; *DeMeo and Carry*, 2013, 2014):

1. Two main asteroid populations were identified: the so-called S-types [comprising mostly but not only ordinary chondrite (OC)-like asteroids] and C-types [comprising mostly but not only carbonaceous chondrite (CC)-like asteroids], accounting for more than 50% of all MBAs, and several minor populations (comprising the parent bodies of the remaining meteorite classes and possibly compositions presently unsampled by meteorites).

2. A heliocentric gradient was recognized (*Gradie and Tedesco*, 1982) with water-poor S-type asteroids being pref-

erentially located in the inner belt while water-rich C-types are the dominant population in the outer belt.

3. The existence of a compositional overlap was established (e.g., a large number of C-types are currently located where S-types are the most abundant and vice versa).

Since the early 2000s, we have entered a new era of asteroid exploration, mainly because of the emergence of numerous high-quality spectroscopic measurements in the near-infrared [obtained essentially with the NASA Infrared Telescope Facility (IRTF) groundbased telescope], but also because of the Hayabusa asteroid sample return mission (*Nakamura et al.*, 2011). Near-infrared spectra for several hundreds of near-Earth asteroids (NEAs) (see chapter by Binzel et al. in this volume; *Thomas et al.*, 2014) and MBAs (e.g., *DeMeo et al.*, 2009; *Vernazza et al.*, 2014) have now been collected. These new datasets allowed us to enter the second phase of the exploration of the compositional distribution of the asteroid belt and of the compositional characterization of the NEA population. While previous

measurements in the visible allowed us to establish, for example, that ordinary chondrites (OCs) formed closer to the Sun than CCs, measurements in the near-infrared — which offer significantly more constraints on asteroid compositions than in the visible range alone (see the chapter by Reddy et al. in this volume) — allow us to constrain the respective formation location of the various meteorite classes (H, L, LL, CI, CM, etc.) within these broad groups (OCs, CCs), namely whether, for example, H chondrites formed closer to the Sun than LL chondrites or vice versa (*Vernazza et al.*, 2014). Near-infrared measurements also allow us to attack important questions such as determining the source regions of both meteorites and NEAs (e.g., *Vernazza et al.*, 2008; *Thomas and Binzel* 2010).

In parallel, samples of the S-type asteroid (25143) Itokawa were brought back to Earth by the Hayabusa mission, which demonstrated that OCs originate from S-type asteroids and validated the numerous laboratory space weathering experiments that had been performed on various meteorite classes (including OCs). In particular, these experiments had predicted that space weathering processes were responsible for the observed spectral mismatch between OCs and S-type asteroids. As a matter of fact, this work resolved the S-type/OC conundrum (*Chapman*, 2004) that lasted for more than 30 years, and demonstrated that S-type asteroids are mostly OCs or OC-like and not differentiated asteroids, as was advocated by *Bell et al.* (1989) and *Gaffey et al.* (1993).

The aim of the present chapter is to summarize the evidence concerning the origin of OCs and discuss the constraints that have been accumulated over the years regarding the formation and evolution of their parent bodies (S-type asteroids). While we give appropriate space to the resolution of the S-type/OC conundrum, the main emphasis of the chapter is placed on what was learned from the recently established spectroscopic links between specific OC classes (H, L, and LL) and their S-type asteroid parent bodies. We will show that these links, along with new laboratory work on OCs, have not only allowed us to gain a better knowledge of the formation mechanism of OC parent bodies and planetesimals in general, but they also boosted our understanding of the collisional and dynamical evolution of asteroids.

The structure of this review chapter is as follows. We start by reviewing in section 2 the most important constraints on the formation and early evolution of the OC parent bodies and sometimes, more generally, of the solar system, that were derived from laboratory studies of OCs. Then, in section 3, we will review the outstanding efforts that have been accomplished over the last 40 years by a large fraction of the asteroid-meteorite community to unambiguously identify the parent bodies of OCs. In section 4, we will review the constraints on the formation and evolution of OC parent bodies that were obtained from telescope observations of S-type asteroids and that nicely complement the laboratory constraints presented in section 2. In section 5, we will review the remaining issues in the S-type/OC field that require critical new data.

## 2. CONSTRAINTS DERIVED FROM ORDINARY CHONDRITE STUDIES ON THE FORMATION AND EARLY EVOLUTION OF THEIR PARENT BODIES

Ordinary chondrite meteorites (OCs) are silicate-rich meteorites composed mostly of olivine and low-calcium pyroxene that are by far the most abundant meteorites [80% of all falls (*Hutchison*, 2004)]. They have been subdivided into three groups (H, L, and LL) based on variations in bulk composition, such as molecular ratios [ $\text{FeO}/(\text{FeO} + \text{MgO})$ ] in olivine and pyroxene (*Mason*, 1963; *Keil and Fredriksson*, 1964) and the ratio of metallic Fe to total Fe (*Dodd et al.*, 1967) (Table 1). The L group slightly outnumbers the H group among falls (Table 1), but the reverse is true among finds. The LL group is distinctly less abundant than either group (*Hutchison*, 2004).

H chondrites have the highest total abundance of Fe (and the highest Fe/Si atomic ratio) among OCs (H stands for «High» Fe). They are also the most reduced OCs, their iron being mostly in metallic form. When equilibrated, they exhibit the lowest FeO contents in their silicates. At the other extreme, LL chondrites contain the least total Fe, corresponding to the lowest Fe/Si atomic ratio, and they are the most oxidized OCs, with little metal and with the silicates that have the highest FeO contents when equilibrated. They are «Low» in total iron and «Low» in metal, hence the LL denomination. H and LL chondrites also differ in terms of oxygen isotopes, with LL chondrites containing a very small but measurable depletion of  $^{16}\text{O}$  with respect to the other two isotopes compared to H chondrites. L chondrites («Low» in total iron) are intermediate between H and LLs in all these properties — somewhat closer to LLs in terms of total Fe.

TABLE 1. Properties of equilibrated ordinary chondrites.

	H	L	LL
Fall statistics (%)	34	37	9
Fe (wt%)	28	22	19
Fe/Si (atomic)	0.81	0.57	0.52
Metal (vol%)	8.4	4.1	2
Fa content of olivine*	16–20	21–26	27–31
Fs content of pyroxene*	15–17	18–22	22–30
$\sim\Delta^{17}\text{O}^\dagger$ (‰)	0.7	1.1	1.3
Ol/(Ol + Px)*	51–60	60–67	70–82

\* Olivine (Ol) is  $(\text{Fe}, \text{Mg})_2\text{SiO}_4$ ; pyroxene (Px) is  $(\text{Fe}, \text{Mg}, \text{Ca})_2\text{Si}_2\text{O}_6$ . Fayalite (Fa) content of olivine and ferrosilite (Fs) content of pyroxene correspond to the relative abundance of Fe atoms compared to other cations:  $\text{Fe}/(\text{Fe} + \text{Mg})$  and  $\text{Fe}/(\text{Fe} + \text{Mg} + \text{Ca})$  respectively. Ol/(Ol + Px) values are after *Vernazza et al.* (2008) and *Dunn et al.* (2010). The properties listed above are those of equilibrated (metamorphosed) ordinary chondrites. Fa content of olivine and Fs content of pyroxenes are highly variable in unequilibrated chondrites.

†  $\Delta^{17}\text{O}$  measures the distance to the terrestrial fractionation line in the oxygen three-isotope plot. It is defined as  $\Delta^{17}\text{O} = \delta^{17}\text{O} - 0.52 \times \delta^{18}\text{O}$ , where  $\delta^{17}\text{O}$  and  $\delta^{18}\text{O}$  measure respectively the excess of  $^{17}\text{O}$  and  $^{18}\text{O}$  with respect to  $^{16}\text{O}$  and to a standard (Standard Mean Ocean Water), multiplied by 1000.

Textural variations and corresponding mineral and chemical trends indicate that differing degrees of thermal metamorphism (heating) took place within each OC group (*Van Schmus and Wood*, 1967; *Dunn et al.*, 2010). Based on these variations, a petrologic classification scheme (*Van Schmus and Wood*, 1967) for OCs was developed (H, L, and LL groups are further subdivided into four groups — from 3 to 6), which consisted in distinguishing the less metamorphosed (heated) chondrites [type 3, called unequilibrated ordinary chondrites (UOCs)] from chondrites that have undergone higher degrees of thermal metamorphism [types 4 to 6, called equilibrated ordinary chondrites (EOCs); see *Huss et al.* (2006) for a review] (Fig. 1). Type 3s are further divided into 3.0–3.9 based on induced thermoluminescence properties (*Sears et al.*, 1980), but also by textures of opaque minerals (*Bourot-Denise et al.*, 1997) and the structure of organics as seen in Raman spectroscopy (*Bonal et al.*, 2006, 2007). An even finer division of petrographic types <3.2 was defined based on the distribution of Cr<sub>2</sub>O<sub>3</sub> within olivine (*Grossman and Brearley*, 2005).

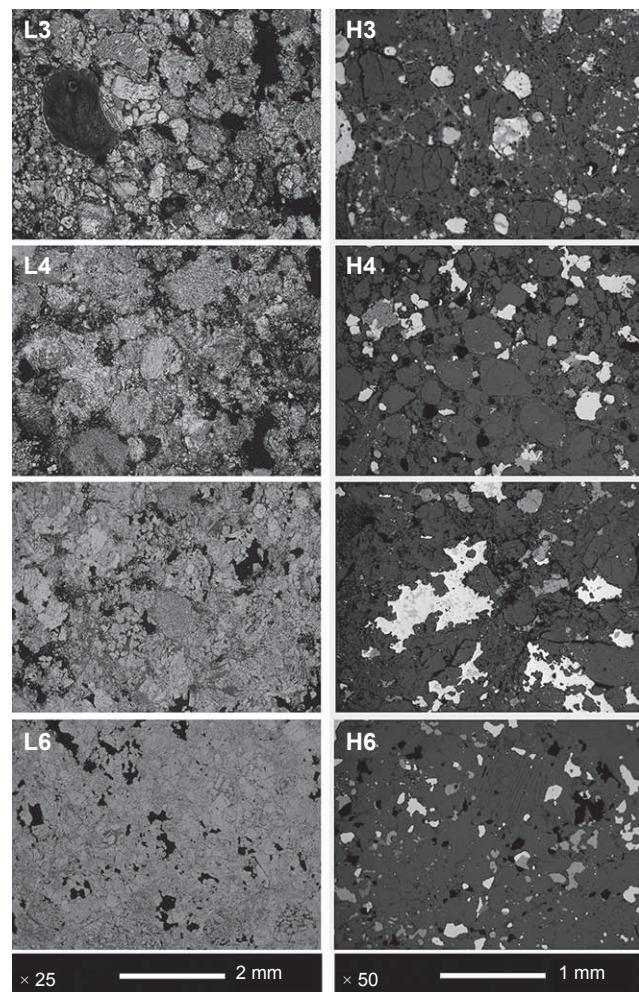

The study of OCs and of other chondrite classes has provided numerous constraints on the formation and early evolution of planetesimals, including (1) the processes that occurred in the protoplanetary disk prior to primary accretion (i.e., planetesimal formation) and their associated timescales (*Cuzzi et al.*, 2001; *Cuzzi and Weidenschilling*, 2006), (2) the heating mechanisms at the origin of metamorphism in planetesimals (*Ghosh et al.*, 2006), and (3) the post- (and syn-) accretional heating and collisional events (*Haack et al.*, 1996, and references therein; *Hutchison*, 2004; *Huss et al.*, 2006; *Ghosh et al.*, 2006; *Scott et al.*, 2014).

## 2.1. Constraints on the Processes that Occurred in the Protoplanetary Disk Prior to Accretion

Unequilibrated ordinary chondrites, which represent ~15% of all OCs (*Hutchison*, 2004), are the most primitive OCs. Several thermometers indicate that a number of UOCs did not experience metamorphic temperatures (*Hutchison*, 2004) > ~370°C and that all were < ~600°C. As such, UOCs give us the best indication of the initial material (a sort of snapshot of the protoplanetary disk) from which their parent asteroids accreted, as well as key constraints on the events that occurred in the protoplanetary disk prior to primary accretion.

Unequilibrated ordinary chondrites are mainly aggregates of high-temperature (>1600°C) components, including chondrules (~80% of the volume), which are millimeter-sized silicate spherules that formed through rapid melting and cooling of precursor material via a still-elusive mechanism (*Connolly and Desch*, 2004; *Jacquet et al.*, 2012), as well as metal and sulfide grains. All these components are set in a fine-grained interchondrule matrix (10–15 vol% of the rock) (*Hutchison*, 2004), which is believed to have always remained at low temperature (<200°C) in the disk.

As of today, the most likely explanation for the simultaneous presence in OCs of low-temperature and high-tem-

**Fig. 1.** Compositional and textural evolution of H and L chondrites as a function of petrologic type (silicate textures seen in transmitted light in L3–L6 chondrites and opaque mineral textures seen in reflected light in H3–H6 chondrites). Metamorphic heating in OCs results in chemical and textural changes, the most spectacular of which is the progressive disappearance of chondrules and matrix from petrologic type 3 (least heated) to 6 (most heated). As a result of long-duration heating (millions of years), the mineralogy of the rock is modified. Elemental diffusion allows minerals in chemical disequilibrium at the onset to react with one another. Minerals thus “equilibrate,” e.g., all olivine grains in one given rock end up with the same (FeO-rich) composition (Table 1). Glass disappears while feldspar grows. Textures also tend to equilibrate with the disappearance of the smaller grains (Ostwald ripening). This makes chondrule outlines become blurry and the typical chondritic texture hence tends to disappear.

perature components believed to have formed respectively far from and close to the Sun is that radial mixing was extensive in the solar nebula and thus played a prominent role in shaping the composition of these chondrites and that of planetesimals overall. Indeed, evidence of the simultaneous presence of low-temperature and high-temperature

components is also observed in other chondrite classes (*Hutchison*, 2004, and references therein) and in comets (*Kelley and Wooden*, 2009, and references therein).

Further evidence of the importance of radial mixing in all classes of chondrites, and OCs in particular, is provided by (1) the “universal shape” of the size distribution of chondrules that is centered at different sizes from chondrite class to chondrite class (*Grossman et al.*, 1989, and references therein; *Cuzzi et al.*, 2001, 2008), indicative of size-sorting; and (2) the simultaneous presence in a given chondrite of various proportions of two different types of chondrules [reduced type I and oxidized type II chondrules, which are made in different environments (*Zanda et al.*, 2006)].

Recently, *Fu et al.* (2014) have provided new constraints on the early evolution of the solar system by measuring the remnant magnetization in olivine-bearing chondrules from the primitive Semarkona meteorite (LL3.0). They report that these chondrules were magnetized in a nebular field of  $54 \pm 21 \mu\text{T}$ . This intensity supports chondrule formation by nebular shocks or planetesimal collisions rather than by electric currents, the x-wind, or other mechanisms near the Sun. This implies that background magnetic fields in the terrestrial planet-forming region were likely  $5\text{--}54 \mu\text{T}$ , which is sufficient to account for measured rates of mass and angular momentum transport in protoplanetary disks.

## 2.2. Heating Mechanisms Leading to Metamorphism in Chondrites

Whereas petrographic types were first discovered and described in OCs, it appears that most chondrites show evidence of metamorphism. Indeed, most enstatite chondrites have petrologic types that range from 4 to 6 with only two unequilibrated objects among observed falls (EH3). Carbonaceous chondrites also show evidence of metamorphism: CK chondrites have petrologic types that range from 3 to 6 and a few CO and CV chondrites may be somewhat metamorphosed, although most of them are ranked type 3s.

Several heat sources have been proposed to explain the thermal evolution (including metamorphism and/or differentiation) of planetesimals (see the chapter by Scott et al. in this volume for a more detailed discussion) and thus the existence of the different petrologic types (3 to 6) within each OC class (for reviews, see *McSween et al.*, 2002; *Ghosh et al.*, 2006; *Sahijpal et al.*, 2007). These include the decay of short-lived radioactive nuclides (*Urey*, 1955), which is now considered the most likely heat source; the decay of long-lived radioactive elements (*Yomogida and Matsui*, 1984); electromagnetic induction heating (*Sonnett et al.*, 1968; *Menzel and Roberge*, 2013); and impact heating (e.g., *Rubin*, 1995, 2003, 2004). Recent work has shown that neither electromagnetic induction nor impacts alone can explain the thermal processing of planetesimals [see *Marsh et al.* (2006) concerning electromagnetic induction and *Keil et al.* (1997) and *Ciesla et al.* (2013) for impact heating]. There is also no coherent scenario that could favor the decay of long-lived radioactive elements as the only heat source.

More specifically, substantial isotopic evidence suggests that  $^{26}\text{Al}$  was the major source of heat for melting early formed planetesimals and heating bodies that accreted later (e.g., *Bizzarro et al.*, 2005; *Kleine et al.*, 2005; *Hevey and Sanders*, 2006; *Ghosh et al.*, 2006; *Kruijer et al.*, 2012; *Sanders and Scott*, 2012). However, there is also evidence in chondrites for localized impact heating during metamorphism (*Rubin*, 1995, 2004). Impact heating of asteroids, even porous ones, is very inefficient (*Keil et al.*, 1997), but *Davison et al.* (2012) inferred that large projectiles impacting into highly porous chondritic targets could have buried enough impact melt at depth to cause localized slow cooling. In addition, impacts during metamorphism may have excavated hot chondritic rock so that it cooled more rapidly and mixed hot and cold material (*Davison et al.*, 2013; *Ciesla et al.*, 2013).

Over the last ~30 years, several groups have developed a wide range of thermal models of planetesimals based primarily on  $^{26}\text{Al}$  heating (e.g., *Miyamoto et al.*, 1981; *Miyamoto*, 1991; *Grimm and McSween*, 1993; *Bennett and McSween*, 1996; *Akridge et al.*, 1998; *Merk et al.*, 2002; *Ghosh et al.*, 2003; *Tachibana and Huss*, 2003; *Trieloff et al.*, 2003; *Bizzarro et al.*, 2005; *Baker et al.*, 2005; *Mostefaoui et al.*, 2005; *Hevey and Sanders*, 2006; *Sahijpal et al.*, 2007; *Harrison and Grimm*, 2010; *Elkins-Tanton et al.*, 2011; *Henke et al.*, 2012a,b; *Neumann et al.*, 2012; *Monnereau et al.*, 2013). Some authors have included additional heating effects due to  $^{60}\text{Fe}$ , which has a half-life of 2.6 m.y., compared to 0.72 m.y. for  $^{26}\text{Al}$ . However, the abundance of  $^{60}\text{Fe}$  is now thought to have been too low to provide any significant heating (*Tang and Dauphas*, 2012).

If the parent bodies of the OCs had been heated by  $^{26}\text{Al}$  and cooled without impact disturbance, they would have formed an onion-shell structure in which the most metamorphosed type 6 material occupying the central region surrounded by successive shells of less-metamorphosed type 5 through 3 material (*Trieloff et al.*, 2003; *Ghosh et al.*, 2006; *Henke et al.*, 2012a,b, 2013, and references therein).

## 2.3. Thermal and Impact History of the Ordinary Chondrite Parent Bodies

In this section we summarize the evidence that has been accumulated over the years regarding both the thermal and impact history of OC parent bodies.

**2.3.1. Evidence for impact from breccias and cosmic-ray exposure ages.** About 20–30% of all OCs are fragmental breccias composed of various petrologic types (*Bischoff et al.*, 2006). Regolith breccias, which are fragmental breccias containing a small fraction of grains with solar wind gases that were exposed on the surface of the parent asteroid, account for 15%, 3%, and 5% of H, L, and LL chondrites, respectively. Fragmental breccias that lack solar wind gases account for 5%, 22%, and 23% of H, L, and LL chondrites, respectively (*Rubin et al.*, 1983). The fraction of LL chondrites that are breccias may be much higher as *Binns* (1967) found that 62% of LLs were breccias. These breccias show that each OC parent body contains both unequilibrated and

equilibrated petrologic type material and that type 3–6 material can be found in a single body.

Regolith breccias and gas-poor fragmental breccias are dominated by clasts of equilibrated material. Although a few OC regolith breccias contain predominantly type 3 materials, most are largely composed of equilibrated, type 4–6 material. A typical regolith breccia contains clasts of equilibrated type 4–6 material, with rare impact melt clasts in a dark matrix that is mostly fine equilibrated material with a small amount of type 3 material including some unequilibrated chondrules (e.g., Metzler et al., 2011). This suggests that the surfaces of the OC parent bodies are dominated by equilibrated material and that each body contains a variety of different types. Few breccias contain more than a tiny fraction of foreign material. This is mostly CC material, presumably from projectiles.

Interestingly, the range of composition of olivine grains in a section of matrix from a regolith breccia [e.g., Fa<sub>10–29</sub> in the Northwest Africa 869 L chondrite (Metzler et al., 2011) is comparable to the range observed in the Itokawa sample, Fa<sub>24–31</sub> (Nakamura et al., 2011)]. In both cases more than 90% of the grains are derived from equilibrated material.

The presence of solar wind gas and solar-flare tracks in the regolith breccias shows that these breccias were formed after metamorphism of the parent bodies, which would have removed both features. Some gas-poor fragmental breccias may have formed earlier during metamorphism. The L breccia Mezö-Madaras, which contains L4 clasts in a predominantly L3 matrix, probably formed at this time (Scott et al., 2014).

Clues to the recent impact history of the OC parent bodies can be obtained from their cosmic-ray exposure ages, which range from ~1 to 100 m.y. (Herzog and Caffee, 2014). Cosmic rays penetrate a meter of rock, so these ages date the time when meter-sized meteoroids were formed by impacts on much larger bodies. The spectra of ages for OCs are dominated by a few peaks showing that the production of meteorites is dominated by a very small number of impact events on a correspondingly small number of parent bodies (Herzog and Caffee, 2014). H, L, and LL chondrites have different peaks in their age spectra, but petrologic types of the same group show similar peaks, and regolith breccias have similar distributions to other chondrites. These features, together with the abundance and nature of breccias, suggest that the OC parent bodies were well mixed internally by impacts with all types jumbled up. If the OC parent bodies did once have onion-shell structures, this is no longer the case. This conclusion is consistent with the results of Vernazza et al. (2014) discussed below, which show metamorphosed material to be present at the surface of H-chondrite parent bodies.

Finally, about half of all H chondrites have exposure ages of 6–10 m.y. This peak in the cosmic-ray exposure age spectrum is broader than other OC peaks and it may result from multiple impacts. Another group of meteorites, the acupulcoites and lodranites, have a similar cosmic-ray exposure age range of 5–10 m.y. (Terribilini et al., 2000; Herzog and Caffee, 2014). Numerous impacts on different

bodies during this period may result from a nearby major impact that produced a family of fragments that peppered nearby asteroids. Thus the 6–10-m.y. H-chondrite peak should not be taken as evidence that all these meteorites come from one body.

### 2.3.2. Constraints on the thermal evolution and impact history of the H-chondrite parent body from cooling rates.

Here we summarize what has been learned about the metamorphic and early impact histories of the H chondrites in relatively unshocked H3–6 chondrites.

Pellas and Storzer (1981) found that cooling rates for six H4–6 chondrites derived from Pu fission track thermometry decreased with increasing petrologic type. They concluded that the parent body of the H chondrites had been heated by <sup>26</sup>Al decay and had cooled with an onion-shell structure.

Cooling rates of more than 30 OCs have also been inferred from Ni concentrations at the centers of zoned taenite grains (Wood, 1967; Willis and Goldstein, 1981, 1983). Scott and Rajan (1981) and Taylor et al. (1987) found no evidence that the parent bodies had cooled with an onion-shell structure, as cooling rates did not decrease systematically from type 3 to type 6. They concluded that either the parent bodies never had onion-shell structures or their interiors were rearranged by impacts, possibly by catastrophic disruption and reassembly, as Grimm (1985) suggested, prior to cooling below ~600°C when taenite grains start to develop Ni concentration gradients. Because metallographic cooling rates for the six H chondrites studied by Pellas and Storzer (1981) were consistent with fission-track cooling rates, Taylor et al. (1987) suggested that the apparent conflict between the two techniques was merely a result of the small sample size of the fission track dataset.

The most detailed evidence for the onion-shell model was presented by Trieloff et al. (2003), who measured Ar-Ar ages and fission-track cooling rates for nine H chondrites and compared them with the Pb-Pb ages of Göpel et al. (1994). Both sets of radiometric ages were found to correlate inversely with petrologic type and closely matched ages calculated for various depths in a 100-km-radius asteroid that was heated by <sup>26</sup>Al to 850°C in its central regions and cooled without disturbance by impact to ~100°C in ~150 m.y. Trieloff et al. (2003) did not discuss the conflicting metallographic cooling rates of Taylor et al. (1987), but suggested that the samples studied by these authors had been modified by shock or impact heating. Wood (2003) concluded that Trieloff et al. (2003) had resolved the controversy in favor of the onion-shell model.

Subsequent studies of the radiometric ages of H chondrites or thermal modeling of their parent body have largely endorsed the conclusions of Trieloff et al. (2003). Kleine et al. (2008) found that Hf-W ages of five H4–6 chondrites, including four of those studied by Trieloff et al. (2003), decreased with increasing petrologic type. They concluded that the parent body had cooled with an onion-shell structure after heating by <sup>26</sup>Al. Harrison and Grimm (2010) used radiometric ages and metallographic cooling rates for H chondrites to constrain various thermal models and concluded that nearly

all data could be accounted for by an onion-shell body with a radius of 75–130 km. They questioned the accuracy and validity of some metallographic cooling rates and suggested that the relatively small number of nonconforming data might be attributed to impacts that left the parent body largely intact. Finally, *Henke et al.* (2012b) and *Monnereau et al.* (2013) focused on the eight H chondrites for which precise radiometric ages are available at three different closure temperatures (*Trieloff et al.*, 2003). They concluded that an onion-shell body with a radius 110–130 km that accreted rapidly (in <0.2 m.y.) around 1.8–2.1 m.y. after CAI formation could successfully reproduce their cooling histories without invoking any disturbance by impacts.

Constraints on the thermal histories of OCs from silicates and oxides suggest that the parent bodies did not cool with an onion-shell structure. Cation ordering temperatures in orthopyroxene in eight H4–6 chondrites indicated similar cooling rates at ~400°–500°C (*Folco et al.*, 1996). Olivine-chromite thermometry gave similar mean temperatures for H4, H5, and H6 chondrites of ~690°–770°C (*Wlotzka*, 2005). *Kessel et al.* (2007) also found several inconsistencies with the onion-shell model. *Ganguly et al.* (2013) measured compositional profiles across coexisting orthopyroxene-clinoptyroxene, olivine-spinel, and orthopyroxene-spinel grains in five H4–6 chondrites and found all grains to be essentially homogeneous. From calculated compositional profiles, they inferred that the chondrites cooled very rapidly above 700°C at rates of 25°–100°C k.y.<sup>-1</sup>, several orders of magnitude faster than the rates generally inferred from radiometric ages and metallography. *Ganguly et al.* (2013) concluded that the H-chondrite parent body had been fragmented and then reaccreted prior to cooling below 700°C.

Recently, *Scott et al.* (2014) have studied cloudy taenite, metallographic cooling rates, and shock effects in 30 H3–6 chondrites to elucidate the thermal and early impact history of the H-chondrite parent body. They focused on H chondrites with old Ar-Ar ages (>4.4 G.y.) and unshocked and mildly shocked H chondrites, as strongly shocked chondrites with such old ages are very rare. They found that cooling rates for most H chondrites at 500°C are 10°–50°C m.y.<sup>-1</sup> and do not decrease systematically with increasing petrologic type (see Fig. 2), as predicted by the onion-shell model, in which types 3–5 are arranged in concentric layers around a type 6 core. Some type 4 chondrites cooled slower than some type 6 chondrites and type 3 chondrites did not cool faster than other types, contrary to the onion-shell model. The three H4 chondrites that were used to develop the onion-shell model (*Trieloff et al.*, 2003), Ste. Marguerite, Beaver Creek, and Forest Vale, cooled through 500°C at >5000°C m.y.<sup>-1</sup>, at least 50× faster than any sample in a body that was heated by <sup>26</sup>Al and cooled without impact disturbance. Since such fast-cooled H4 chondrites are rare and cooling rates of types 3–6 overlap considerably, *Scott et al.* (2014) infer that the suite of chondrites studied by *Trieloff et al.* (2003) are simply not representative of unheated H4–6 chondrites. To explain their metallographic data, *Scott et al.* (2014) rely on recent work by *Ciesla et al.*

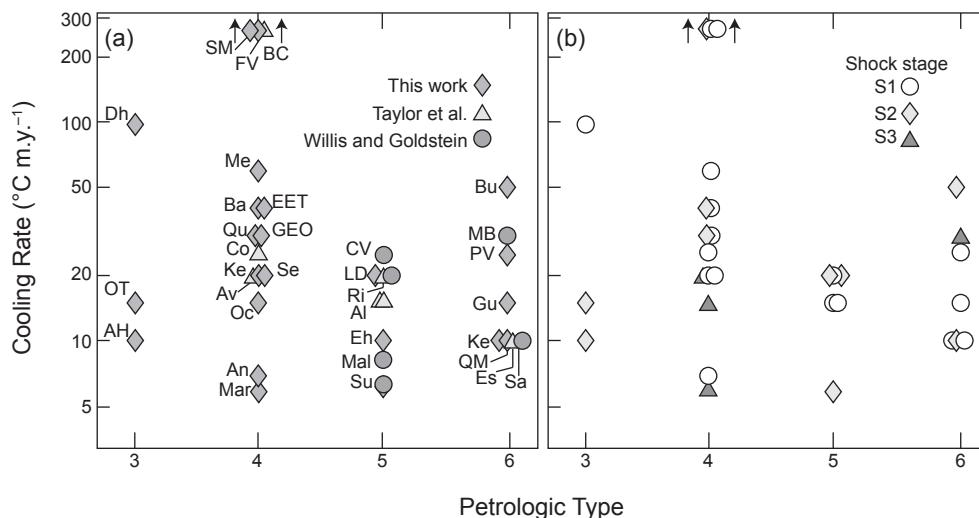

(2013) and propose that several early impacts punctured the H-chondrite parent body (bodies) to type 6 depths (assuming an onion-shell structure) while it was cooling, causing disturbances in the thermal histories of many H chondrites and leading to surfaces containing rocks that originated at a wide range of depths. They stress that the metallographic data do not require catastrophic disruption by impact during cooling. Considering the conflicting results reported above, it is reassuring that their results are coherent with the observed surface composition of large S-type asteroids (*Vernazza et al.*, 2014) (see section 4.2).

**2.3.3. Constraints on the thermal evolution and impact history of the L-chondrite parent body.** About two-thirds of L-chondrite meteorites were heavily shocked and degassed with <sup>39</sup>Ar–<sup>40</sup>Ar ages near 470 m.y. (*Korochantseva et al.*, 2007), suggesting that the L-chondrite parent body suffered a major impact ~470 m.y. ago and catastrophically disrupted (see also *Heymann*, 1967; *Haack et al.*, 1996, and references therein). Metallographic cooling rates of lightly shocked or unshocked L chondrites are in the range 1°–10°C m.y.<sup>-1</sup> (*Taylor et al.*, 1987). These slow cooling rates imply that the original parent body had a diameter >100 km (*Haack et al.*, 1996).

It is striking that the timing of the shock event coincides with the stratigraphic age ( $467 \pm 2$  m.y.) of the mid-Ordovician strata where abundant fossil L chondrites, meteorite-tracing chromite grains, and iridium enrichment were found in the active marine limestone quarry in southern Sweden (*Schmitz et al.*, 1997, 2003, 2007; *Greenwood et al.*, 2007). The recent shocked and fossil L chondrites may thus apparently record the same event, a catastrophic disruption of a large MBA that produced an initially intense meteorite bombardment of Earth and at least ≈30% of the OC falls today.

**2.3.4. Thermal history of the (25143) Itokawa parent body.** On the basis of the mineralogy and mineral chemistry of ~50 Itokawa dust particles, we will briefly summarize the current understanding of the thermal history of the Itokawa parent asteroid, Itokawa likely being a collisional fragment from a once larger body (*Nakamura et al.*, 2011). Mineralogical evidence indicates that Itokawa's parent body experienced thermal metamorphism and slow cooling (*Nakamura et al.*, 2014). It reached a peak metamorphic temperature of ~800°C (*Nakamura et al.*, 2011), which is lower by ~100°C than the peak temperature obtained for LL6 chondrites (*Slater-Reynolds and McSween*, 2005), suggesting that the most abundant material among Itokawa dust particles is likely LL5 material. In addition, the temperature during cooling appears to have remained higher than 700°C for 7.6 m.y. after CAI formation based on the absence of radiogenic <sup>26</sup>Mg in plagioclase (*Yurimoto et al.*, 2011a,b).

Both constraints have been used by *Wakita et al.* (2014) to reproduce the thermal evolution of the Itokawa parent asteroid via numerical simulations. They found that the Itokawa parent body appears to have formed with a radius greater than 20 km and accreted between 1.9 and 2.2 m.y. after CAI formation. Further modeling work by *Nakamura et al.* (2014) shows that a 50-km-sized body formed around

**Fig. 2.** Metallographic cooling rate vs. petrologic type for 35 H3–6 chondrites: **(a)** source of data; **(b)** shock stage of chondrites. Cooling rate ranges in types 3–6 overlap considerably, contrary to the onion-shell model, and are not correlated with shock stage. Most cooling rates have a precision of a factor of 2. From Scott et al. (2014).

~2.2 m.y. after CAIs is one of the best formation models for the Itokawa parent asteroid. In short, both papers infer that the parent body was 20–50 km in radius or larger and that it accreted 1.9–2.2 m.y. after CAI formation. However, since most LL chondrites and asteroids with LL chondrite spectral characteristics probably come from the large Flora family of asteroids, which dominates the inner part of the asteroid belt (section 5), it is likely that the Itokawa asteroid does as well and is simply deficient in type 6 material. The parent body of the Flora family of asteroids was ~100 km in radius, judging from the inferred size of the known family members (Durda et al., 2007).

### 3. IDENTIFICATION OF THE PARENT BODIES OF ORDINARY CHONDRITES

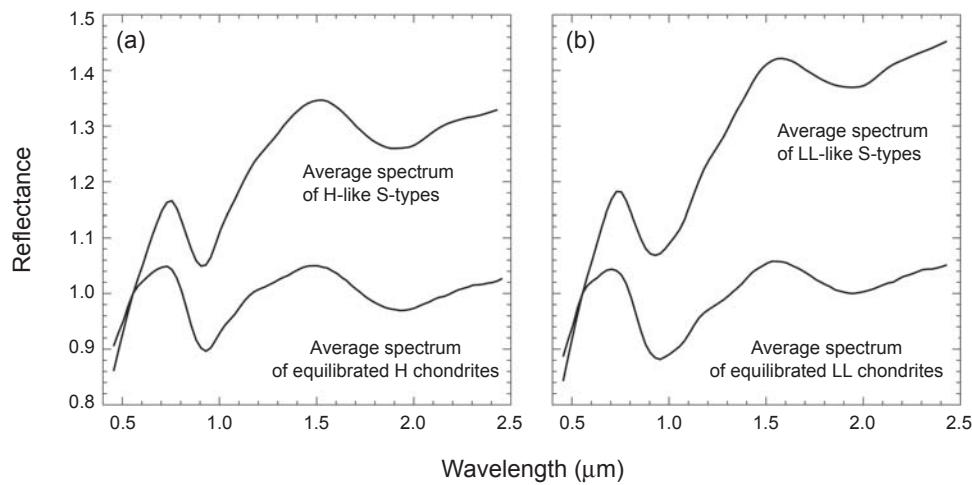

In this section, we describe the outstanding efforts that have been accomplished by a large fraction of the asteroid-meteorite community to unambiguously identify the parent bodies of OCs. These efforts include 4 decades of telescopic observations, more than 20 years of laboratory measurements and experiments, and the first asteroid sample return mission.

#### 3.1. Ordinary Chondrite Parent Bodies Among S-Type Asteroids?

The parent bodies of OCs have been searched for via visible and near-infrared photometric and/or spectroscopic observations for more than 40 years. Early photometry of asteroids based on photoelectric sensors (Chapman et al., 1971; Hapke 1971) revealed two predominant colorimetric groups: (1) those with slightly reddish sloping reflectance spectra throughout the visible out to 1 μm and with an absorption feature starting longward of 0.7 μm and with a band

minimum around 0.95 μm (such asteroids are commonly in the inner half of the belt), and (2) those with flat reflectance spectra [commonly located in the outer half of the main belt (Chapman, 2004)]. Chapman et al. (1975) introduced the taxonomy that called the reddish, moderate-albedo first group the “S-type” (mnemonic for silicaceous because the 0.95-μm band had been interpreted as being due to silicate minerals), and called the neutral-colored, low-albedo second group the “C-type” (mnemonic for carbonaceous, by analogy with carbonaceous meteorites). Thus began the C-, S-, and, later, M-, etc., asteroid taxonomy (Chapman, 2004), which has now been expanded to include most letters of the alphabet and has been further refined by many researchers [the latest taxonomy is from DeMeo et al. (2009); for a review, see the DeMeo et al. chapter in this volume]. More recent surveys, including the Sloan Digital Sky Survey (SDSS), which surveyed more than 100,000 asteroids in the visible (DeMeo and Carry, 2013, 2014), have not changed the global view presented in Chapman et al. (1975), i.e., most asteroids can still be regarded as being S or C.

Early comparisons between meteorite and asteroid optical reflectance spectra (e.g., Chapman and Salisbury, 1973) suggested that only S-type asteroids have spectral characteristics (e.g., absorption band near 0.95 μm) compatible with those seen in OCs, although S-type asteroids have a redder reflectance. Subsequent measurements in the near-infrared range have not altered this picture (e.g., Gaffey et al., 1993; Vernazza et al., 2008, 2009, 2014; DeLeon et al., 2010; Thomas and Binzel, 2010; Dunn et al., 2013). The spectral slope difference between OC and S-type spectra (see Fig. 3), however, has for more than 30 years been an obstacle to establishing a definite link between both groups and has constituted one of the greatest conundrums in the asteroid-meteorite field [see Chapman (2004) for an extensive review

**Fig. 3.** Spectral comparisons of S-type asteroids and ordinary chondrite meteorites. Comparison between the visible to near-infrared spectral signatures of main-belt S-type asteroids [(a) asteroids with H-like compositions; (b) asteroids with LL-like compositions] and the average spectra of equilibrated (type 4–6) H- and LL-chondrite meteorites. Space weathering processes similar to those acting on the Moon (e.g., Pieters *et al.*, 2000) redden the ordinary chondrite-like spectrum of a fresh asteroid surface, giving it the appearance of an S-type spectrum (e.g., Vernazza *et al.*, 2008, and references therein). Adapted from Vernazza *et al.* (2014).

on this subject]. The conundrum was even reinforced on the basis of mineralogical arguments (Gaffey *et al.*, 1993) that were suggesting that a large fraction of S-type asteroids are partly differentiated and thus not OC-like (Abell *et al.*, 2007). This view was held by a small fraction of the community until the Itokawa sample return (Abell *et al.*, 2007).

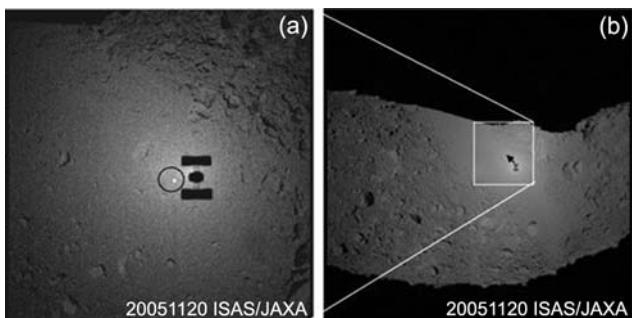

### 3.2. Hayabusa Confirms a Linkage Between S-Type Asteroids and Ordinary Chondrites

The Japanese spacecraft Hayabusa was launched onboard an M-V-5 rocket on May 9, 2003. The aims of the Hayabusa mission were to (1) confirm a linkage between S-type asteroids and OCs, and (2) uncover the mechanisms of space weathering, responsible for the mismatch of reflectance spectra between S-type asteroids and OCs (see the chapter by Yoshikawa *et al.* in this volume for an overview of the mission and its main results). Hayabusa arrived at the S-type asteroid (25143) Itokawa (Fig. 4) in September 2005 and observed its surface using a variety of onboard apparatus (Fujiwara *et al.*, 2006). The results of the *in situ* measurements indicated that the reflectance spectra (Abe *et al.*, 2006) are similar to those of equilibrated LL chondrites, thus confirming Binzel *et al.*'s (2001) earlier prediction. Hayabusa touched down twice on smooth terrain at "MUSES-C Regio" (Fig. 4a) and tried to recover surface samples from the asteroid. Although projectiles that planned to hit the asteroid surface did not fire, the sampling horn of the spacecraft touched the surface several times, which likely stirred up the Itokawa particles captured by the spacecraft (Yano *et al.*, 2006). The spacecraft finally came back to Earth in June 2010, five years after the touchdown.

Numerous small particles mostly less than 50 μm in size were found in the Hayabusa sample container and were recovered one by one by electrostatic manipulator operation in a pure nitrogen atmosphere (Nakamura *et al.*, 2011; Yada *et al.*, 2014). The initial analysis for basic characterization of approximately 60 Itokawa dust particles showed that the mineralogy and mineral chemistry of the Itokawa dust particles were identical to those of equilibrated LL chondrites (Nakamura *et al.*, 2011) (see Fig. 5). Oxygen-isotope ratios of silicates also indicate the similarity to equilibrated LL chondrites (Yurimoto *et al.*, 2011a,b; Nakashima *et al.*, 2014). Minor and major elemental abundances were found to be similar to those of OCs (Ebihara *et al.*, 2011). In addition, the modal abundance of minerals, bulk density, porosity, and grain size of the Itokawa particles were found to be similar to those of LL chondrites (Tsuchiyama *et al.*, 2014).

Figures 6a,b show typical Itokawa particles. Olivine is the most abundant mineral, as is the case for LL chondrites. Most of the olivine particles have compositions equilibrated around Fa<sub>29</sub> (Fig. 5), which is within the compositional range of equilibrated LL chondrites, but some olivines show Mg-rich compositions, suggesting that they were on the way to final equilibration (Nakamura *et al.*, 2011). The next most abundant minerals are — as usually observed among equilibrated LL chondrites — low- and high-Ca pyroxenes and plagioclase, and their compositions are also almost homogeneous.

In summary, all measurements performed on Itokawa both *in situ* and in terrestrial laboratories indicate that the asteroid has an LL-like composition. This result confirms what many researchers had predicted (e.g., Pellas, 1988), namely that S-type asteroids comprise the parent bodies of

**Fig. 4.** Itokawa's landing site. **(a)** Hayabusa is descending toward MUSES-C Regio and the shadow of the spacecraft is projected on the surface. **(b)** A whole view of the MUSES-C region. JAXA digital images P-043-15285.

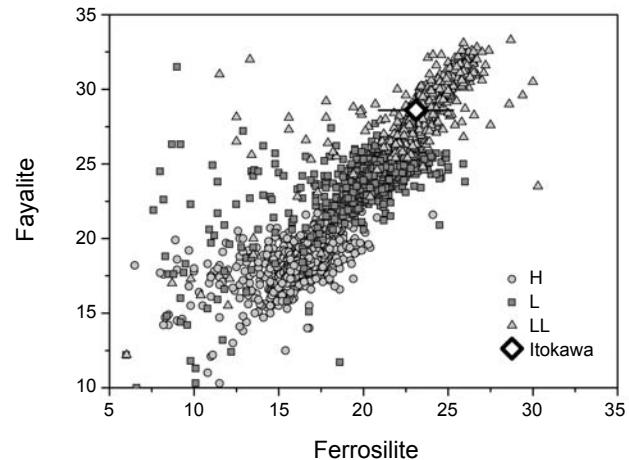

OCs. This fact implies that space weathering processes are generally responsible for the spectral mismatch between OCs and S-type asteroids (e.g., *Sasaki et al.*, 2001; *Strazzulla et al.*, 2005; see the chapter by Brunetto et al. in this volume for a detailed review), which we summarize in the next subsection.

### 3.3. Space Weathering Processes Responsible for the Spectral Mismatch Between Ordinary Chondrites and S-Type Asteroids

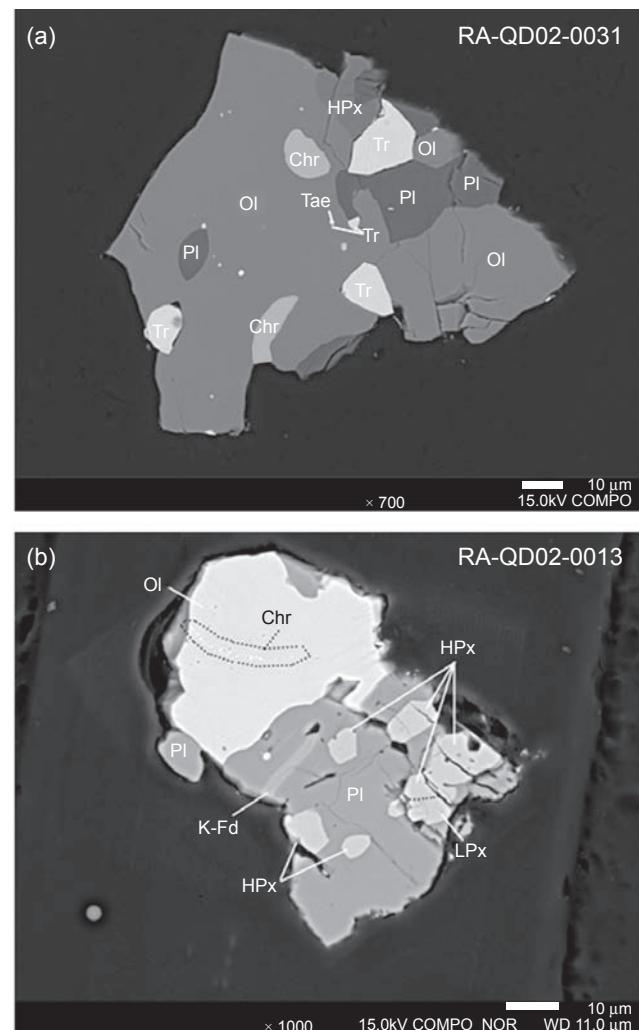

Over the last 15 years, laboratory experiments simulating space weathering effects on OCs and its main minerals (olivine, pyroxene) (e.g., *Sasaki et al.*, 2001; *Strazzulla et al.*, 2005; *Marchi et al.*, 2005; *Brunetto et al.*, 2006; see the chapter by Brunetto et al. in this volume for more information) have established unambiguously that OC-like material naturally reddens (spectrally) in space under both bombardment by micrometeorites and irradiation by solar wind particles, a conclusion that was reinforced by the analysis of both the images and near-infrared spectra of Itokawa's surface collected by Hayabusa as well as the S-type samples that Hayabusa brought back to Earth (*Nakamura et al.*, 2011).

Spatially resolved images and near-infrared spectra of Itokawa's surface by Hayabusa (*Hiroi et al.*, 2006) revealed developing space weathering on Itokawa's surface. Specifically, *Hiroi et al.* (2006) showed that dark areas on Itokawa possess on average redder spectra than bright areas, in agreement with space weathering spectral trends predicted by laboratory experiments (e.g., *Sasaki et al.*, 2001; *Strazzulla et al.*, 2005; see the chapter by Brunetto et al.).

Subsequent laboratory measurements of the three-dimensional structure of the Itokawa particles determined by X-ray microtomography suggested that they have been impacted by meteoroids (*Tsuchiyama et al.*, 2011); the discovery of microcraters on the surface of some Itokawa particles reinforced the evidence of interplanetary dust particles impacting asteroid surfaces (*Nakamura et al.*, 2012). Large amounts of solar wind noble gases were also detected within the Itokawa

**Fig. 5.** Comparison between the mineral chemistry of the Itokawa particles and that of H, L, and LL chondrites. From *Nakamura et al.* (2011).

**Fig. 6.** Backscattered electron images of polished sections of typical Itokawa particles: **(a)** RA-QD02-0031; **(b)** RA-QD02-0013. OI = olivine, PI = plagioclase, Tae = taenite, Tr = troilite, Chr = chromite, LPx = low-Ca pyroxene, HPx = high-Ca pyroxene, K-fd = K feldspar.

particles, implying that solar wind implantation into the regolith particles is a common process (Nagao *et al.*, 2011). In parallel, a careful inspection of the Itokawa surface samples revealed sulfur-bearing and sulfur-free Fe-rich nanoparticles at the outermost layers of the Itokawa particles (Noguchi *et al.*, 2011), thus identifying the reddening agent responsible for the color difference between S-types and OCs. The results of further TEM analysis identified three types of particle surface modifications induced by space weathering processes (Noguchi *et al.*, 2014). In summary, all these results indicate that the Itokawa dust particles — recovered from the space-weathered area MUSES-C Regio — record intensive interactions between the asteroid regolith and incoming particles such as solar wind ions and interplanetary dust. The Hayabusa mission has thus confirmed what was suspected for a long time, namely that OCs originate from S-type asteroids and that the spectral mismatch between OCs and S-types is mainly due to space weathering processes.

As a consequence (and ironically, considering how long the S-type/OC conundrum lasted), the *normal* appearance of an OC-like asteroid is an S-type asteroid (spectral mismatch between OCs and their parent bodies), while the *anomalous* appearance of an OC-like asteroid is a Q-type asteroid (spectral match between OCs and their parent bodies)! The existence of Q-type asteroids, which indicates that rejuvenating processes do occur on some asteroids (see the chapter by Brunetto *et al.*), has offered us the opportunity to unveil a new physical process in asteroid science, namely seismic shaking during planetary encounters (Nesvorný *et al.*, 2005; Marchi *et al.*, 2006; Binzel *et al.*, 2010; DeMeo *et al.*, 2014; see also the chapter by Binzel *et al.* in this volume). Note that thermal fatigue (Delbo *et al.*, 2014) and spin-up due to the YORP effect (see the chapter in this volume by Vokrouhlický *et al.* and references therein) may also play a role in refreshing asteroid surfaces.

### 3.4. How Many S-Type Asteroids Actually Have Ordinary-Chondrite-Like Mineralogies?

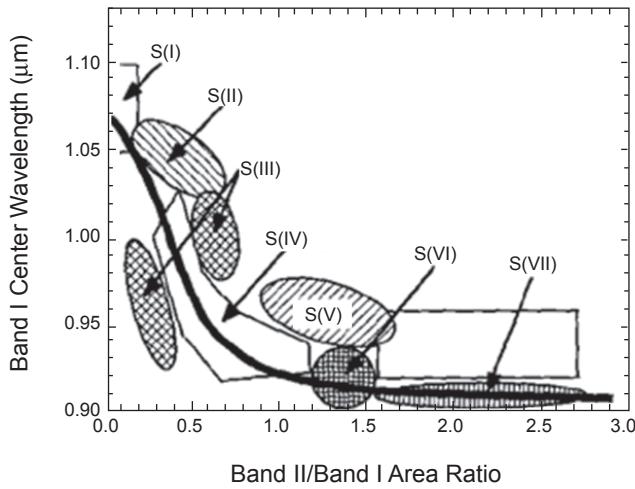

At a time when it was still not fully accepted that S-type asteroids comprise the parent bodies of OCs, researchers started comparing the surface mineralogy of S-type asteroids with that of OCs to test a possible link between the two groups of objects (e.g., Gaffey *et al.*, 1993). Such compositional investigation could not be performed in the visible domain only: It required extended wavelength coverage into the near-infrared (ideally, a spectral coverage over the 0.4–2.5  $\mu\text{m}$  range; see the chapter by Reddy *et al.* in this volume). In this extended wavelength range, both S-types and OCs possess prominent 1- and 2- $\mu\text{m}$  spectral features due to the presence of olivine and pyroxene in the two populations (see Fig. 6).

Gaffey *et al.* (1993) were the first to perform this type of mineralogical investigation for a large number of S-type asteroids (39 objects; it actually turns out that only 32 of these objects are S-type MBAs). They used a classification scheme (see Fig. 7) based on band area ratios (BAR) (area

of Band II divided by area of Band I) and Band I centers to break the S-types into seven subtypes [from S(I) to S(VII)], corresponding to varying ratios of olivine to pyroxene. The BAR value tends to increase and the Band I center value tends to decrease as the subtype number increases in value, which indicates an increasing pyroxene concentration (Burbine, 2014). Their S(I) type has an olivine-dominated mineralogy, and in the new classification by DeMeo *et al.* (2009) corresponds mostly to A-types (and thus not to S-types anymore), while the S(IV) subtype has an olivine-pyroxene mineralogy similar to that of OCs. Both the S(II) and S(III) subtypes were interpreted as having olivine-dominated mineralogies with a high-Ca pyroxene component, while the S(V) and S(VII) were interpreted as having a higher and significant high-Ca pyroxene component.

The main conclusion of Gaffey *et al.*'s (1993) investigation is that few S-type asteroids have silicate mineralogies consistent with those of OCs, and that the diversity within the S-class arises from several sources, including the coexistence of undifferentiated, partially differentiated, and fully differentiated bodies within the general S-type population.

Concerning the few objects that were considered OC-like, Gaffey *et al.* (1993) noticed that they are concentrated near the 3:1 Kirkwood gap at 2.5 AU and proposed that their favorable location close to this resonance might explain why OCs are so abundant among meteorite falls. A few years later, Gaffey and Gilbert (1998) proposed asteroid (6) Hebe as the probable parent body of H-type OCs and, since then, many authors have relied on this association in their studies (e.g., Akridge *et al.*, 1998; Ghosh *et al.*, 2003; Bottke *et al.*, 2010; Henke *et al.*, 2012, 2013). In the early 2000s, the idea that several S-type asteroids have high fractions of

**Fig. 7.** Distribution of Gaffey *et al.* (1993) S subtypes on a plot of Band Area Ratio vs. Band I center. The thick black line is the olivine-orthopyroxene mixing line. The ordinary chondrite region is the same as the S(IV) region. The HED region (rectangle above SVII) is also plotted. From Gaffey *et al.* (1993).

high-Ca pyroxene on their surfaces, which is an indication that these bodies have undergone either melting or partial melting and thus cannot be linked to OCs, was brought up again by Sunshine et al. (2004), Hardersen et al. (2006), and Abell et al. (2007) in the case of Itokawa.

During the following years, the emergence of numerous high-quality spectroscopic measurements in the near-infrared (obtained essentially with the NASA IRTF), along with the growing utilization within the community of new spectral analysis tools [modified Gaussian method (MGM) and radiative transfer model; see the chapter by Reddy et al. in this volume] has progressively overturned the view by Gaffey et al. (1993) that many S-types are compositionally unconnected to OCs. Using both MGM and a radiative transfer model to constrain the mineralogy of a large sample of S-type NEAs, Vernazza et al. (2008) showed that most of these objects have silicate mineralogies that are compatible with those of OCs. Their findings were later confirmed by DeLeon et al. (2010), Dunn et al. (2013), and Thomas et al. (2014) for even larger samples of S-type NEAs, and by Vernazza et al. (2009), De Leon et al. (2010), and Vernazza et al. (2014) for large samples of S-type MBAs. Various authors derived the mineralogy of smaller samples of S-types and found OC-like mineralogies in most cases (Binzel et al., 2001, 2009; Reddy et al., 2009, 2011a,b, 2012; Fieber-Beyer and Gaffey, 2011, 2014; Fieber-Beyer et al., 2012; Gietzen et al., 2012; Sanchez et al., 2013).

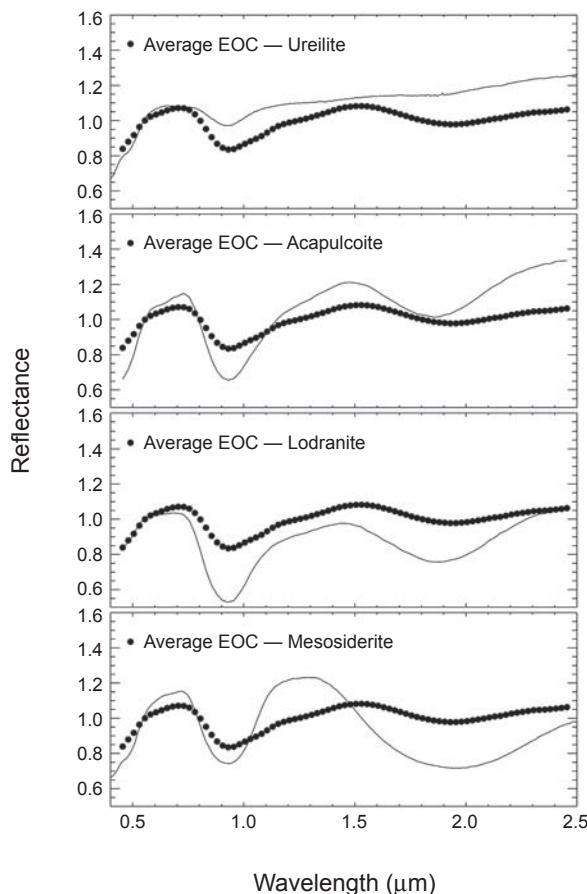

### 3.5. Are There Meteorites Other than the Ordinary Chondrites Derived from S-Type Asteroids?

S-type asteroids are a diverse group of objects, and one cannot exclude that some meteorites other than the OCs could also originate from them (e.g., Burbine et al., 2002). Possibilities include differentiated meteorites, as proposed by Sunshine et al. (2004), such as pallasites, brachinites, ureilites, lodranites, winonaites, IAB irons, and mesosiderites (Gaffey et al., 1993).

Primitive achondrites (including winonaites, lodranites, acapulcoites, and brachinites) are meteorites with affinities to chondrites. They have undergone partial melting but the silicate and metal portions have not segregated, and so they retain their chondritic bulk composition; they are therefore likely to have spectral similarities to chondrites. Indeed, it appears that both lodranites and acapulcoites have spectral properties and ol/(ol + low Ca-px) ratios that are very similar to OCs and H chondrites in particular (see Fig. 8), although they are on average slightly more pyroxene-rich than H chondrites. However, there are two reasons as to why most H-like S-type asteroids may not be linked to either of these meteorite classes. The first is that the center of Band II for both lodranites and acapulcoites is located between 1.8 and 1.9  $\mu\text{m}$ , while the band center for H chondrites [and H-like S-types (see Vernazza et al., 2014)] and other OCs is located between 1.9 and 2  $\mu\text{m}$ , indicating differences in terms of pyroxene composition between the two groups. The second reason is that both lodranites and acapulcoites together

represent ~0.2% of the falls, implying that they are ~150× less abundant than H chondrites among falls (and ~400× less abundant than OCs in general). Although it is clear that even at similar densities and tensile strength (which is typically the case for the H, L, and LL chondrites but also for lodranites and acapulcoites), meteorite falls are not exactly representative of the compositional diversity of the asteroid belt (Vernazza et al., 2014), they still are within a factor of ~10, implying that lodranite-like and acapulcoite-like bodies should be rare among S-types.

Mesosiderites are complex brecciated meteorites consisting of metal-rich and silicate-rich portions. Their spectra (Burbine et al., 2007) are at odds with those of S-type asteroids and/or OCs (see Fig. 8). The same applies to ureilites, which are igneous meteorites composed of olivine and pyroxene with notably large amounts of carbon (several percent). The possibility that ureilites could have an S-type asteroid source could be tested when the Almahatta Sitta ureilite breccia fell near Nahr an Nil in Sudan in 2008. The

**Fig. 8.** Comparison between an average spectrum of equilibrated H, L, and LL chondrites and the spectra of ureilites, acapulcoites, lodranites, and mesosiderites (data taken from the RELAB database). While the spectra of both ureilites and mesosiderites appear quite different from the OC spectra, both lodranites and acapulcoites have similar spectra with respect to OCs.

spectroscopic features of the parent asteroid for Almathatta Sitta, 2008 TC<sub>3</sub>, were determined by Jenniskens *et al.* (2010). They concluded that the asteroid most closely resembled an F-type asteroid, and that this asteroid type is more likely to be the parent to ureilites than S-type asteroids.

Brachinites, whose spectra are not described here, are far more olivine-rich than LLs. Their spectra are great analogs for A-type asteroids but certainly not for S-type ones (Sunshine *et al.*, 2007). Finally, pallasites are also olivine-rich meteorites. As in the case of brachinites, their parent asteroids should be hidden among A-type asteroids (Sunshine *et al.*, 2007).

#### 4. CONSTRAINTS ON THE FORMATION AND EVOLUTION OF ORDINARY CHONDRITE PARENT BODIES FROM TELESCOPE OBSERVATIONS

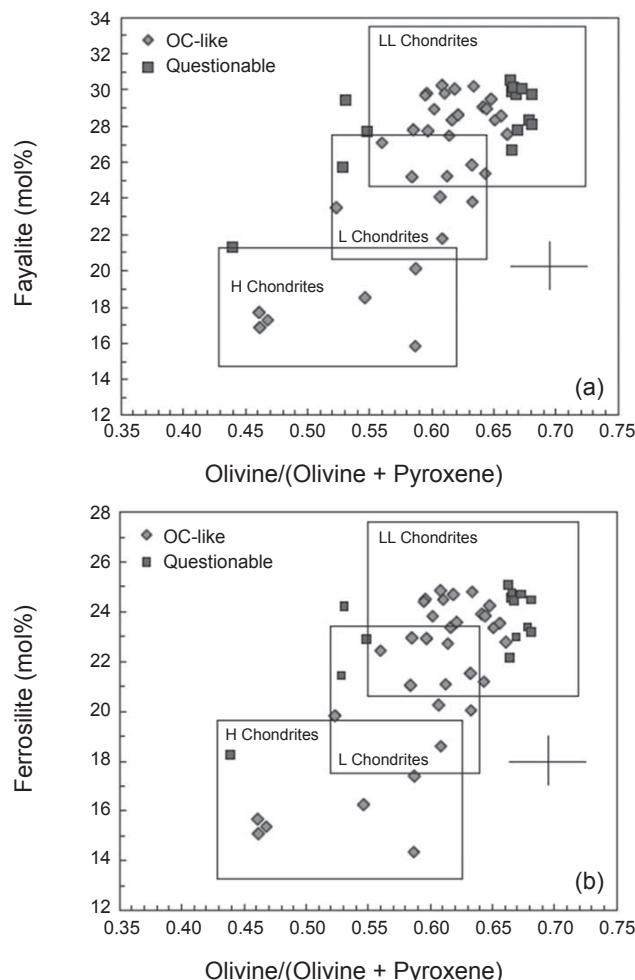

The ability to link specific OC classes (H, L, and LL) to specific S-type asteroids via visible and near-infrared spectroscopy has not only provided us with a better understanding of the formation mechanism of OC parent bodies and planetesimals in general, it has also boosted our understanding of asteroid dynamics and in particular the delivery process of meteorites and NEAs from the main belt to near-Earth space.

##### 4.1. What Have We Learned from S-Type Near-Earth Asteroids?

Spectroscopic observations of more than 400 NEAs in visible wavelengths show that 65% of NEAs have S- and Q-type spectral properties (Binzel *et al.*, 2004). When corrected for discovery biases (Stuart and Binzel, 2004), the near-Earth population of S- and Q-type asteroids is estimated to be 36% of the total NEA population. Vernazza *et al.* (2008) used both MGM and a radiative transfer model to analyze the visible and near-infrared spectra of 38 S- and Q-type NEAs from Binzel *et al.* (2004) and reported that most NEAs (approximately two-thirds) have spectral properties similar to LL chondrites (see Fig. 9). This result is surprising, because LL chondrites are the least-abundant OCs (they represent only 10% of all OCs, and 8% of all meteorites). Vernazza *et al.* (2008) argued that the NEAs we sample telescopically (with radii of 0.3 km to 10 km) are not the immediate parent bodies of smaller objects that fall to Earth as meteorites (i.e., preatmospheric meteorite parent bodies having radii on the order of meters) and that different dynamical mechanisms (mainly a size-dependent process such as the Yarkovsky effect) and/or main-belt source regions may be responsible for supplying these two sample populations. They further proposed the Flora family (near the v<sub>6</sub> secular resonance) as the source region for NEAs with LL-like compositions.

Thomas and Binzel (2010) used MGM to determine meteorite analogs for a sampling of S-type NEAs and then used the Bottke *et al.* (2002) dynamical model to determine the probable source region for each of those NEAs. They

found that H chondrites have a higher than average delivery preference though the 3:1 mean-motion resonance, whereas LL chondrites are mostly injected in the near-Earth space via the v<sub>6</sub> resonance. De León *et al.* (2010) and Dunn *et al.* (2013) also concluded that the Flora family is the dominant source of NEAs and LL chondrites, based on inferred mineralogies of large samples of NEAs. A more recent study by Thomas *et al.* (2014) of an even larger sample of S-type NEAs (109 objects) concluded that NEAs have elevated percentages of potential LL OCs compared to the meteorite fall statistics. However, they also concluded that the relative proportions among NEAs of the OC spectral types lie somewhere between the H- and L-chondrite dominant meteorite fall statistics and the LL-chondrite spectral types

**Fig. 9.** Comparison between the mineralogies of 47 NEAs and those of ordinary chondrites. NEAs are plotted as (a) ol/(ol + px) vs. mol% Fa in olivine and (b) ol/(ol + px) vs. mol% Fs in low-Ca pyroxene. Compositional regions for the H, L, and LL chondrites were defined by Dunn *et al.* (2010). NEAs with definitive OC-like spectral parameters are represented by boxes, while NEAs with questionable spectral classification are represented by diamonds. Error bars represent the least-mean-square error of spectrally derived mineralogies: 0.03 for ol/ol + px, 1.3 for mol% Fa, and 1.4 for mol% Fs. From Dunn *et al.* (2013).

dominant NEA statistics as calculated by Dunn *et al.* (2013) and seen in Vernazza *et al.* (2008) and De León *et al.* (2010).

#### 4.2. What Have We Learned from S-Type Main-Belt Asteroids?

As stated above, Gaffey *et al.* (1993) observed 32 main-belt S-types and found that most of these objects do not have OC-like mineralogies. They suggested that most of the non-OC-like S-type asteroids originate from partially or fully differentiated bodies. More recently, Vernazza *et al.* (2014) revisited this question by conducting an extensive spectroscopic survey of 83 main-belt S-type asteroids and 3 S-type families, and obtaining the biggest spectral dataset yet assembled for the largest S-type asteroids (95% of all objects larger than 60 km). In parallel, they built up the existing database of OC laboratory spectral measurements by collecting spectra for 53 unequilibrated OCs (i.e., for the most primitive OCs). Thus the database now spans a much broader range of temperature history (from unheated to significantly metamorphosed) than previously analyzed. On the basis of these two spectral surveys, they reach the following conclusions:

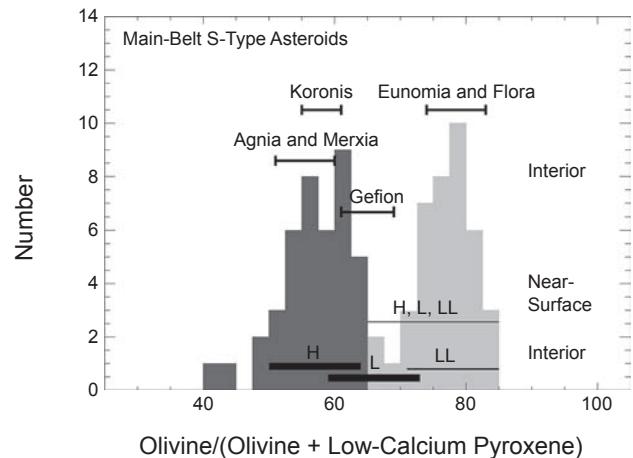

1. Most S-type asteroids, including large ones ( $D \approx 100\text{--}200$  km), although not members of one family, are distributed into two well-defined compositional groups (see Fig. 10), Hebe-like and Flora-like (H-like and LL-like). This indicates that identical compositions among multiple asteroids are a natural outcome of planetesimal formation, making it possible that meteorites within a given class originate from multiple parent bodies.

2. The surfaces of nearly all these asteroids (up to 200 km) show the same compositional characteristics as high-temperature meteorites (type 4–6 OCs) that were metamorphosed in their interiors, these exposed interiors being a likely consequence of impacts by small asteroids ( $D < 10$  km) in the early solar system (Ciesla *et al.*, 2013).

3. The lack of compositional variation within both H-like asteroid families and the surfaces of the family members showing the same compositional characteristics as high-temperature meteorites (type 4–6 OCs) is consistent with their parent bodies having been metamorphosed throughout, which implies — following current thermal models — that their formation process must have been rapid. Note that such a short duration of accretion as implied by the observations of Vernazza *et al.* (2014) is consistent with current models of planet formation through streaming and gravitational instabilities (Youdin and Goodman, 2005; Johansen *et al.*, 2007; Chiang and Youdin, 2010) that show that bodies of several hundred kilometers in size form on the timescale of a few orbits (Johansen *et al.*, 2011; Youdin, 2011; Johansen *et al.*, 2012).

4. LL-like bodies formed closer to the Sun than H-like bodies, a possible consequence of radial mixing and size sorting of chondrules in the protoplanetary disk prior to accretion.

5. LL-like bodies formed on average with larger sizes than H-like bodies.

**Fig. 10.** Bimodal compositional distribution of main-belt S-type asteroids. The S-type sample comprises 83 objects, including 54 of the 56 main-belt S-types with  $D > 60$  km. Objects belonging to collisional families are not included in the histogram counts. Instead, the compositional range for the six main asteroid families (Agnia, Merxia, Koronis, Gefion, Eunomia, Flora) are shown at the top. The compositional ranges for the individual ordinary chondrite classes of «interior» samples (H, L, and LL having petrologic types  $>3.5$ ; temperature histories  $>400^\circ\text{C}$ ) are shown at the bottom. Above, we display the compositional range for the least-metamorphosed OCs (types 3.0–3.5; temperatures  $<400^\circ\text{C}$ ) that are interpreted as surface samples. The thickness of the various compositional ranges for meteorites is proportional to their fall statistics. Finally, the diversity of S-type asteroids includes compositions outside the range of ordinary chondrites, as seen for the two objects having  $\text{ol}/(\text{ol} + \text{low-Ca px}) < 45\%$ . From Vernazza *et al.* (2014).

#### 5. SUMMARY AND CONCLUSIONS

The nature of the parent bodies of OCs is no longer a mystery (Nakamura *et al.*, 2011). It has now been clearly established that the parent bodies of OCs are hidden among the S-type asteroids. Actually, most S-type asteroids are plausible OC parent bodies as they share similar spectral properties and thus similar mineralogies (Vernazza *et al.*, 2014).

Spectroscopic surveys have allowed determining rather precisely the compositional distribution among S-type NEAs and S-type MBAs. It appears that the majority of the S-type NEAs have LL-like mineralogies, implying important compositional differences between NEAs and meteorites (Vernazza *et al.*, 2008; De León *et al.*, 2010; Dunn *et al.*, 2013; Thomas *et al.*, 2014) and therefore different source regions for both populations. Concerning S-type MBAs, it appears that most S-type asteroids, including large ones ( $D \approx 100\text{--}200$  km), are distributed into two well-defined compositional groups, Hebe-like and Flora-like (H-like and LL-like), with Flora-like bodies being located — on average — closer to the Sun than Hebe-like bodies (Vernazza *et al.*, 2014). In addition, the surfaces of nearly all these asteroids (up

to 200 km) show the same compositional characteristics as high-temperature meteorites (type 4–6 OCs) that were metamorphosed in their interiors, suggesting that impacts may have played an important role in their structural evolution (Vernazza *et al.*, 2014). Interestingly, the metallographic cooling rates of H chondrites are in agreement with those observations, as they suggest that several early impacts punctured the H-chondrite parent body (or bodies) while it was cooling, causing disturbances in the thermal histories of many H chondrites and leading to surfaces containing rocks that originated at a wide range of depths (Taylor *et al.*, 1987; Scott *et al.*, 2011, 2013, 2014).

Although significant progress has been made since the *Asteroids III* book in linking OCs to S-types, there are several issues remaining that require critical new data:

1. The source regions of the individual OC classes remain to be determined. Currently, we only have predictions for the source regions of both L and LL chondrites; namely, the Gefion family is predicted, based on dynamical and compositional aspects (Nesvorný *et al.*, 2009; Vernazza *et al.*, 2014), to be the source of L chondrites, while the Flora family is proposed to be the source of most LL chondrites (e.g., Vernazza *et al.*, 2008). The source of H chondrites is currently unknown; Vernazza *et al.* (2014) have shown that several prominent S-type families could be the source of these meteorites.

Over the next decade, the ongoing development and installation of several fireball observation networks across the world [e.g., the Fireball Recovery and InterPlanetary Network (FRIPON), <http://ceres.geol.u-psud.fr/fripo/>] will help solve this long-standing issue. These camera networks will observe a statistically significant number of falls within the next 10 years and thus allow the determination of precise orbits (and hence directly the source region) for a large number of meteoroids. Hopefully, they will also allow us to recover a nonnegligible number of meteorites. Recent successful meteorite recoveries include the Tagish Lake, Almahata Sitta, Maribo, Kosice, Bunburra Rockhole, and Sutter's Mill falls (see the chapters by Borovička *et al.* and Jenniskens in this volume).

2. It remains to be explained why there are so few LL chondrites and so many H and L chondrites among falls (Vernazza *et al.*, 2008) given that the prominent LL-like Flora family is located next to the most prolific (in terms of delivery) resonance (namely, v<sub>6</sub>). In other terms, the observed compositional difference between meteorites and NEAs (Vernazza *et al.*, 2008) has yet to be explained.

3. It remains to be established whether the individual OC classes (H, L, LL) originate from one or several parent bodies. Spectroscopic surveys have opened the possibility that the individual OC classes can come from several parent bodies (Vernazza *et al.*, 2014). A new generation of meteorite measurements may shed light on this issue. Fireball observation networks will also help provide answers to this question.

4. The diversity of the fall statistics between H, L, and LL chondrites as a function of petrologic type remains to be explained [62% of H chondrites are type 4 and 5, while

type 6 represents only 21%, 68% of Ls are type 5 and 6, and 59% of LLs are type 5 and 6 (Hutchison, 2004)]. Modeling the thermal evolution of OC parent bodies as a function of the parent body's size may certainly help to shed light on this issue. [With Hebe not necessarily being the parent body of H chondrites, a D ~ 100-km-sized parent body should be envisioned along with a D ~ 200-km-sized one for H chondrites, while larger parent bodies should be considered for the L- and LL-chondrite parent bodies (see Vernazza *et al.*, 2014)]. Determining whether all meteorites within a given OC class (e.g., H chondrites) come from the same parent body via both fireball observation networks and refined measurements on OCs will also help explain the diversity of the fall statistics.

5. Spectroscopic surveys have revealed that the parent bodies of LL chondrites formed on average larger than that of H chondrites (Vernazza *et al.*, 2014). An explanation of this observation remains to be found.

6. The parent bodies of lodranites and acapulcoites are likely hidden among S-type asteroids. A careful spectral analysis of these meteorites will help to pinpoint their possible parent bodies.

7. The nature of the parent bodies of HH (Burnwell and Willaroy), H/L, and L/LL chondrites remains to be understood. The paucity of H/L and L/LL chondrites may hint at a rather clear separation between the H, L, and LL rings in the disk during accretion.

---

Most chondrite parent bodies accreted water ice together with anhydrous minerals and subsequently experienced aqueous/hydrothermal alteration and fluid-assisted thermal metamorphism, resulting in formation of a diverse suite of secondary minerals. The  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  chronology of datable secondary minerals indicates aqueous activity on the ordinary (OC) and carbonaceous chondrite (CC) parent bodies started  $\sim$ 3–5 m.y. after the beginning of the solar system formation ( $t_0$ ), consistent with  $^{26}\text{Al}$  being the major heat source of these bodies. The  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of aqueous alteration, the  $^{26}\text{Al}$ - $^{26}\text{Mg}$  ages of chondrule formation, and the peak metamorphic temperatures reached by the OC and CC parent bodies suggest that they accreted  $\sim$ 2.0–4 m.y. after  $t_0$ . There are significant variations in the degree of aqueous alteration within and between different chondrite groups, possibly due to the heterogeneous distribution of water ice in their parent bodies. The CI (Ivuna-type) carbonaceous chondrites that are composed almost entirely of aqueously formed minerals are the only exception. The estimated water ice-to-rock mass ratios in OC and CC parent bodies range from  $<0.1$  to  $\sim0.6$  (could be higher in CIs), which is significantly lower than the solar value of 1.2. We suggest that most chondrite parent bodies accreted close to the snow line; CIs may have accreted further away from the Sun than other chondrite groups. Because the snow line for the 2.5–4-m.y.-old disk is expected to be within 2–3 AU of the Sun, we conclude that chondrite parent bodies are sampled by meteorites accreted in the main asteroid belt, consistent with the inferred deuterium/hydrogen (D/H) ratio of asteroidal water. The existing meteorite observations provide no clear evidence supporting the predictions of the Grand Tack and Nice dynamical models of the solar system evolution, wherein hydrated asteroids formed between and beyond giant planets and were subsequently implanted into the main asteroid belt during migration of the giant planets. We note, however, that there could be other types of hydrated or water-ice-bearing planetesimals that were implanted into the main asteroid belt, but have not been sampled by the known meteorites.

## 1. INTRODUCTION

In this paper, we address the nature of aqueous activity in and the sources of water ice accreted by the chondrite parent bodies. We also discuss how these observations could be used for testing some of the predictions of the recently proposed Nice (Gomes *et al.*, 2005; Morbidelli *et al.*, 2005; Tsiganis *et al.*, 2005; Levison *et al.*, 2009) and Grand Tack (Walsh *et al.*, 2011) dynamical models of the evolution of the solar system. This chapter is organized as follows: In section 2, we

describe the modern classification of chondritic meteorites, emphasizing the large chemical and isotopic diversity among the carbonaceous chondrites. In section 3, we summarize the current views about the location (nebular vs. parent body) and conditions (temperature and water/rock ratio) of aqueous alteration of chondritic meteorites, and list the major minerals produced during aqueous alteration of different chondrite groups. In section 4, we review the structural and compositional modifications of chondrite organics during aqueous alteration. In section 5, we summarize recent results

on  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  dating of aqueously formed minerals in several chondrite groups. In section 6, we discuss the cosmochemical constraints on the timing of accretion of hydrated chondrite parent bodies, including the  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of aqueous alteration, the  $^{26}\text{Al}$ - $^{26}\text{Mg}$  ages of chondrule formation, the peak metamorphic temperatures reached by these bodies, and the results of physical modeling of their thermal evolution. In section 7, we discuss the results of hydrogen- and oxygen-isotopic measurements of cometary water ice, the estimates of hydrogen- and oxygen-isotopic compositions of chondritic water, and the results of astrophysical modeling of the spatial and temporal evolution of oxygen and hydrogen-isotopic compositions of the protoplanetary disk water. In section 8, we discuss the cosmochemical constraints on the accretion regions of the chondrite parent bodies, and their implications for testing the predictions of the Grand Tack and Nice models. In section 9, we summarize our main conclusions and outline future research.

## 2. CLASSIFICATION OF CHONDRITIC METEORITES

Chondritic meteorites (chondrites) consist of four major components: chondrules, refractory inclusions [Ca, Al-rich inclusions (CAIs) and amoeboid olivine aggregates (AOAs)], and fine-grained matrix. CI (Ivuna-type) chondrites, which are composed almost entirely of matrix material, are the only exception. It is generally accepted that refractory inclusions and chondrules formed in the protoplanetary disk by high-temperature processes that included evaporation, condensation, and melting during transient heating events of a poorly known nature; the currently discussed mechanisms include shock waves, planetary collisions, and current sheets (e.g., Joung *et al.*, 2004; Alexander *et al.*, 2008; Krot *et al.*, 2009; Morris *et al.*, 2010; McNally *et al.*, 2013; Asphaug *et al.*, 2011; Johnson *et al.*, 2015). Matrix escaped melting, but a significant fraction of it may have experienced evaporation and condensation prior to and/or during chondrule formation (e.g., Huss *et al.*, 2005; Scott and Krot, 2014, and references therein).

Based on bulk chemistry, bulk oxygen-isotopic compositions, mineralogy, and petrography (e.g., chondrule/matrix ratio, chondrule sizes and textures), 14 chondrite groups (+ a grouplet of two Kakangari-type chondrites) are currently recognized (Krot *et al.*, 2014a). They comprise three major chondrite classes: carbonaceous [CI (Ivuna-type), CM (Mighei-type), CR (Renazzo-type), CV (Vigarano-type), CK (Karoonda-type), CO (Ornans-type), CB (Bencubbin-type), CH (high metal abundance)], ordinary (H, L, LL) plus R (Rumuruti type) chondrites, and enstatite (EH, EL) chondrites. Several chondrites are mineralogically and/or chemically unique and defy classification into the existing chondrite groups; these are referred to as ungrouped (e.g., Tagish Lake and Acfer 094).

The term carbonaceous is somewhat of a misnomer, because only the CI, CM, and CR chondrites are significantly enriched in carbon ( $\sim 1\text{--}10\text{ wt\%}$ ) compared to other

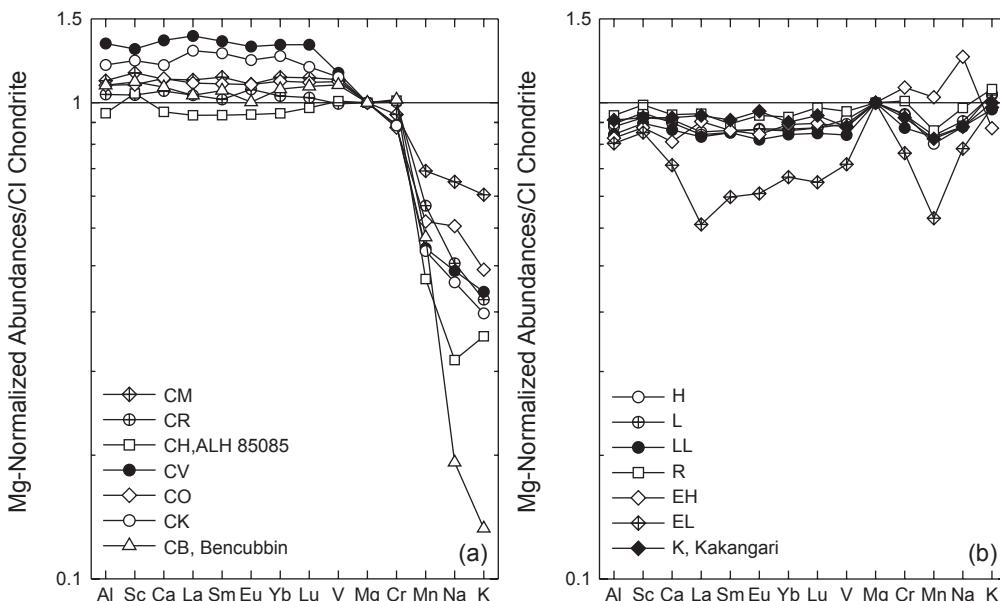

chondrite groups ( $<1\text{ wt\%}$ ) (Fig. 5 in Krot *et al.*, 2014a). Instead, the carbonaceous and noncarbonaceous chondrites can be resolved (with some exceptions) by several characteristics, including (1) mean refractory lithophile/silicon abundance ratios relative to CI chondrites —  $\geq 1.00$  in carbonaceous chondrites, and  $\leq 0.95$  in noncarbonaceous chondrites (Fig. 1); (2) bulk oxygen-isotopic compositions (Fig. 2) — on a three-isotope oxygen diagram, most carbonaceous chondrite groups (except CI chondrites) plot below the terrestrial fractionation line, whereas noncarbonaceous chondrites (except EH and EL chondrites) plot above it; and (3) bulk chromium- and titanium-isotopic compositions — carbonaceous chondrites are enriched in  $^{54}\text{Cr}$  and  $^{50}\text{Ti}$ , whereas noncarbonaceous chondrites are depleted in these isotopes relative to Earth (Fig. 1 in Warren, 2011).

It is commonly assumed that each chondrite group sampled a single parent body. Based on the similar bulk chemical and oxygen-isotopic compositions, it has been recently suggested that CK and CV chondrites may represent different lithologies of the same parent body that experienced aqueous/hydrothermal alteration to different degrees, and were subsequently thermally metamorphosed (Greenwood *et al.*, 2010; Wasson *et al.*, 2013).

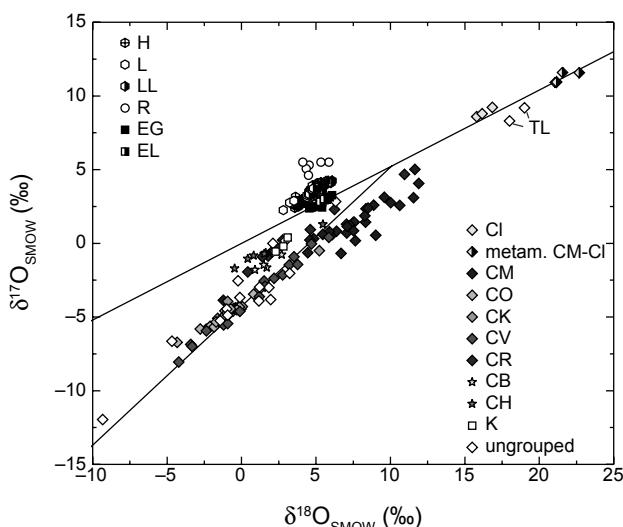

Once the chondrite parent bodies formed, they experienced different levels of alteration driven by fluids and heating by the decay of short-lived (half-life  $<10\text{ m.y.}$ ) radionuclides. To provide a guide to the degree of thermal and aqueous alteration experienced by chondrites, they are divided into six petrologic types (1–6). The sequence type 3 to type 6 represents an increasing degree of chemical equilibrium and textural recrystallization due to thermal metamorphism. Type 3 chondrites are commonly called “unequilibrated.” The type 3 ordinary, CO, and CV chondrites are subdivided into 10 subtypes (3.0–3.9), of which 3.0 is the least metamorphosed (e.g., Grossman and Brearley, 2005; Bonal *et al.*, 2006, 2007). Types 1 and 2 represent a higher degree of aqueous alteration compared to type 3. In one classification scheme, the CM and CR chondrites are divided into 10 subtypes (2.9–2.0), of which 2.0 is the most aqueously altered (Rubin *et al.*, 2007; Harju *et al.*, 2014). In this scheme, type 1 is reserved for CI chondrites. The classification scheme for aqueously altered chondrites is not universally accepted. In the past, nearly completely hydrated CM and CR chondrites have been referred to as CM1 and CR1, respectively, and an alternative classification scheme uses a 1–3 alteration scale for all chondrite groups (e.g., Alexander *et al.*, 2013; Beck *et al.*, 2014; Howard *et al.*, 2015).

## 3. PLACE AND CONDITIONS OF AQUEOUS/HYDROTHERMAL ALTERATION

Refractory inclusions, chondrules, and matrices of the most primitive chondrite known, Acfer 094, show little evidence for preterrestrial aqueous alteration (Greshake, 1997; Abreu and Brearley, 2010), and thus nearly completely avoided this process on its parent body. Mineralogical and petrographic observations of aqueously altered chondrites

**Fig. 1.** Magnesium- and Cl-normalized bulk lithophile-element abundances of the (a) carbonaceous and (b) noncarbonaceous chondrite groups. The elemental abundances of bulk CI chondrites are viewed as a measure of average solar system abundances and are used as a reference composition. In carbonaceous and noncarbonaceous chondrites, mean refractory lithophile/Mg abundance ratios relative to CI chondrites are  $\geq 1.00$  and  $\leq 0.95$ , respectively. From Krot et al. (2014a).

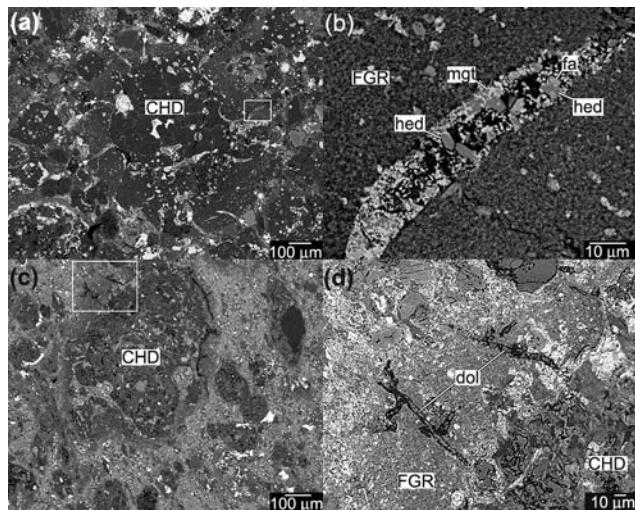

**Fig. 2.** See Plate 20 for color version. Bulk oxygen-isotope compositions of chondrite groups and ungrouped chondrites. Terrestrial fractionation line (TFL) and carbonaceous chondrite anhydrous mineral (CCAM) line are shown for reference. Oxygen-isotopic compositions are reported as  $\delta^{17}\text{O}$  and  $\delta^{18}\text{O}$ , deviations from Vienna Standard Mean Ocean Water (SMOW) [ $^{17}\text{O}/^{16}\text{O}_{\text{SMOW}} = 0.000380$ ;  $^{18}\text{O}/^{16}\text{O}_{\text{SMOW}} = 0.002005$  (De Laeter et al., 2003)] in parts per thousand:  $\delta^{17,18}\text{O}_{\text{SMOW}} = [(^{17,18}\text{O}/^{16}\text{O}_{\text{sample}})/(^{17,18}\text{O}/^{16}\text{O}_{\text{SMOW}}) - 1] \times 1000$ . Carbonaceous chondrites, except CIs, plot below the TFL; noncarbonaceous chondrites, except EHs and ELs, plot above it. After Krot et al. (2014a). Data for Tagish Lake (TL) are from Brown et al. (2000).

(e.g., Brearley, 2006; Zolensky et al., 2008; Brearley and Krot, 2012, and references therein) and the slow kinetics of hydration reactions in the solar nebula (Fegley, 2000) suggest that aqueous alteration occurred exclusively on the chondrite parent bodies. Although Ciesla et al. (2002) suggested that hydration of micrometer-sized olivine and formation of serpentine

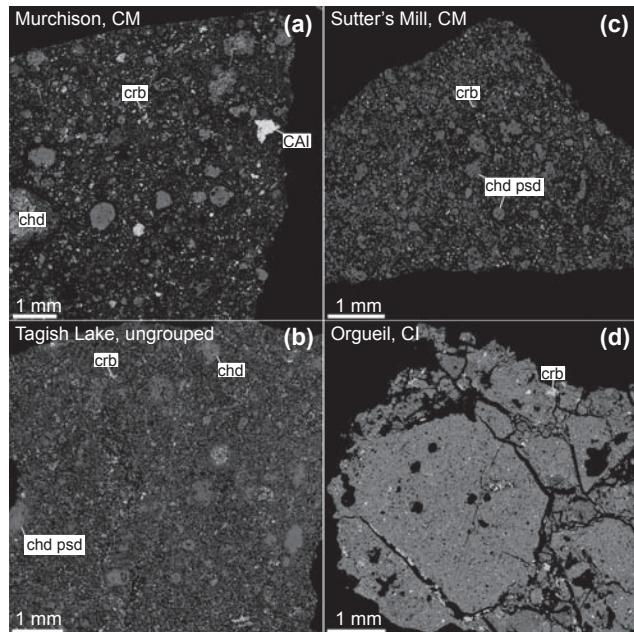

might have occurred in icy-rich regions of the solar nebula that experienced shock-wave heating, it is generally agreed that aqueous alteration resulted from melting of water ice that accreted together with anhydrous silicates into chondrite parent bodies. The presence of veins crosscutting chondrite matrices (Fig. 3), for instance, provides clear evidence for *in situ* aqueous alteration.

With the exception of enstatite chondrites, at least some members of all known chondrite groups show evidence for aqueous alteration, but to various degrees and under variable physicochemical conditions, such as temperature and water/rock ratio. Figures 4 and 5 illustrate combined X-ray elemental maps in Mg (red), Ca (green), and Al (blue) of representative members of the major chondrite groups (CI, CM, CR, CV, CO, and LL) and the ungrouped carbonaceous chondrite Tagish Lake, which experienced aqueous alteration. In these maps, CAIs and chondrules have bluish and bright red colors, respectively; interstitial matrix has different colors reflecting variations in mineralogy and chemical compositions.

**Fig. 3.** Backscattered electron images of aqueously formed veins. (a,b) Magnesian porphyritic olivine-pyroxene chondrule (CHD) surrounded by a fine-grained rim (FGR) in MAC 88107 (CO3.1). The fine-grained rim is crosscut by veins composed of fayalite (fa), hedenbergite (hed), and magnetite (mgt). Fe,Ni-metal nodules in the chondrule are replaced by magnetite. (c,d) Porphyritic chondrule surrounded by a fine-grained rim and pseudomorphically replaced by phyllosilicates in Sutter's Mill (CM2.1). The fine-grained rim is crosscut by dolomite (dol) veins.

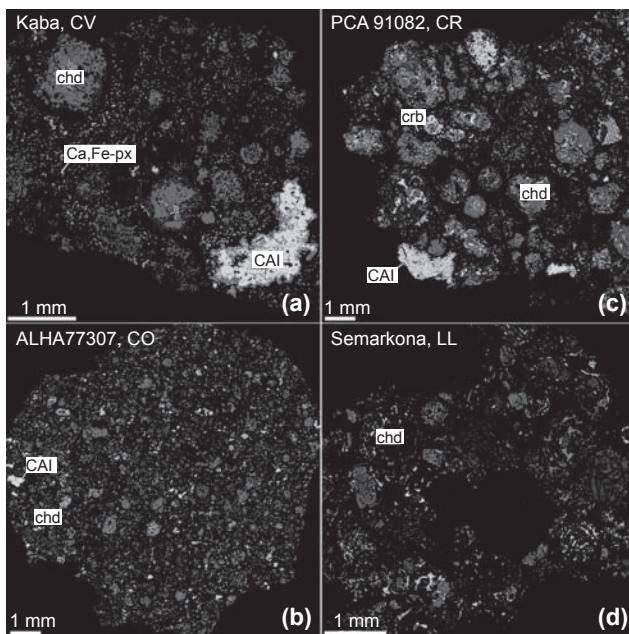

The CIIs, CMs, CRs, and different lithological units of Tagish Lake experienced various but often high degrees of aqueous alteration. The major secondary minerals produced during the alteration are phyllosilicates, carbonates, magnetite, and sulfides (Table 1). The CI chondrites consist almost entirely of aqueously formed minerals (Fig. 4d), and probably never contained abundant chondrules (Huss and Lewis, 1995); rare chondrule fragments (<5 vol%) have been reported in CIs by Leshin *et al.* (1997). Like CI chondrites, several CMs and CRs experienced nearly complete aqueous alteration (Zolensky *et al.*, 1997; Weisberg and Huber, 2007). In contrast to CIs, these CM and CR chondrites contain abundant chondrule pseudomorphs (Figs. 3c, 4b). Most CMs and CRs, however, experienced incomplete aqueous alteration (Rubin *et al.*, 2007; Abreu and Brearley, 2010; Harju *et al.*, 2014; Hewins *et al.*, 2014); the CM chondrites, on average, being more aqueously altered than CR chondrites. Modal mineralogy of CM chondrites measured by X-ray diffraction has been recently reported by Howard *et al.* (2009, 2011, 2015), who showed that the abundance of phyllosilicates increases and their chemical compositions change with increasing degree of aqueous alteration. Based on thermodynamic modeling (e.g., Zolensky *et al.*, 1989; Zolotov and Mironenko, 2008; Berger *et al.*, 2011; Zolotov, 2012), experimentally determined phase diagrams of the Fe-Ni-Co-S system (Bullock *et al.*, 2005; Berger *et al.*, 2011), and oxygen-isotopic compositions of aqueously formed minerals (e.g., Leshin *et al.*, 1997; Clayton and Mayeda, 1999; Benedix *et al.*, 2003; Guo and Eiler, 2007; Schrader *et al.*, 2011), it is inferred that the CIIs, CMs,

**Fig. 4.** See Plate 21 for color version. Combined elemental maps (Mg = red, Ca = green, Al = blue) of extensively aqueously altered chondrites: (a) Murchison (CM2.5), (b) ungrouped carbonaceous chondrite Tagish Lake, (c) Sutter's Mill (CM2.1), and (d) Orgueil (CI1). Murchison contains abundant magnesian chondrules (chd, red), CAIs (bluish), and heavily hydrated matrix (purple) containing relatively rare grains of carbonate (crb, green). In Sutter's Mill, CAIs, chondrules, and matrix are nearly completely replaced by phyllosilicates and carbonates; chondrule pseudomorphs (chd psd) are common. Tagish Lake contains a higher proportion of heavily hydrated matrix and carbonates, and fewer chondrules and CAIs than Murchison; incompletely altered chondrules are common; some chondrules are nearly completely replaced by phyllosilicates. Orgueil consists entirely of hydrated matrix material; chondrule pseudomorphs are absent.

CRs, and Tagish Lake experienced relatively low-temperature aqueous alteration (~20–150°C) under variable but generally high water/rock (W/R) mass ratio (up to 0.6; could be higher for CIs). Dry asteroids would have W/R = 0, whereas those that formed outside the snow line are expected to have W/R = 1.2 (Lodders, 2003).

The CV3, CO3, and unequilibrated ordinary chondrites (UOCs) experienced a much lower degree of aqueous alteration than CI, CM, and CR chondrites, and contain only minor amounts of hydrated silicates (e.g., Howard *et al.*, 2010; Brearley and Krot, 2012, and references therein); they are all classified as petrologic type  $\geq 3.0$ . It is inferred that aqueous alteration of CVs, COs, and UOCs took place at relatively high temperatures (100°–300°C) and low W/R mass ratios (<0.1–0.2) (e.g., Zolotov *et al.*, 2006; Krot *et al.*, 2013; Doyle *et al.*, 2015). Subsequently, most meteorites from these groups were heated to higher temperatures (>400°C) and experienced fluid-assisted thermal metamorphism. These processes resulted in the formation of a diverse suite of

**Fig. 5.** See Plate 22 for color version. Combined elemental maps (Mg = red, Ca = green, Al = blue) of weakly aqueously altered chondrites: (a) Kaba (CV3.1), (b) ALH A77307 (CO3.1), (c) PCA 91082 (CR2), and (d) Semarkona (LL3.0). Chondrules (chd) and CAIs in these meteorites show little evidence for aqueous alteration; matrices are more aqueously altered and contain phyllosilicates, magnetite, and fayalite (except PCA 91082). The Kaba matrix contains abundant Ca,Fe-rich pyroxenes (Ca,Fe-px); the PCA 91082 matrix contains rare carbonate (crb) grains.

secondary minerals; most of them are anhydrous (Table 1) (Brearley and Krot, 2012, and references therein; Jones et al., 2014). The major secondary minerals include magnetite, ferroan olivine ( $Fa_{50-100}$ ), and hedenbergite.

Most R chondrites experienced extensive thermal metamorphism (petrologic types  $>3.6$ ) and, as a result, preserved little evidence for aqueous alteration. The important exception is the R5 chondrite LaPaz Ice Field (LAP) 04840, which contains abundant OH-rich silicate minerals: ferri-magnesiohornblende and phlogopite (Table 1) (McCanta et al., 2008). Based on their stabilities, it is estimated that these minerals formed at  $670^\circ \pm 60^\circ\text{C}$  and  $\text{H}_2\text{O}$  pressures of 250–500 bar (McCanta et al., 2008). Treiman and McCanta (2010) pointed out that even this low water pressure is problematic to generate inside a typical asteroid ( $\sim 75$  km in radius), because it could exceed the tensile strength of a rock ( $\sim 100$  bar) (Grimm and McSween, 1989). Treiman and McCanta (2010) suggested that the high water pressure recorded by LAP 04840 may have been produced in the interior of a relatively large asteroid that was sealed by an impermeable water-ice-filled regolith.

The oxygen-isotopic compositions of aqueously formed minerals (see section 7.4 for details) and bulk chondrites (Fig. 1) have been used to argue for both open-system (in the presence of a fluid flow) and closed-system (with a stagnant

TABLE 1. Aqueously formed minerals in CI, CM, CR, CV, CO, R, and ordinary chondrites.

Mineral	Composition
<i>CI, CM, and CR chondrites</i>	
serpentine	$\text{Mg}_3\text{Si}_2\text{O}_5(\text{OH})_4$
cronstedtite	$\text{Fe}_{2+}\text{Fe}^{3+}(\text{Si},\text{Fe}^{3+})_2\text{O}_5(\text{OH})_4$
saponite	$\text{Ca}_{0.25}(\text{Mg},\text{Fe})_3(\text{Si}_4\text{O}_{10})(\text{OH})_2 \cdot n\text{H}_2\text{O}$
tochilinite	$2[(\text{Fe},\text{Mg},\text{Cu},\text{Ni})\text{S}] \cdot 1.57-1.85[(\text{Mg},\text{Fe},\text{Ni},\text{Al},\text{Ca})(\text{OH})_2]$
calcite	$\text{CaCO}_3$ (trigonal)
aragonite	$\text{CaCO}_3$ (orthorhombic)
dolomite	$\text{CaMg}(\text{CO}_3)_2$
siderite	$\text{FeCO}_3$
breunnerite	$(\text{Mg},\text{Fe},\text{Mn})\text{CO}_3$
troilite	$\text{FeS}$
pyrrhotite	$\text{Fe}_{1-x}\text{S}$
pentlandite	$(\text{Fe},\text{Ni})_9\text{S}_8$
magnetite	$\text{Fe}_3\text{O}_4$
cubanite	$\text{CuFe}_2\text{S}_3$
sphalerite	$(\text{Fe},\text{Zn})\text{S}$
<i>CV, CO, R, and ordinary chondrites</i>	
saponite	$\text{Ca}_{0.25}(\text{Mg},\text{Fe})_3(\text{Si}_4\text{O}_{10})(\text{OH})_2 \cdot n\text{H}_2\text{O}$
phlogopite	$\text{KMg}_3\text{AlSi}_3\text{O}_{10}(\text{OH})_2$
amphibole	$(\text{Ca},\text{Na})_{2-3}(\text{Mg},\text{Fe}^{2+},\text{Al})_5(\text{Si},\text{Al},\text{Fe}^{3+})_8\text{O}_{22}(\text{OH},\text{F},\text{Cl})_2$
magnetite	$\text{Fe}_3\text{O}_4$
fayalite	$\text{Fe}_3\text{SiO}_4$
hedenbergite	$\text{CaFeSi}_2\text{O}_6$
andradite	$\text{Ca}_3\text{Fe}_2\text{Si}_3\text{O}_{12}$
kirschsteinite	$\text{CaFeSiO}_4$
Fe,Ni-carbides	$(\text{Fe},\text{Ni})_3\text{C}; (\text{Fe},\text{Ni})_{23}\text{C}_6$
pentlandite	$(\text{Fe},\text{Ni})_9\text{S}_8$
pyrrhotite	$\text{Fe}_{1-x}\text{S}$
Ni-rich metal	$\text{FeNi}; \text{FeNi}_3$
whitlockite	$\text{Ca}_9(\text{Mg},\text{Fe})(\text{PO}_4)_6(\text{PO}_3\text{OH})$
merrillite	$\text{Ca}_{18}\text{Na}_2\text{Mg}_2(\text{PO}_4)_{14}$
anorthite	$\text{CaAl}_2\text{Si}_2\text{O}_8$ (triclinic)
dmisteinbergite	$\text{CaAl}_2\text{Si}_2\text{O}_8$ (hexagonal)
corundum	$\text{Al}_2\text{O}_3$
forsterite	$\text{Mg}_2\text{SiO}_4$
grossular	$\text{Ca}_3\text{Al}_2\text{Si}_3\text{O}_{12}$
kushiroite	$\text{CaAl}_2\text{SiO}_6$
monticellite	$\text{CaMgSiO}_4$
Na-melilite	$(\text{CaNa})_2(\text{Al},\text{Mg})[(\text{AlSi})_2\text{O}_7]$
nepheline	$\text{NaAlSiO}_4$
sodalite	$\text{Na}_8\text{Al}_6\text{Si}_6\text{O}_{24}\text{Cl}_{12}$
wadelite	$\text{Ca}_6(\text{Al},\text{Si},\text{Mg})_7\text{O}_{16}\text{Cl}_3$
wollastonite	$\text{CaSiO}_3$
calcite	$\text{CaCO}_3$

fluid) aqueous alteration, and for constraining water/rock ratios in hydrated chondrites (Young et al., 1999; Clayton and Mayeda, 1999). The estimated low permeability of chondritic meteorites (Bland et al., 2009) and the lack of clear evidence for variations in bulk chemical compositions between meteorites with different degrees of aqueous alteration within chondrite groups appear to be consistent with the closed-system alteration. The closed-system alteration, however, is just an

approximation of reality: Highly diffusive gases (e.g., H<sub>2</sub>) at least partly escaped from the altered regions; in addition, collisions between planetesimals must have resulted in their fracturing and sudden release of the fluids (see the chapter by Wilson et al. in this volume). Given the variable degrees of aqueous alteration experienced by most chondrite groups, there probably was a heterogeneous distribution of water ice in the chondrite parent bodies at the time of alteration. This heterogeneity may be a primary (as a result of heterogeneous accretion of water ice) or a secondary (early redistribution of water ice in the chondrite parent bodies) feature. It has been suggested that carbonaceous chondrite parent bodies were not lithified during accretion and, after melting of ice, fluids and solids would have moved together as a viscous but convective mud (Bland et al., 2013; Bland and Travis, 2014). Chondrules in this scenario would have behaved as a suspended load in the mud, and would have settled out, resulting in a coarse core and a mud ocean mantle above. In this “mudball” model, convective mixing moderated internal temperature and alteration was necessarily isochemical. However, it is unclear whether the variation in the degrees of alteration observed for CM and CR chondrites could be produced in a well-mixed mud mantle.

#### 4. MODIFICATIONS OF CHONDRITE ORGANICS DURING AQUEOUS ALTERATION AND THERMAL METAMORPHISM

The organic matter present in chondrites was originally derived from precursors that formed and/or were modified in the presolar molecular cloud, the protosolar nebula, and the chondrite parent bodies. The relative importance of these different sources and processes is a matter of intense debate among cosmochemists. The organics are found in the matrix, where they are intimately intermixed with both unaltered and aqueously altered minerals (e.g., Le Guillou and Brearley, 2014; Le Guillou et al., 2014; Volmer et al., 2014). While the mineralogical effects of aqueous alteration in matrix are well documented (e.g., Brearley, 2006; Zolensky et al., 2008; Brearley and Krot, 2012), there has been a long-standing debate about the extent to which the altering fluids have modified the soluble and insoluble organic matter (SOM and IOM, respectively). Recent *in situ* studies indicate that aqueous alteration resulted in some redistribution, oxidation, and aromatization of organic matter (Le Guillou and Brearley, 2014; Le Guillou et al., 2014; Volmer et al., 2014). However, a detailed understanding of how and to what extent alteration has modified the organic matter in chondrites is still some way off. Insights into conditions of aqueous alteration gained from the study of organics are currently very limited.

There is clear evidence that aqueous alteration has modified the absolute and relative abundances of amino acids in CM and CR chondrites and Tagish Lake (Martins et al., 2007; Glavin and Dworkin, 2009; Glavin et al., 2010a,b; Herd et al., 2011; Pizzarelli et al., 2012; Elsila et al., 2012; Hilts et al., 2014). Most striking is the decrease in the abundance of  $\alpha$ -amino acids and the development of

increasing L-enantiomeric excesses in isovaline with increasing aqueous alteration. Pizzarelli et al. (2012) reported large L-enantiomeric excesses in one of the least-altered CRs and suggested that the excesses are primary rather than secondary, but their results have been challenged (Elsila et al., 2012; Pizzarelli and Munroe, 2012). The effects of alteration on other components of the soluble organic fractions in chondrites have been less well studied, but monocarboxylic acids at least do seem to have been affected by alteration (Aponte et al., 2011). Hilts et al. (2014) suggested that the variations in carboxylic acid compositions between differently altered lithologies in the Tagish Lake meteorite reflected oxidative cleavage of side chains from the IOM during alteration. Cody and Alexander (2005) and Callahan et al. (2011) have suggested this may be the case for most or all chondrites, although Aponte et al. (2011) found no evidence for this in the CM chondrites.

The origin of carboxylic acids notwithstanding, the role of aqueous alteration in the post-accretionary evolution of IOM is also a matter of debate. There are considerable variations in the elemental, isotopic, and functional group compositions of the IOM within and between the different chondrite groups. Alexander et al. (2007, 2013) proposed that these variations are primarily the result of secondary processes in the chondrite parent bodies acting on a common precursor that most closely resembled the IOM found in CR chondrites. Support for this comes from the Tagish Lake lithologies because their widely varying IOM compositions change systematically with the extent of alteration (Herd et al., 2011; Alexander et al., 2014). Comparisons with hydrothermal experiments suggest that the extent of the IOM transformations in the Tagish Lake lithologies, and by inference other chondrites, reflect differences in the temperature and/or duration of alteration. Based on a systematic characterization of IOM by Raman and IR spectroscopy, Quirico et al. (2014) and Orthous-Daunay et al. (2013) also found evidence that their Tagish Lake sample had been heated, probably by impact. However, to explain the differences in compositions of IOM from apparently unheated meteorites from different chondrite groups, these and other authors (e.g., Rémusat et al., 2006, 2010) favor variations in the accreted organic precursors. Nevertheless, there is agreement on the relative temperatures during aqueous alteration of the carbonaceous chondrite groups CR < CM < CI < CV (Alexander et al., 2014; Quirico et al., 2014), although experiments will be needed to constrain the absolute temperatures and timescales of alteration.

The effects of thermal metamorphism on the structure of the IOM are described in several papers (e.g., Quirico et al., 2003; Bonal et al., 2006, 2007; Busemann et al., 2007; Yabuta et al., 2010).

#### 5. DATING OF AQUEOUS ALTERATION

In this section, we explain the main principles and uncertainties of Mn-Cr isotope dating of aqueously formed minerals using secondary ion mass spectrometry (SIMS). We then summarize recent results of <sup>53</sup>Mn-<sup>53</sup>Cr dating of

fayalite ( $\text{Fe}_2\text{SiO}_4$ ), kirschsteinite ( $\text{CaFeSiO}_4$ ), and different carbonates [calcite,  $\text{CaCO}_3$ ; dolomite,  $\text{CaMg}(\text{CO}_3)_2$ ; siderite,  $\text{FeCO}_3$ ; and breunnerite,  $(\text{Mg},\text{Fe},\text{Mn})\text{CO}_3$ ] in several chondrite groups.

### 5.1. Principles of Manganese-Chromium Isotope Dating of Aqueously Formed Minerals by Secondary Ion Mass Spectrometry

The short-lived radionuclide  $^{53}\text{Mn}$  decays to  $^{53}\text{Cr}$  with a half-life of  $\sim 3.7$  m.y. and appears to have been uniformly distributed in the protoplanetary disk (Trinqueir *et al.*, 2008; Yin *et al.*, 2009). Aqueously formed fayalites [ $\text{Fa}_{>95}$ , where  $\text{Fa} = (\text{atomic ratio}) \text{Fe}/(\text{Fe} + \text{Mg}) \times 100$  in olivine] in L, LL, CO, and CV chondrites of low petrologic types ( $\leq 3.1$ ) and carbonates in CI, CM, and CR chondrites contain high MnO contents (several weight percent) and low concentrations of  $\text{Cr}_2\text{O}_3$  ( $\ll 0.1$  wt%), and therefore are suitable for age dating using  $^{53}\text{Mn}-^{53}\text{Cr}$  isotope chronology. The excess of radiogenic  $^{53}\text{Cr}$  ( $\delta^{53}\text{Cr}^*$ ) in 5–10- $\mu\text{m}$ -sized fayalite and carbonate grains can be measured *in situ* by SIMS. Excess  $^{53}\text{Cr}$  relative to stable  $^{52}\text{Cr}$ , correlated with the  $^{55}\text{Mn}/^{52}\text{Cr}$  ratio, indicates *in situ* decay of  $^{53}\text{Mn}$ , and the initial  $^{53}\text{Mn}/^{55}\text{Mn}$  ratio [ $(^{53}\text{Mn}/^{55}\text{Mn})_0$ ] during crystallization of these minerals can be calculated from the slope of the correlation (Fig. 6).

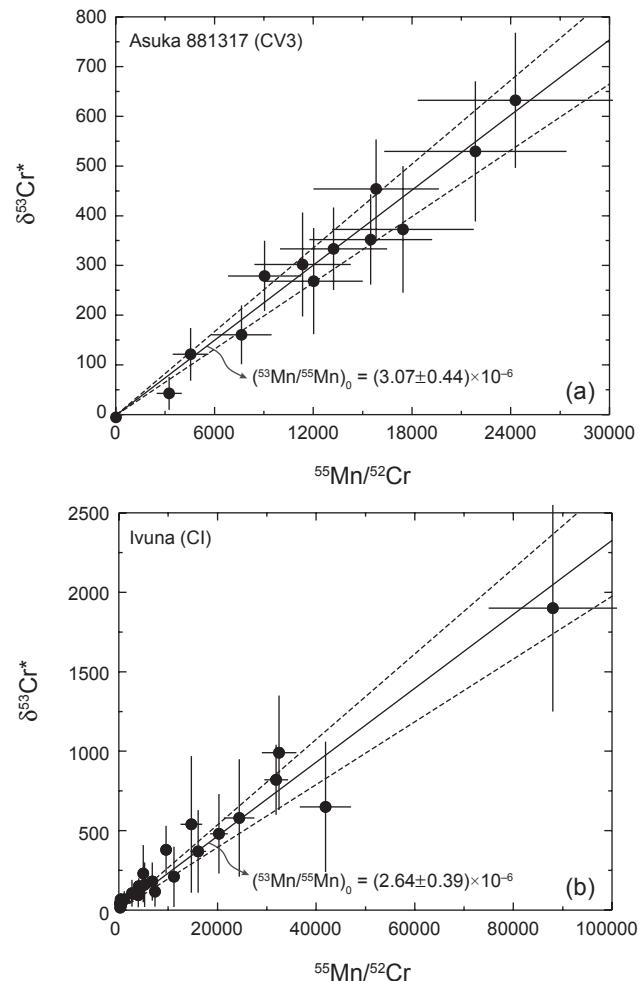

Manganese-53–chromium-53 dating is a relative chronometer, and the  $^{53}\text{Mn}-^{53}\text{Cr}$  ages are typically calculated relative to CV CAIs, which are the oldest solar system solids to have been dated [ $4567.30 \pm 0.16$  Ma (Connelly *et al.*, 2012)], and in cosmochemistry are considered to represent the beginning of the solar system formation ( $t_0$ ). The time of mineral formation after CV CAIs is given by

$$\Delta t_{\text{min-CAIs}} = 1/\lambda_{^{53}\text{Mn}} \times \ln[(^{53}\text{Mn}/^{55}\text{Mn})_{\text{CAIs}}/(^{53}\text{Mn}/^{55}\text{Mn})_{\text{min}}]$$

where  $\lambda_{^{53}\text{Mn}}$  is the decay constant of  $^{53}\text{Mn}$ .

The initial  $^{53}\text{Mn}/^{55}\text{Mn}$  ratio in CAIs has not been measured due to the lack of minerals having high Mn/Cr ratios as well as post-crystallization disturbance of their Mn-Cr isotope systematics (e.g., Papanastassiou *et al.*, 2002). Instead, the initial  $^{53}\text{Mn}/^{55}\text{Mn}$  ratio in CAIs,  $\sim 6.8 \times 10^{-6}$ , is estimated using the measured  $(^{53}\text{Mn}/^{55}\text{Mn})_0$  in the D'Orbigny angrite (basaltic meteorite),  $(3.24 \pm 0.04) \times 10^{-6}$  (Glavin *et al.*, 2004), its U-corrected Pb-Pb absolute age of  $4563.4 \pm 0.3$  Ma (Brennecke and Wadhwa, 2012), and the U-corrected Pb-Pb absolute age of CV CAIs,  $4567.30 \pm 0.16$  Ma (Connelly *et al.*, 2012).

Secondary ion mass spectrometry measurements of Mn-Cr isotope systematics in a mineral require the use of a proper standard to correct for the relative ionization efficiencies of  $^{55}\text{Mn}^+$  and  $^{52}\text{Cr}^+$  ions in order to determine accurate  $^{55}\text{Mn}/^{52}\text{Cr}$  abundance ratios. It has been recently shown for both fayalitic olivine (Sugiura *et al.*, 2005; McKibbin *et al.*, 2013; Doyle *et al.*, 2013, 2015) and carbonates (Sugiura *et al.*, 2010; Fujiya *et al.*, 2012; Steele and McKeegan, 2014) that past studies [fayalite (Hutcheon *et al.*, 1998; Krot *et al.*, 2000; Hua *et al.*, 2005; Jogo *et al.*, 2009) and carbonates (En-

**Fig. 6.** Manganese-chromium evolutionary diagrams of (a) fayalite in Asuka 881317 (CV3) and (b) dolomite in Ivuna (CI1).  $\delta^{53}\text{Cr}^* = [(^{53}\text{Cr}/^{52}\text{Cr})_{\text{fa}} \text{ or dol} / (^{53}\text{Cr}/^{52}\text{Cr})_{\text{terrestrial}} - 1] \times 1000$ , where  $(^{53}\text{Cr}/^{52}\text{Cr})_{\text{terrestrial}} = 0.113459$ . Excess of  $\delta^{53}\text{Cr}^*$  is well correlated with  $^{55}\text{Mn}/^{52}\text{Cr}$  ratios, indicative of *in situ*  $^{53}\text{Mn}$  decay to  $^{53}\text{Cr}$ . The initial  $(^{53}\text{Mn}/^{55}\text{Mn})_0$  are indicated; all uncertainties including error envelope are  $2\sigma$ . Data from Doyle *et al.* (2015) and Fujiya *et al.* (2013).

dress *et al.*, 1996; Hoppe *et al.*, 2007; Petitet *et al.*, 2009a,b; de Leuw *et al.*, 2009; Lee *et al.*, 2012)] used inappropriate standards, rendering their inferred ages unreliable.

### 5.2. Manganese-53–Chromium-53 Ages of Fayalite Formation in Type 3 Ordinary, CO, and CV Chondrites

The  $^{53}\text{Mn}-^{53}\text{Cr}$  ages of aqueously formed fayalite measured with a proper standard have been reported so far for only three meteorites: Elephant Moraine (EET) 90161 (L3.05), Asuka 881317 (CV3), and MacAlpine Hills (MAC) 88107 (CO3-like), with ages of  $2.4^{+1.8}_{-1.3}$ ,  $4.2^{+0.8}_{-0.7}$ , and  $5.1^{+0.5}_{-0.4}$  m.y. after CV CAIs, respectively (Doyle *et al.*, 2015). Mineralogical observations and thermodynamic analysis suggest that fayalite formation occurred during the initial stages

of aqueous alteration, contemporaneously or slightly later than formation of magnetite and phyllosilicates (Krot *et al.*, 1998; Jogo *et al.*, 2009; Zolotov *et al.*, 2006; Doyle *et al.*, 2015). As a result, the  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of fayalite formation roughly marks the beginning of aqueous alteration of the L, CO, and CV chondrite parent bodies.

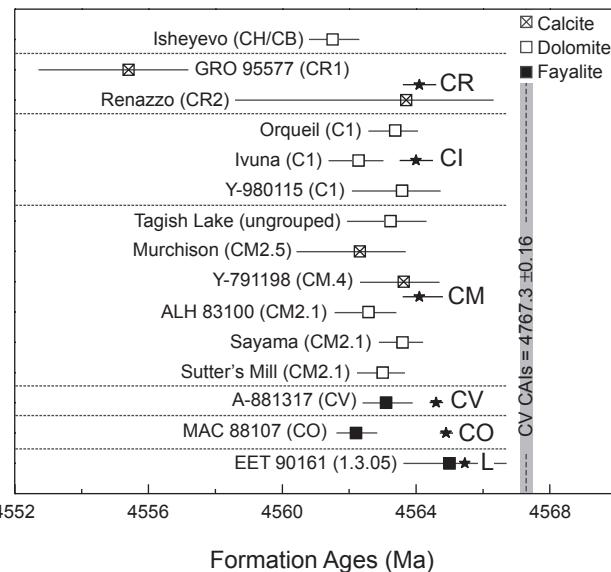

### 5.3. Manganese-53-Chromium-53 Ages of Kirschsteinite Formation in CV Chondrites

*MacPherson et al.* (2015) reported preliminary results of SIMS measurements of  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of secondary kirschsteinite in matrices of several CV chondrites (Vigarano, Efremovka). Synthetic Cr- and Mn-doped glass with a composition that is intermediate between kirschsteinite and fayalite was used as a standard. The  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  age of kirschsteinite,  $3.7^{+0.7}_{-0.6}$  m.y. after CV CAIs, is indistinguishable from that in CV fayalite,  $4.2^{+0.8}_{-0.7}$  m.y. after CV CAIs, and in combination with mineralogical observations suggests contemporaneous formation of these minerals during aqueous/ hydrothermal alteration on the CV parent body.

### 5.4. Manganese-53-Chromium-53 Ages of Carbonate Formation in CI, CM, CR, and Lithic Clasts in CH Chondrites

The CI, CM, and CR chondrites lack fayalite but contain carbonates (dolomite, calcite, siderite, and breunnerite) that are often enriched in manganese and depleted in chromium, making them suitable for  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  age dating with SIMS. Using synthetic Mn- and Cr-doped calcite (*Sugiura et al.*, 2010) as a standard, *Fujiya et al.* (2012, 2013) and *Jilly et al.* (2014a) reported  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of calcite and dolomite in CI and CM chondrites. The calcite and dolomite have a narrow range of ages of  $\sim 4\text{--}5$  m.y. after CV CAIs (Fig. 9). We note, however, that the lack of an appropriate standard for dolomite makes  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of its formation uncertain (*Steele and McKeegan*, 2014). The duration of aqueous alteration on the CM and CI parent bodies is not known. There is some correlation between the  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of carbonate formation and the degrees of aqueous alteration experienced by the host meteorites (Fig. 7). Mineralogical observations, chemical compositions, and carbon- and oxygen-isotope data suggest the presence of multiple generations of carbonates in CM and CI chondrites (e.g., *Brearley*, 2006; *Rubin et al.*, 2007; *Tyra et al.*, 2012; *Lee et al.*, 2012, 2013). The crystallization sequence of different carbonates are not well understood (*Petitat et al.*, 2009b, 2010; *Lee et al.*, 2012), and no reliable differences in age between the different types of carbonates have been reported. An  $\sim 7$ -m.y. age difference has been reported between dolomites and breunnerites in CI chondrites (*Endress et al.*, 1996; *Hoppe et al.*, 2007; *Petitat et al.*, 2009b), but the use of improper standards for both minerals makes these chronological inferences uncertain (*Steele and McKeegan*, 2014).

*Jilly et al.* (2013) reported  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of calcite in two CR chondrites, Renazzo and Grosvenor Mountains (GRO) 95577. The  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  age of calcite in Renazzo is

**Fig. 7.**  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of calcite, dolomite, and fayalite in unequilibrated ordinary (L) and carbonaceous chondrites (CV, CO, CM, CI, CR, and hydrated clasts in CH/CB) anchored to the U-corrected Pb-Pb age of the D'Orbigny angrite and CV CAIs. Data from *Fujiya et al.* (2012, 2013), *Jilly et al.* (2013, 2014a), *van Kooten et al.* (2014), and *Doyle et al.* (2015). The U-corrected Pb-Pb absolute age of CV CAIs is from *Connelly et al.* (2012). Note that *Fujiya et al.* (2012, 2013) used U-uncorrected absolute ages of a CV CAI reported by *Bouvier and Wadhwa* (2010), which is different from that reported by *Connelly et al.* (2012), and an LEW 86010 angrite anchor (*Amelin*, 2008) to calculate carbonate ages. As a result, the carbonate ages reported by *Fujiya et al.* (2012, 2013) are systematically younger, by  $\sim 0.7$  m.y., than those plotted here. The estimated accretion ages (indicated by stars) of the L, CO, CV, CI, CM, and CR chondrite parent bodies are from *Sugiura and Fujiya* (2014).

indistinguishable from those of calcite and dolomite in CM and CI chondrites. Calcite in the more aqueously altered GRO 95577 has a much younger age,  $\sim 12 \pm 2$  m.y. after CV CAIs. In addition, siderite in GRO 95577 shows no resolvable excess of  $\delta^{53}\text{Cr}^*$  (*Tyra et al.*, 2010), suggesting a very late formation of  $>23$  m.y. (with San Carlos olivine as a standard) after CV CAIs. Together with the reported  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  age of calcite in GRO 95577, these observations imply prolonged aqueous alteration on the CR parent body.

Although CH and CB chondrites avoided aqueous alteration, they contain extensively hydrated chondrite lithic clasts that may represent fragments of separate parent body(ies) that were accreted after collisions disrupted their original parent bodies (*Greshake et al.*, 2002; *Bonal et al.*, 2010). Dolomite grains in the lithic clasts from the Isheyev (CH/CB) chondrite have a  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  age of  $5.8^{+0.8}_{-0.7}$  m.y. after CV CAIs, similar to or slightly younger than  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of carbonates in CI and CM chondrites (*van Kooten et al.*, 2014).

## 5.5. Manganese-53-Chromium-53 Ages of Aqueously Formed Minerals in Ordinary and Carbonaceous Chondrites: Summary

The  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of carbonates in CI, CM, CR, and CH chondrites, and of fayalite in CO, CV, and L chondrites, are summarized in Fig. 7. The  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of fayalite and carbonates in several groups of carbonaceous chondrites are similar, suggesting that aqueous alteration on their parent bodies started within a narrow range in time,  $\sim 3.5\text{--}5$  m.y. after CV CAIs. The beginning of aqueous alteration on the L-chondrite parent body may have predated aqueous activity on the carbonaceous chondrite parent bodies by  $\sim 1$  m.y., but the uncertainties are large. The early and nearly contemporaneous onset of aqueous activity on the chondrite parent bodies is consistent with the short-lived radionuclide  $^{26}\text{Al}$  (decays to  $^{26}\text{Mg}$  with a half-life of  $\sim 0.7$  m.y.) being their major heat source.

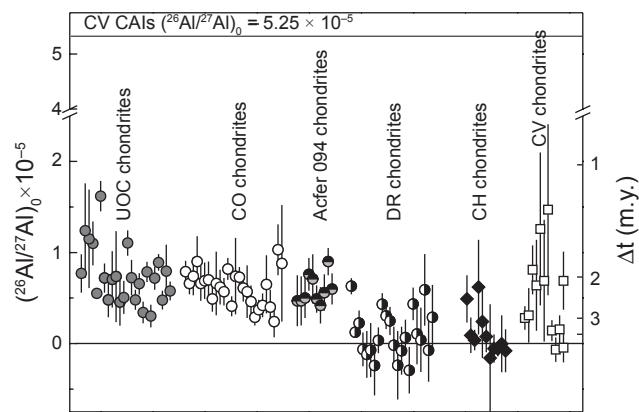

## 6. ACCRETION AGES OF CHONDRITE PARENT BODIES

The duration and mechanism(s) of accretion of chondrite parent bodies are poorly understood: Prolonged accretion by grain coagulation (Brauer et al., 2008) and rapid accretion after chondrule formation through turbulent concentration (Cuzzi et al., 2010; Chambers, 2010) and streaming and gravitational instability in a dusty midplane (Youdin and Shu, 2002; Johansen and Klar, 2011) are currently being debated. Rapid accretion after chondrule formation appears to be consistent with the high dust/gas ratios inferred for the regions where chondrules formed (e.g., Alexander et al., 2008); it may also explain the unique chemical, isotopic, and mineralogical characteristics of known chondrite groups, and the relatively narrow ranges of  $^{26}\text{Al}$ - $^{26}\text{Mg}$  ages of chondrules in an individual chondrite group (Fig. 8). Note that rapid accretion after chondrule formation is model-dependent, because (1) mechanisms of chondrule formation are still poorly understood, and the idea of chondrule formation by collisions between planetesimals becomes quite popular (e.g., Krot et al., 2005; Alexander et al., 2008; Asphaug et al., 2011; Johnson et al., 2015), and (2) CI chondrites appear to have accreted without a significant abundance of chondrules.

The accretion ages of chondrite parent bodies can be constrained using (1) the  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of aqueous alteration, (2) the  $^{26}\text{Al}$ - $^{26}\text{Mg}$  ages of chondrules, and (3) the peak metamorphic temperatures reached by these bodies.

1. Because aqueous alteration occurred exclusively in the chondrite parent bodies (see section 3), the inferred  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of aqueously formed minerals (Fig. 7) provide the upper limits on the chondrite accretion ages.

2. Formation of chondrules predated their accretion into their host meteorites. Therefore, chondrule ages provide the lower limits on the chondrite accretion ages. This approach cannot be used for CM and CI chondrites, because (a) due to extensive aqueous alteration of CM chondrules, the  $^{26}\text{Al}$ - $^{26}\text{Mg}$  ages of their chondrules are not known, and (b) chondrules are absent in CI chondrites.

**Fig. 8.** Inferred initial  $^{26}\text{Al}/^{27}\text{Al}$  ratios  $[(^{26}\text{Al}/^{27}\text{Al})_0]$  and  $^{26}\text{Al}$ - $^{27}\text{Al}$  relative ages of porphyritic chondrules (relative to CV CAIs) from unequilibrated ordinary [UOC, Semarkona (LL3.0)], Y-81020 (CO3.0), Acfer 094 (type 3.0 ungrouped), CR2-3, CH3.0, and CV3.1-3.6 chondrites [data for Semarkona from Hutcheon and Hutchison (1989), Kita et al. (2000), Mostefaoui et al. (2002), and Rudraswami et al. (2008); for Y-81020 from Kunihiro et al. (2004) and Kurashiki et al. (2008); for CVs from Hutcheon et al. (2009); for Acfer 094 from Ushikubo et al. (2013); for CRs from Nagashima et al. (2014) and Schrader et al. (2013); for CHs from Krot et al. (2014b)]. The inferred initial  $^{26}\text{Al}/^{27}\text{Al}$  ratio in CV CAIs is from Jacobsen et al. (2008).

Chondrule ages have been measured by SIMS using  $^{26}\text{Al}$ - $^{26}\text{Mg}$  relative chronology (e.g., Kita and Ushikubo, 2012), and by thermal ionization mass spectrometry (TIMS) using U-Pb absolute chronology (e.g., Connelly et al., 2012). The U-Pb ages of chondrules are very limited: Less than 10 individual chondrules from CV3, CB3, and L3 chondrites have been measured so far (Amelin et al., 2002; Connelly et al., 2012; Bollard et al., 2014). These ages provide clear evidence that chondrule formation started almost contemporaneously with CAIs and lasted for at least 5 m.y. However, because of the limited number of chondrules measured, use of their U-Pb absolute ages for constraining the accretion time of chondrite parent bodies is premature.

It is commonly assumed that by the end of a brief epoch of CAI formation, characterized by a heterogeneous distribution of  $^{26}\text{Al}$  (e.g., Krot et al., 2012, and references therein),  $^{26}\text{Al}$  became uniformly distributed in the protoplanetary disk at the canonical level,  $(^{26}\text{Al}/^{27}\text{Al})_0 \sim 5.2 \times 10^{-5}$  (Jacobsen et al., 2008; Villeneuve et al., 2009; Kruijer et al., 2014); for an alternative view, i.e., possible evidence for heterogeneous distribution of  $^{26}\text{Al}$  in the protoplanetary disk, see Larsen et al. (2011) and Bizzarro et al. (2014). The canonical  $^{26}\text{Al}/^{27}\text{Al}$  ratio was defined on the basis of high-precision Al-Mg isotope measurements of bulk CAIs from CV chondrites by multicollector inductively coupled plasma mass spectrometry (MC-ICPMS) (Jacobsen et al., 2008; Larsen et al., 2011) and of individual CAIs by SIMS (MacPherson et al., 2011).

The  $^{26}\text{Al}$ - $^{26}\text{Mg}$  ages of chondrules are calculated relative to the canonical CAIs

$$\Delta t_{\text{chd-CAIs}} = 1/\lambda_{^{26}\text{Al}} \times \ln[(^{26}\text{Al}/^{27}\text{Al})_{\text{CAIs}}/(^{26}\text{Al}/^{27}\text{Al})_{\text{chd}}]$$

where  $\lambda_{^{26}\text{Al}}$  is the decay constant of  $^{26}\text{Al}$ .

The reported  $^{26}\text{Al}$ - $^{26}\text{Mg}$  ages of chondrules from Se-markona (LL3.0), Yamato (Y)-81020 (CO3.0), Acfer 094 (ungrouped type 3.0 carbonaceous chondrite), CR2-3, CH3.0, and CV3.1–3.6 chondrites are summarized in Fig. 8. Chondrules in most chondrite groups, except chondrules in thermally metamorphosed CV3.1–3.6 chondrites, show relatively narrow ranges of the initial  $^{26}\text{Al}/^{27}\text{Al}$  ratios. Thermal metamorphism of the CV chondrules could have disturbed their Al-Mg isotope systematics, and may explain the observed large range of  $^{26}\text{Al}$ - $^{26}\text{Mg}$  ages of the CV chondrules (Fig. 8). The mean values  $\pm$  one standard deviation of  $(^{26}\text{Al}/^{27}\text{Al})_0$  in chondrules from the least-metamorphosed chondrites — Se-markona, Y-81020, and Acfer 094 — are  $(0.78 \pm 0.3) \times 10^{-5}$ ,  $(0.62 \pm 0.19) \times 10^{-5}$ , and  $(0.57 \pm 0.15) \times 10^{-5}$ , respectively, which correspond to  $1.9 \pm 0.4$ ,  $2.2 \pm 0.3$ , and  $2.3 \pm 0.3$  m.y. after CV CAIs. These age uncertainties cannot be considered as estimates for the duration of chondrule formation recorded by these chondrite groups, because they all may contain multiple generations of chondrules (e.g., Connolly *et al.*, 2012; Bollard *et al.*, 2014). Instead, these ages may provide the upper limits of the formation age of a dominant generation of chondrules within a chondrite group. Alexander and co-workers argue that the spread in the measured  $^{26}\text{Al}$ - $^{26}\text{Mg}$  ages of chondrules within a chondrite group largely reflects measurement uncertainties and possibly resetting by alteration and thermal metamorphism (Alexander and Ebel, 2012; see also the chapter by DeMeo *et al.* in this volume). It is also possible that some of the chondrules within a chondrite group formed by impacts (e.g., Johnson *et al.*, 2015) after accretion of the chondrite parent body. Such chondrules, if they exist, are expected to have a lower  $^{26}\text{Al}/^{27}\text{Al}$  ratio than the chondrules predating the accretion.

If  $^{26}\text{Al}$  was uniformly distributed in the protoplanetary disk and was the major heat source of planetesimals, as is currently believed, the accretion time of the ordinary, CO, and CV parent bodies can be constrained using the estimated peak metamorphic temperatures they have experienced: ordinary chondrites  $\sim 950^\circ\text{C}$ , and CO and CV chondrites  $\sim 600^\circ$ – $700^\circ\text{C}$  (e.g., Huss *et al.*, 2006, and references therein; Cody *et al.*, 2008). Assuming instantaneous accretion of the L, CO, and CV parent bodies composed a homogeneous mixture of anhydrous silicates and water ice/rock volume ratio of 0.2, Doyle *et al.* (2015) modeled thermal evolution of these bodies, and concluded that they accreted  $\sim 1.8$ ,  $\sim 2.4$ , and  $\sim 2.6$  m.y. after CV CAIs, respectively (Fig. 9). Using slightly different initial parameters, Sugiura and Fujiya (2014) inferred that the accretion ages of the ordinary, CO, and CV chondrite parent bodies are  $\sim 2.1$ ,  $\sim 2.7$ , and  $\sim 3.0$  m.y. after CV CAIs, respectively. The inferred accretion ages of the enstatite, R, and CK chondrite parent bodies are  $\sim 1.8$ ,  $\sim 2.1$ , and  $\sim 2.6$  m.y. after CV CAIs, respectively (Sugiura

and Fujiya, 2014). Note that if known meteorites have not sampled the innermost regions of these bodies, the peak metamorphic temperatures reached by these bodies could be higher and the estimated accretion ages may provide only the upper limits. For example, it has suggested that the CV chondrites are the unmelted crust of a differentiated body (Elkins-Tanton *et al.*, 2011), in which case at least the central portion of the CV chondrite parent body accreted prior to the ordinary chondrites.

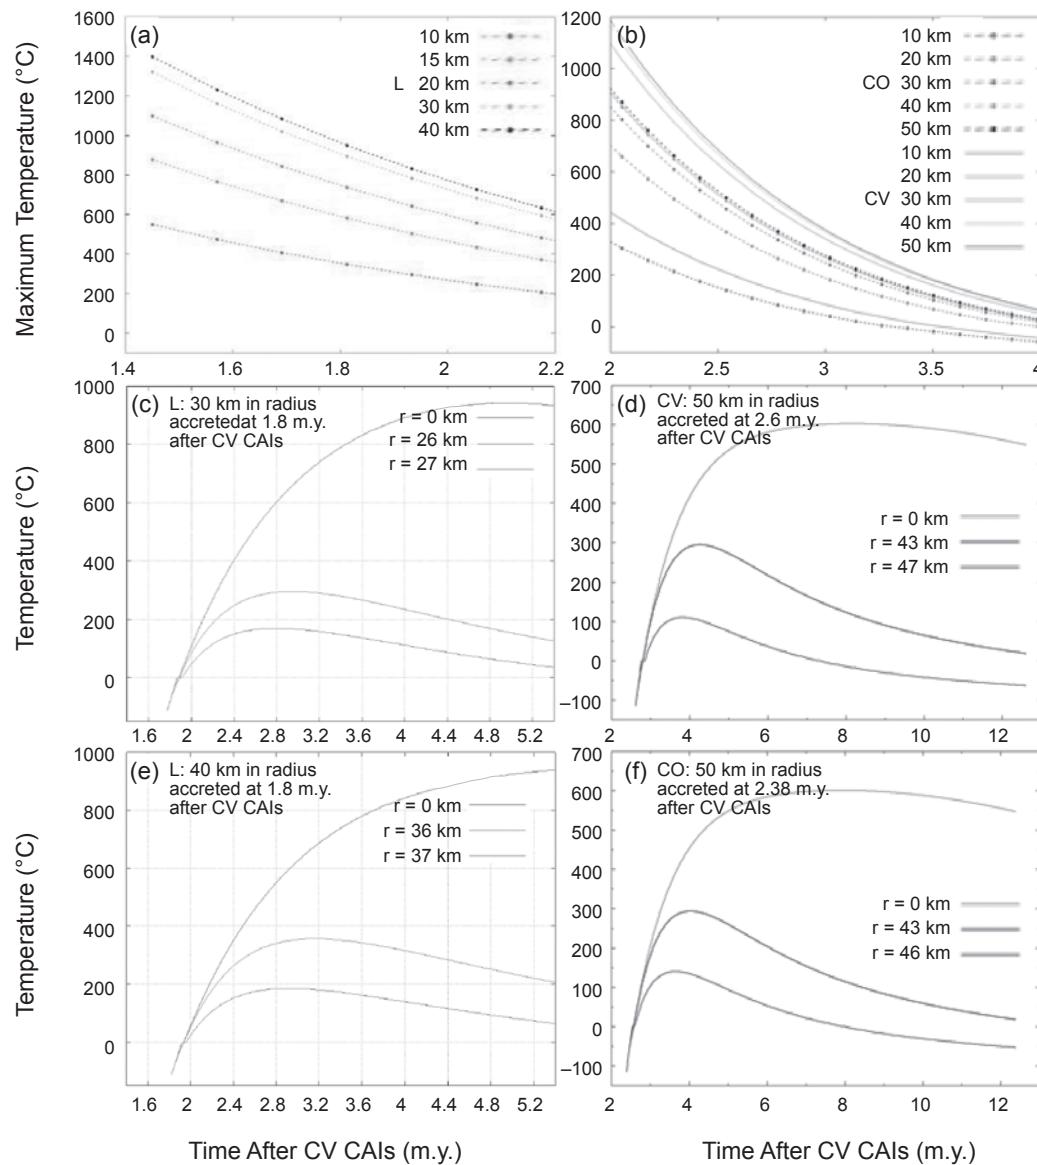

The accretion ages of the CI and CM chondrite parent bodies can be constrained using the formation temperatures and  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of carbonates, and the peak metamorphic temperatures reached by these bodies (Fujiya *et al.*, 2012, 2013). Based on the oxygen-isotope compositions of calcite and dolomite (Clayton and Mayeda, 1984; Guo and Eiler, 2007) and thermodynamic modeling (Zolensky *et al.*, 1989), it is estimated that these minerals precipitated in the earliest stages of aqueous alteration of the CM and CI chondrite parent bodies, at  $\sim 20^\circ$ – $70^\circ\text{C}$  and  $100^\circ$ – $150^\circ\text{C}$ , respectively. These estimates are model-dependent, and it is possible that both groups may have experienced similar peak metamorphic temperatures,  $\sim 100^\circ\text{C}$ . For example, the organic matter in CM and CI chondrites is structurally similar, suggesting similar peak-alteration temperatures (Alexander *et al.*, 2014). Alexander *et al.* (2014) found that the CM and CR organic matter is more aromatic than that in CR chondrites, and, as a result, suggested that CMs and CIs experienced higher peak-alteration temperatures than CRs. Based on the oxygen-isotopic compositions of carbonates and magnetite in CR chondrites, the alteration temperature of CRs was separately estimated to be  $\sim 50^\circ\text{C}$  (Jilly *et al.*, 2014b). Fujiya *et al.* (2012, 2013) modeled the thermal evolution of the CM and CI parent bodies, assuming that these bodies were  $\sim 60$ – $100$  km in diameter; that they accreted instantaneously; that they consisted of a homogeneous mixture of anhydrous silicates, water ice (W/R volume ratio of 0.56 and 1.0 for CM and CI bodies, respectively), and pore space; and that they were heated both by the decay of  $^{26}\text{Al}$  and by the hydration reactions. The thermal histories of these bodies were successfully reproduced only if they accreted  $\sim 3$ – $4$  m.y. after CV CAIs (Figs. 10, 11).

## 7. HYDROGEN AND OXYGEN-ISOTOPIC COMPOSITIONS OF COMETARY AND CHONDRITIC WATER

### 7.1. Measured Deuterium/Hydrogen Ratio of Cometary Water

While the genetic relationships between asteroids and comets remains unclear, they are both considered to represent leftover planetesimals from the formation of the solar system. As such, comparisons of their bulk properties allow us to better understand the types and ranges of processes that shaped primitive materials in the solar nebula.

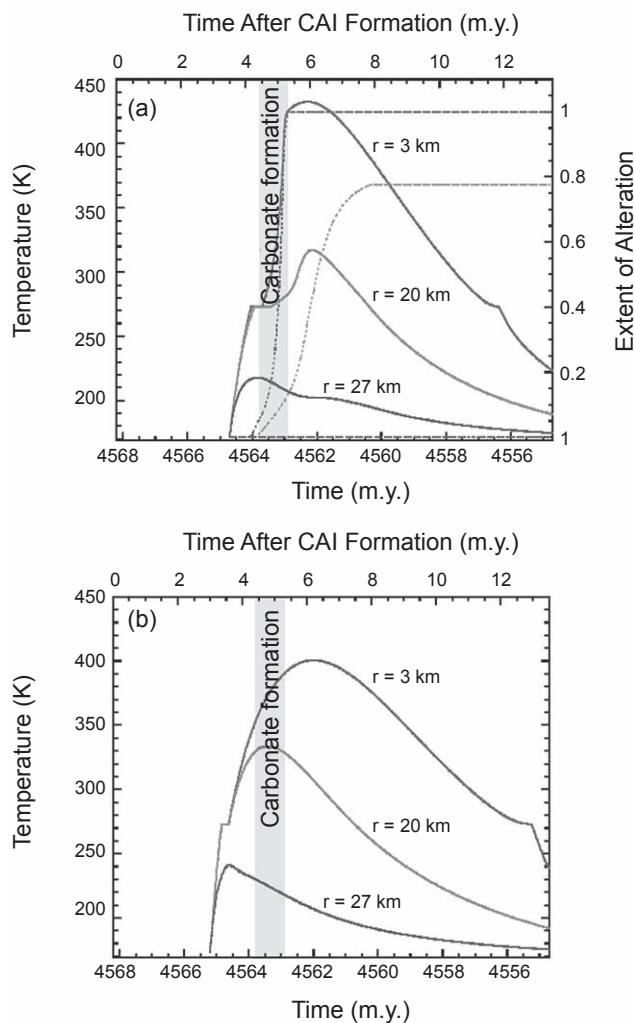

Before discussing deuterium/hydrogen (D/H) values of cometary water, we note that all D/H isotope ratios reported

**Fig. 9.** See Plate 23 for color version. (a,b) Modeled peak metamorphic temperature for L-, CV-, and CO-like chondrite parent bodies ranging from 10 to 50 km in radius as a function of time after CV CAIs. (c–f) Temperature evolution diagrams at different depths shown for (c,e) L-like chondrite parent body of 30 and 40 km in radius, (d) CV-like chondrite parent body of 50 km in radius, and (e) CO-like chondrite parent body of 50 km in radius. Blue and green lines in (c) and (e) and blue and red lines in (d) and (f) correspond to regions where thermal conditions ( $\sim 100\text{--}300^\circ\text{C}$ ) would be suitable for the formation of fayalite at the time inferred from  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  relative chronology. Figure from Doyle et al. (2015).

for comets to date have been done only on cometary comae (e.g., Balsiger et al., 1995; Eberhardt et al., 1995; Hartogh et al., 2011; Bockelée-Morvan et al., 2012; Altweegg et al., 2014); there are no direct measurements of the icy portions of cometary nuclei. Brown et al. (2012) reported on the experimental and theoretical simulations of ice sublimation at  $10^{-7}\text{--}10^{-9}$  bar pressure. They observed quasiperiodic sublimation cascades on timescales of hours to days, that the D/H ratio in the vapor issuing from the sample is in general

different from that of the sample, and in many cases, that quasiperiodic changes in the D/H ratio of the vapor accompany the sublimation cascades. Brown et al. (2012) suggested that vacuum sublimation of water ice is a diffusive process that works to leave behind the most strongly bound molecules. Therefore, it is highly unlikely that the D/H ratio in cometary comae is representative of the bulk D/H ratio in the nucleus. Subsequently, Moores et al. (2012) carried out water-ice-sublimation experiments to determine the effect of the

**Fig. 10.** Temperature (solid lines) and the extent of alteration (dotted lines) are given at three depths ( $r$ : distance from the center) in an asteroid with a radius of 30 km. The vertical gray band shows the  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  age of CM carbonates. (a) Accretion at 3.5 m.y. after CV CAIs; the heat of hydration reaction is included. The extent of alteration is defined by  $(1 - \text{olivine}_{\text{res}}/\text{olivine}_{\text{ini}})$ , where  $\text{olivine}_{\text{res}}$  and  $\text{olivine}_{\text{ini}}$  are the moles of the residual and initial olivine, respectively. (b) Accretion at 3.0 m.y. after CV CAIs; the heat of hydration reaction is not included. Figure from Fujiya *et al.* (2012). Note the simulation was based on the  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  carbonate ages with LEW 86010 angrite anchor (Amelin, 2008) and CAI from Bouvier and Wadhwa (2010).

mineral dust content of porous ice on the isotopic composition of the sublimated gas over days to weeks. They reported that if dust was present, the D/H ratio of the sublimated gas decreased with time from the bulk ratio. The more dust was added to the mixture, the more pronounced was this effect. Adsorption onto the dust grains is able to explain the low D/H ratios in the sublimate gas if adsorption favors retention of HDO over  $\text{H}_2\text{O}$ . This leads to significant isotopic enrichment of HDO on the dust over time and depletion in the amount of HDO escaping the system as sublimate gas. Moores *et al.*

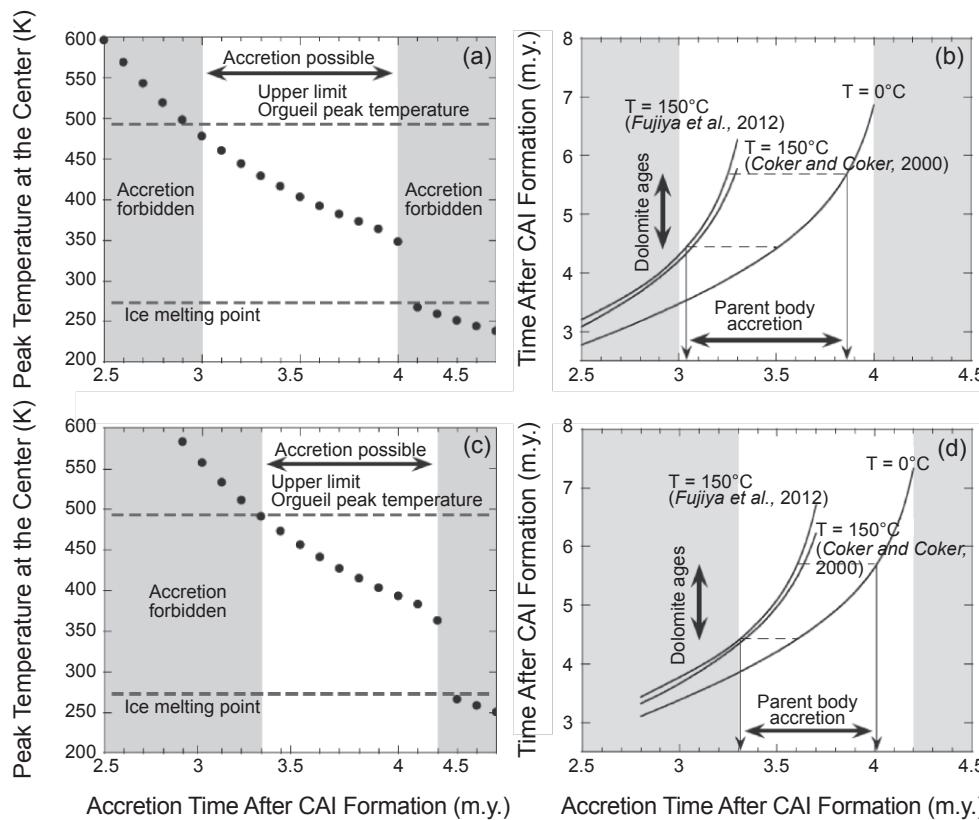

(2012) suggested that this effect was significant for water-ice-bearing bodies with dust-rich surfaces through which water moves mainly in vapor phase, such as in comets. However, it remains unclear whether such fractionation affected the D/H ratio of cometary water.

Almost all the Oort cloud comets (OCCs) measured have water ice that is enriched in deuterium ( $\text{D}/\text{H} \sim 3 \times 10^{-4}$ ) relative to Earth's oceans ( $\text{D}/\text{H} \sim 1.5 \times 10^{-4}$ ) by a factor of  $\sim 2$ , although an intermediate D/H ratio,  $\sim 2 \times 10^{-4}$ , has been recently reported in the OCC C/2009 P1/Garradd (Bockelée-Morvan *et al.*, 2012). On the other hand, water ice in the Jupiter-family comet (JFC) 103P/Hartley 2 has a D/H ratio of  $\sim 1.6 \times 10^{-4}$  (Hartogh *et al.*, 2011), which is close to the terrestrial value (Fig. 12). In another JFC, 5P/Honda-Mrkos-Pajdusáková, only an upper limit of D/H ratio in water ice,  $< 2 \times 10^{-4}$ , was reported (Lis *et al.*, 2013). Finally, in the recently measured JFC 67P/Churyumov-Gerasimenko, the D/H ratio was found to be  $(5.3 \pm 0.7) \times 10^{-4}$  (Altweegg *et al.*, 2014). These observations indicate a diversity of D/H ratios of water ice in both comet populations.

## 7.2. Estimated Deuterium/Hydrogen Ratio of Chondritic Water

Chondrites have not retained water ice, and therefore the hydrogen-isotopic composition of chondritic water cannot be measured directly. The major carriers of hydrogen in chondrites are organics and phyllosilicates (e.g., Alexander *et al.*, 2010). Although the phyllosilicates resulted from water-rock interaction on the chondrite parent bodies, determining the original D/H of chondritic water is problematic, because of (1) the physically intimate association between organics and hydrated phyllosilicates, (2) the similar release temperature for hydrogen-bearing organics and water/OH in phyllosilicates, (3) the hydrogen-isotopic exchange between water and organics during parent-body alteration and metamorphism, and (4) the hydrogen-isotopic fractionation associated with oxidation of iron by water during aqueous alteration and metamorphism (Alexander *et al.*, 2010; Bonal *et al.*, 2013).

Assuming that bulk hydrogen-isotope compositions of chondrites are a two-component mixture of deuterium-rich organics and deuterium-poor phyllosilicates, in a plot of the D/H vs. C/H abundance ratio, the compositions of bulk chondrites that experienced various degrees of aqueous alteration should form a line with the D/H intercept representing the composition of the chondritic water. Using this approach, Alexander *et al.* (2012) estimated the D/H ratio of water in CI, CM, CR, CO, CV, R, and ordinary chondrites and Tagish Lake (Fig. 13). These estimates for CIs, CMs, COS, CVs, and Tagish Lake fall between the terrestrial value ( $\sim 1.5 \times 10^{-4}$ ) and the estimated protosolar value [ $\sim 2 \times 10^{-5}$  (Geiss and Gloeckler, 2003)]; the CR water is slightly heavier than the terrestrial value, while the water in ordinary and R chondrites is highly deuterium-enriched (Fig. 13). The estimated D/H ratios of chondritic water provide the upper limits of the initial compositions of accreted water ice because of possible isotopic fractionations associated with iron oxidation on the

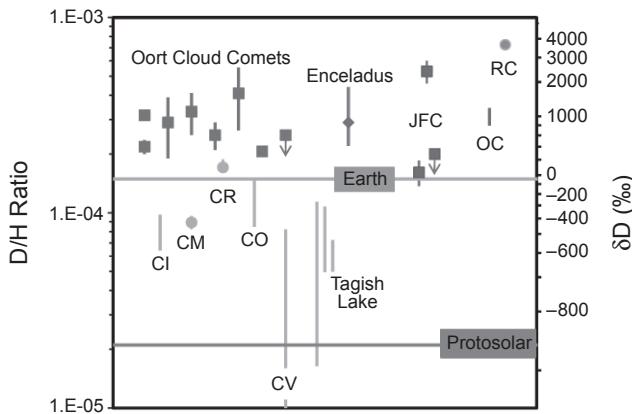

**Fig. 11.** (a,b) Peak temperatures of a CI-like asteroid with a 50-km radius as a function of accretion time; W/R volume ratio is 1 in (a) and 0.56 in (b). The accretion time between 3 and 4 in (a) and between 3.3 and 4.2 m.y. after CV CAIs in (b) is constrained by a peak metamorphic temperature of Orgueil (Busemann et al., 2007) and melting temperature of water ice. (c,d) Accretion time of the CI-like parent body vs. the time when the temperature goes up to 0°C or 150°C at the center (temperature range when CI dolomites may have crystallized) of a CI-like asteroid with W/R ratio of 1 in (c) and 0.56 in (d). The estimated accretion time of the CI parent body is 3.0–3.9 in (c) and 3.3–4.0 m.y. after CV CAIs in (d). Note that the time when temperature reaches 150°C depends on the hydration reaction rate. Two values of the hydration reaction are considered, from Cohen and Coker (2000) and from Fujiya et al. (2012). Figure from Fujiya et al. (2013). Note the simulation was based on the  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  carbonate ages with LEW 86010 angrite anchor (Amelin, 2008) and CAI age from Bouvier and Wadhwa (2010).

chondrite parent bodies (Alexander et al., 2010). Alexander et al. (2010, 2012) suggested that this fractionation was very significant in ordinary and R chondrites that contained very little water.

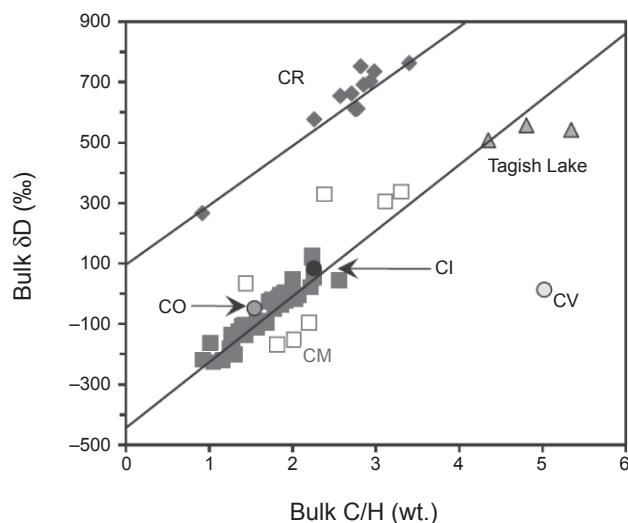

Because water in the molecular clouds has high D/H ratios [up to  $10^{-2}$  (e.g., Rodgers and Millar, 1996; Bergin et al., 2010; Coutens et al., 2012)] compared to the estimated protosolar hydrogen-isotopic composition ( $\sim 2 \times 10^{-5}$ ), these observations suggest that the inferred D/H ratio of chondritic water must have recorded varying degrees of reequilibration between the primordial (molecular cloud) water with protosolar H<sub>2</sub> at different times and at different radial distances from the Sun. Both the temporal and the spatial distributions of the D/H ratio of water in the solar system have been recently modeled (Yang et al., 2013; Jacquet and Robert, 2013; Furuya et al., 2013; Albertsson et al., 2014) and are discussed in the next section.

### 7.3. Modeling of the Evolution of the Deuterium/Hydrogen Ratio of Water in the Protoplanetary Disk

Yang et al. (2013) developed a one-dimensional viscous disk model for the transport and mixing of water within a forming and evolving protoplanetary disk, and combined it with a kinetic study of D/H-isotopic exchange among gas-phase molecules to explore the isotopic evolution of the initially highly deuterated molecular cloud water (D/H =  $1 \times 10^{-3}$ ) in the disk. In this model, viscous expansion and radial diffusion carry high-temperature inner disk materials outward. Their calculations show that the (D/H)<sub>water</sub> is low ( $\sim 2 \times 10^{-5}$ ) in the warm ( $T > 300$  K) inner disk due to rapid isotopic exchange with molecular hydrogen, and then increases toward the cold ( $T < 300$  K) outer disk where deuterated molecular cloud water was added, and the exchange reactions are sluggish (Fig. 14). Contrary to

**Fig. 12.** Comparison of the estimated hydrogen isotopic compositions of water in various chondrite groups with those measured in Oort cloud comets, Jupiter-family comets (JFCs), and Saturn's icy moon Enceladus. After Alexander *et al.* (2012). Additional data for comets are from Bockelée-Morvan *et al.* (2012) and Altwegg *et al.* (2014).

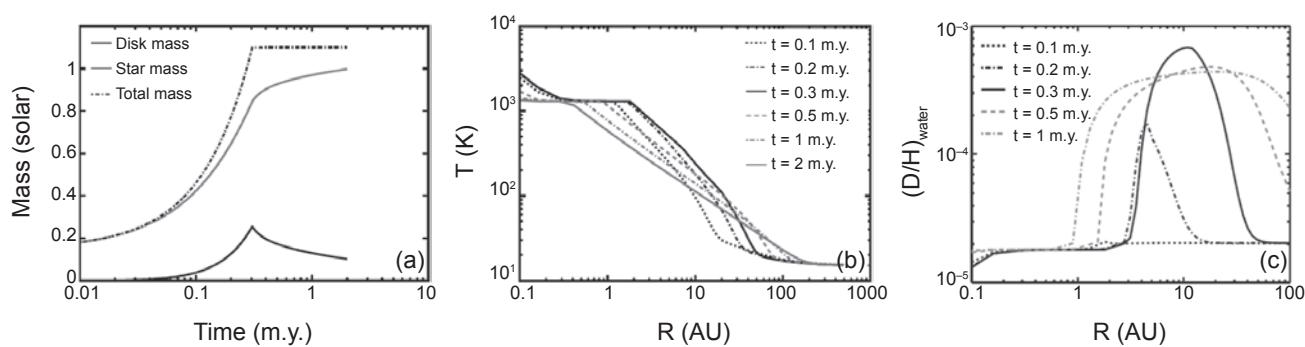

**Fig. 13.** Bulk hydrogen isotopic compositions vs. bulk C/H elemental ratio of the ungrouped carbonaceous chondrite Tagish Lake and CR, CM, CI, CO, and CV chondrites. Figure from Alexander *et al.* (2012).

the previous studies (Drouart *et al.*, 1999; Mousis *et al.*, 2000; Horner *et al.* 2007, 2008), in the outer regions of the disk, the  $(D/H)_{\text{water}}$  decreases again because water that been exchanged at high temperatures near the young star would have been transported outward during the early evolution of the disk. While the exact model results vary depending on the choice of the initial parameters for the molecular cloud and the disk, the nonmonotonic distribution in the D/H ratio of water is robust. This nonmonotonic gradient in D/H may help to explain the observations showing that the  $(D/H)_{\text{water}}$  of JFC 103P/Hartley 2,  $\sim 1.6 \times 10^{-4}$  (Hartogh *et al.*, 2011), is close to the terrestrial water value ( $\sim 1.5 \times 10^{-4}$ ) and lower than that of previously measured OCCs ( $\sim 3 \times 10^{-4}$ ). We note, however, that the accretion ages and radial-formation regions of comets are poorly known.

The model calculations of Yang *et al.* (2013) suggest that there would have been a strong radial gradient in water ice

D/H ratio in the inner solar nebula at the beginning of the solar system formation. The gradient will rapidly smooth out within 1 m.y. of the disk evolution, and a plateau with a D/H ratio of  $\sim 3 \times 10^{-4}$  would be reached. An even shallower gradient should be expected for a 2–4-m.y.-old disk, the time when the chondrite parent bodies appear to have accreted (see section 6). Model calculations for this late disk evolution were reported by Jacquet and Robert (2013). They find that the D/H ratios of carbonaceous chondrite water can be accounted for by radial mixing between water with Oort cloud cometary D/H values ( $\sim 3 \times 10^{-4}$ ) and deuterium-poor water ( $D/H \sim 2 \times 10^{-5}$ ) produced by isotopic exchange in the warm inner disk. If mixing was very efficient, the D/H ratio in nebular water even at a few tens of astronomical units (depending on time) could have been significantly lower than the plateau value of  $\sim 3 \times 10^{-4}$  (Fig. 15), and may also explain the low D/H ratios of water in the JFC 103P/Hartley 2.

**Fig. 14.** Evolution of the (a) disk mass, star mass, and total mass, and (b) disk midplane temperature with time. (c) The radial distribution of D/H ratio of water in the disk at different times. Turbulent viscosity parameter  $\alpha$  in the disk is  $10^{-3}$ . The initial parameters for the molecular cloud are mass = 1.1× solar; T = 15 K;  $H_2O/H_2 = 2 \times 10^{-4}$ ; D/H ratio of water ice and  $H_2$  gas =  $1 \times 10^{-3}$  and  $2 \times 10^{-5}$ , respectively. Black lines represent times when infall continues while gray lines are for times after infall has ceased (at  $\sim 0.3$  m.y.). Coagulation and migration of dust aggregates have not been considered. From Yang *et al.* (2013).

#### 7.4. Oxygen Isotopic Compositions of Aqueously Formed Minerals and Estimated Oxygen Isotopic Composition of Chondritic Water

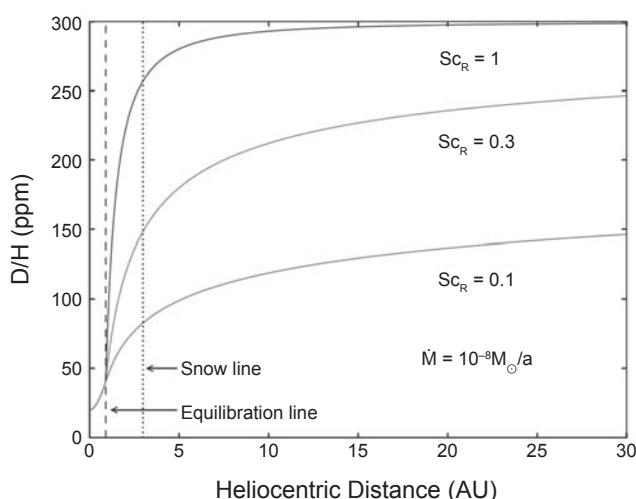

The oxygen-isotopic compositions of chondrule olivines and pyroxenes, and aqueously formed minerals (carbonates, magnetite, fayalite, etc.) in different chondrite groups (CI, CM, CO, CV, and ordinary) and Tagish Lake, are shown in Figs. 16 and 17. Magnetite and carbonates in CIs, CMs, and Tagish Lake plot within 1–2‰ of the terrestrial fractionation line (TFL), but show a large range of  $\delta^{18}\text{O}$  values; the similarly large range of  $\delta^{18}\text{O}$  values has been reported by carbonates and magnetite in CR chondrites (Jilly et al., 2014b). The observed range is consistent with mass-dependent isotope fractionation between the aqueously formed minerals and the fluid at a relatively low temperature (~20°–150°C) (Zolensky et al., 1989; Zolotov and Mironenko, 2008; Zolotov, 2012). The secondary minerals have systematically larger  $\Delta^{17}\text{O}$  values ( $\Delta^{17}\text{O}$ , deviation from the TFL,  $\delta^{17}\text{O} - 0.52 \times \delta^{18}\text{O}$ ) than those of chondrule olivines and pyroxenes, which in Figs. 16 and 17 plot along the ~slope-1 [carbonaceous chondrite anhydrous mineral (CCAM)] line. These observations indicate a lack of oxygen-isotopic equilibrium between the primary high-temperature minerals formed in the nebula and the secondary minerals precipitated from aqueous solutions. There are also small differences in  $\Delta^{17}\text{O}$  values of magnetite, calcite, and dolomite within individual

CI and CM chondrites, possibly reflecting an evolution of oxygen-isotopic composition of aqueous solutions as a result of exchange between the relatively  $^{16}\text{O}$ -poor altering fluids and the more  $^{16}\text{O}$ -rich primary anhydrous minerals during progressive aqueous alteration.

In type 3 ordinary and CO chondrites (Fig. 16d), fayalite and magnetite plot parallel to the TFL, above and below it respectively. These observations suggest that oxygen-isotopic compositions of the fluids from which fayalite and magnetite formed were different in ordinary and CO chondrite parent bodies ( $\Delta^{17}\text{O} \sim +4\text{\textperthousand}$  and  $\sim -1\text{\textperthousand}$ , respectively). The range of  $\delta^{18}\text{O}$  values between fayalite and magnetite in ordinary and CO chondrites is significantly smaller than those between magnetite and carbonates in CIs, CMs, and CRs, consistent with the inferred high-temperature aqueous alteration (100°–300°C) experienced by ordinary and CO chondrites (Zolotov et al., 2006; Krot et al., 2013; Doyle et al., 2015).

In CV chondrites, the  $\Delta^{17}\text{O}$  values of secondary minerals range from  $-4\text{\textperthousand}$  to  $-2\text{\textperthousand}$ , and are similar (uncertainties are quite large) to those of aqueously formed minerals in CO chondrites (Figs. 16, 17).

The oxygen-isotopic compositions of secondary minerals that either precipitated from aqueous solutions (e.g., carbonates, fayalite, kirschsteinite, hedenbergite, andradite) or formed by oxidation of oxygen-free Fe,Ni-metal and sulfides (e.g., magnetite) recorded the  $\Delta^{17}\text{O}$  values of these aqueous solutions. These values, ranging from  $\sim -4\text{\textperthousand}$  to  $+4\text{\textperthousand}$ , are slightly higher than those of chondrule olivines and pyroxenes in their host meteorites (Figs. 16, 17), and significantly higher than the measured  $\Delta^{17}\text{O}$  value of the solar wind ( $-26 \pm 2\text{\textperthousand}$ ) returned by the Genesis spacecraft (McKeegan et al., 2011). If aqueous solutions in the chondrite parent bodies experienced limited oxygen-isotope exchange with anhydrous silicates during alteration, the  $\Delta^{17}\text{O}$  values of carbonates, fayalite, and magnetite ( $-4\text{\textperthousand}$  to  $+4\text{\textperthousand}$ ) can be used as proxies for  $\Delta^{17}\text{O}$  values of water ice that accreted into chondrite parent bodies. Note that the extent of oxygen-isotope exchange during fluid-rock interaction is poorly constrained and model-dependent (e.g., Clayton and Mayeda, 1999; Young et al., 1999; Young, 2001). The oxygen-isotopic compositions of water ice in the outer solar system are not known, but are hypothesized to be very heavy ( $\Delta^{17}\text{O} \sim +100\text{\textperthousand}$ ) (Yurimoto and Kuramoto, 2004). If correct, the inferred near-terrestrial  $\Delta^{17}\text{O}$  values of chondritic water may indicate its local, inner solar system origin.

**Fig. 15.** D/H ratio, expressed in parts per million (ppm), of nebular water as a function of heliocentric distance in a steady disk for three values of the radial Schmidt number  $\text{Sc}_R$ , which ratios the efficiencies of angular momentum transport and turbulent diffusion. In the “reaction zone,” delimited by a vertical dashed line (“equilibration line”), equilibrium isotopic fractionation with hydrogen gas is assumed; beyond, mixing with cometary water controls the D/H ratio. The low value of  $\text{Sc}_R$  enhances outward transport of equilibrated water and results in decrease of D/H ratio up to tens of astronomical units. The position of the snow line is indicated by a vertical dotted line. From Jacquet and Robert (2013).

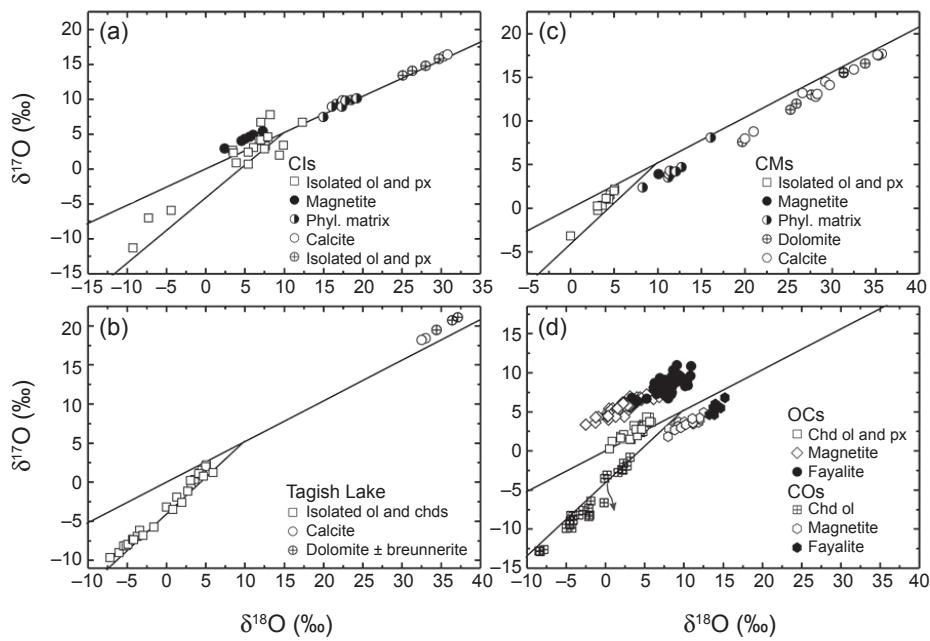

#### 7.5. Modeling of Oxygen-Isotope Evolution of the Protoplanetary Disk Water

There are three major oxygen-bearing components in the solar system: CO,  $\text{H}_2\text{O}$ , and silicates. Although the  $\Delta^{17}\text{O}$  value of the Sun ( $\sim -26 \pm 2\text{\textperthousand}$ ) has been recently inferred (McKeegan et al., 2011), the initial compositions of CO,  $\text{H}_2\text{O}$ , and silicates in the solar nebula are not known. Cosmochemical studies show that the first solids known to have formed in the disk, refractory inclusions, have a range of  $\Delta^{17}\text{O}$  values that bracket the solar value (e.g., Gounelle et al., 2009;

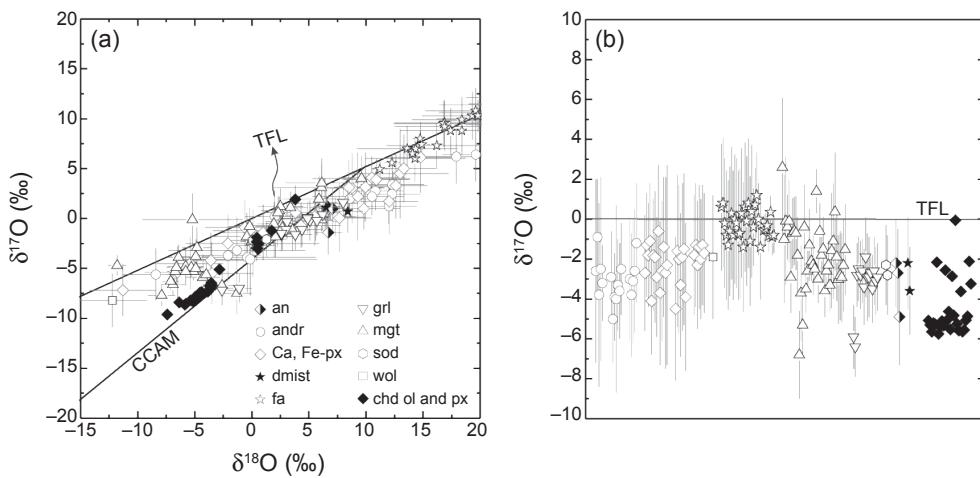

Krot et al., 2010; Ivanova et al., 2012). Based on these data, it is inferred that at least two isotopically distinct oxygen-isotope reservoirs,  $^{16}\text{O}$ -enriched and  $^{16}\text{O}$ -depleted relative to the Sun, coexisted in the early solar system.

In the currently favored CO self-shielding models, the ultraviolet photolysis preferentially dissociates  $\text{C}^{17}\text{O}$  and

$\text{C}^{18}\text{O}$  in certain zones of the protoplanetary disks (Clayton, 2002; Lyons and Young, 2005) or in the molecular clouds (Yurimoto and Kuramoto, 2004; Lee et al., 2008). If this process occurred in the stability field of water ice, the released atomic  $^{17}\text{O}$  and  $^{18}\text{O}$  were incorporated into water ice, while the residual CO gas became enriched in  $^{16}\text{O}$ . Subsequent

**Fig. 16.** Three-isotope oxygen diagrams of isolated olivine (ol) and pyroxene (px) grains, chondrule (chd) olivines and pyroxenes, and aqueously formed minerals: calcite, dolomite + breunnerite, fayalite, magnetite, and phyllosilicate-rich matrix in (a) CI chondrites ( $1\sigma$  uncertainties for isolated olivines and pyroxenes), (b) Tagish Lake (ungrouped), (c) CM chondrites, and (d) ordinary and CO chondrites. The terrestrial fractionation line (TFL) and carbonaceous chondrite anhydrous mineral (CCAM) line are shown for reference. Data from Rowe et al. (1994), Leshin et al. (1997), Clayton and Mayeda (1999), Benedix et al. (2003), Jabeen and Hiyagon (2003), Russell et al. (2010), Jenniskens et al. (2012), Krot et al. (2014b), and Doyle et al. (2015).

**Fig. 17.** (a) Three-isotope oxygen diagram and (b)  $\Delta^{17}\text{O}$  values of chondrule olivines and pyroxenes and aqueously formed minerals in CV chondrites. Most of the secondary minerals (except fayalite, magnetite, and anorthite) were measured by SIMS without proper standards. As a result, only  $\Delta^{17}\text{O}$  values of these minerals [(b)] can be trusted. an = anorthite; andr = andradite; Ca,Fe-px = salite-hedenbergite pyroxenes; dmist = dmisteinbergite; fa = fayalite; grl = grossular, mgt = magnetite; ol = olivine; px = pyroxene; sod = sodalite; wol = wollastonite. The terrestrial fractionation line (TF) and carbonaceous chondrite anhydrous mineral (CCAM) line are shown for reference. From Brearley and Krot (2012).

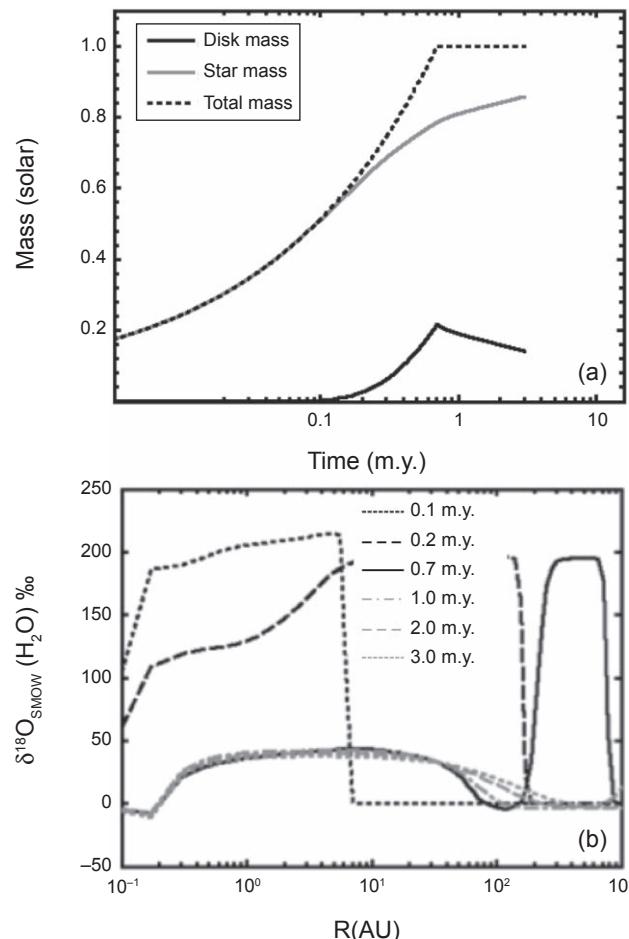

$\text{H}_2\text{O}$  ice–CO gas fractionation followed by evaporation of water ice and isotope exchange could have resulted in the generation of the  $^{16}\text{O}$ -enriched and  $^{17,18}\text{O}$ -enriched gaseous reservoirs in the inner solar system. *Sakamoto et al.* (2007) described isotopically heavy magnetite grains ( $\delta^{17,18}\text{O} \sim +180\text{\textperthousand}$ ) in the ungrouped carbonaceous chondrite Acfer 094 and suggested that these grains recorded the oxygen-isotopic compositions of the primordial (molecular cloud) water in the protoplanetary disk, consistent with the prediction from the CO self-shielding model.

Following the same formalism as in *Yang et al.* (2013), but using different initial parameters, *Yang et al.* (2011) reported preliminary results for the evolution of the oxygen-isotopic composition of water in the protoplanetary disk. In this study, the concentrations and oxygen-isotopic compositions of CO and  $\text{H}_2\text{O}$ , produced via self-shielding photodissociation of CO in the protosolar molecular cloud and modeled by *Lee et al.* (2004, 2008) were used as the input parameters for the dynamical model of the disk evolution. The results of their calculations are illustrated in Fig. 18. *Yang et al.* (2011) find that the  $\delta^{18}\text{O}$  of  $\text{H}_2\text{O}$  varies with time and location in the disk. During the epoch with large mass infall from the protosolar molecular cloud, there are strong spatial and temporal variations in the isotopic composition of water due to the changing isotopic compositions of materials being added to the disk. Once the infall ceases, radial transport and oxygen-isotope exchange smooth out these variations, leading to a more homogenized disk (Fig. 18). Subsequently, *Yang et al.* (2013) considered both oxygen- and hydrogen-isotopic exchange between  $\text{H}_2\text{O}$  and other gas species in the disk. They find that the D-H exchange proceeds much faster than the  $^{18}\text{O}-^{16}\text{O}$  exchange, implying that the initially high D/H signature of the molecular cloud water would be erased more efficiently compared to its initial high  $\delta^{18}\text{O}$  value.

## 8. ACCRETION REGIONS OF CHONDRITE PARENT BODIES: IMPLICATION FOR THE DYNAMICAL MODELS OF THE SOLAR SYSTEM EVOLUTION

### 8.1. Chondrite-Asteroid Linkages and the Presence of Hydrated Asteroids in the Main Belt

Most chondrites are thought to come from the main asteroid belt. Although the spectral reflectance properties in the range of 0.4–2.4  $\mu\text{m}$  have been recently collected for different chondrite groups (*Clark et al.*, 2011; *Cloutis et al.*, 2011a,b, 2012a,b,c,d,e,f), the connections between chondrite groups and asteroid classes are still poorly known. Spectroscopically, the ordinary chondrites have been linked to the S-type asteroids, and the carbonaceous chondrites to multiple taxonomic groups: C-, D-, P-, B-, and K-type asteroids (e.g., *Bell et al.*, 1989; *Hiroi et al.*, 2001; *Burbine et al.*, 2002; *Clark et al.*, 2010, 2011; *Cloutis et al.*, 2011a,b, 2012a,b,c,d,e,f). The linkage of L chondrites to S-type asteroids has been confirmed by the Hayabusa sample return mission from asteroid (25143) Itokawa (*Nakamura et al.*, 2011). No samples have

**Fig. 18.** (a) Evolution of the disk mass, stellar mass, and total mass with time. (b) The radial distribution of  $\delta^{18}\text{O}$  of water in the disk at different times. Turbulent viscosity parameter  $\alpha$  in the disk is  $10^{-3}$ . The initial parameters for the molecular cloud are mass = 1  $\times$  solar;  $T = 10\text{ K}$ ; duration of infall is 0.7 m.y. Coagulation and migration of dust aggregates have not been considered. From *Yang et al.* (2011).

yet been returned from other types of asteroids, although two recent carbonaceous chondrite falls, Tagish Lake (ungrouped) and Sutter's Mill (CM), may represent fragments of D-type (*Hiroi et al.*, 2001) and C-type asteroids (*Zolensky et al.*, 2014), respectively. Some B-type asteroids exhibit selected spectral properties consistent with CI chondrites; however, perfect spectral matches have not been found (*Cloutis et al.*, 2011a). *Clark et al.* (2011) linked the B-type asteroid (101955) Bennu (provisional designation 1999 RQ<sub>36</sub>) to the CIs and/or heavily altered CMs; however, a comparison of RQ<sub>36</sub> to other B-type asteroids measured by *Clark et al.* (2010) shows that this link is inconclusive. Some K-class asteroids exhibit spectral properties similar to CO chondrites; however, unmetamorphosed CO chondrites are difficult to distinguish from the least-altered CMs (*Cloutis et al.*, 2012c). The Hayabusa-2 and Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) sample return missions will target carbonaceous chondrite

asteroids 1999 JU<sub>3</sub> (C-type) and (101955) Bennu (B-type), respectively (*Tachibana et al.*, 2014; *Lauretta et al.*, 2014), which will allow us to explore the meteorite-parent body connection in greater detail.

It is estimated that about 70% of C-complex asteroids show spectroscopic evidence for the presence of hydrated minerals (e.g., *Rivkin*, 2012). Water ice has been recently detected on the C-type asteroid (24) Themis (*Campins et al.*, 2010; *Rivkin and Emery*, 2010). The presence of water ice was also inferred for some of the active asteroids, including (1) Ceres, 133P/Elst-Pizarro, and 238P/Read, named “main belt comets” (*Hsieh and Jewitt*, 2006; *Jewitt*, 2012; *Kuipers et al.*, 2014; see also the chapter by Jewitt et al. in this volume). The survival of ice in the asteroids provide a unique opportunity to study their chemical and isotopic compositions and compare them with those of OCCs and JFCs.

## 8.2. Dynamical Models of Solar System Evolution and Accretion Regions of Hydrated Asteroids

It is currently being debated whether hydrated asteroids formed in the main asteroid belt (*Alexander et al.*, 2012) or whether they formed further away from the Sun and were subsequently implanted into the main belt during dynamical evolution of the solar system (*Levison et al.*, 2009; *Walsh et al.*, 2011). Many dynamical models of solar system evolution fail to reproduce the small mass of Mars at its current location. This issue is commonly referred to as the “small Mars” problem (e.g., *Chambers*, 2001; *Raymond et al.*, 2009; *Morbidelli et al.*, 2012; *Kobayashi and Dauphas*, 2013; *Izidoro et al.*, 2014; *Raymond and Morbidelli*, 2014). According to the Grand Tack model (*Walsh et al.*, 2011), proposed to explain the small mass of Mars, Jupiter accretes at ~3.5 AU from the Sun within the first several million years of solar system formation, migrates inward to about 1.5 AU, and truncates the disk of planetesimals at ~1 AU, at which point Saturn catches up with it, and then the two planets migrate outward again to about 5 and 7 AU, respectively. Uranus and Neptune are also forced to migrate to greater distances (roughly 10 and 13 AU, respectively) as Jupiter and Saturn moved outward. As a result of this migration, not only are the planetesimals at ~1.5–3 AU depleted, but the planetesimals between 4 and 13 AU are strongly perturbed, and some of them are scattered into the inner solar system and become trapped in the outer asteroid belt. According to this model, the dry, S-type asteroids formed close to the main asteroid belt, whereas the wet, C-, P-, D-, B-, and K-type asteroids formed either between the giant planets or in the transneptunian region (>13 AU).

The Grand Tack model reproduces two important aspects of the inner solar system: the strong depletion of the main asteroid belt in mass, and its mixed structure (*DeMeo and Carry*, 2014). The major unknowns of this model are the time and place of Jupiter formation, and the timing of its migration (*Walsh et al.*, 2011; *Raymond and Morbidelli*, 2014). If this model explains the small size of Mars, the migration may have started very early, as Hf-W-Th age dating suggests that 50% of Mars’ mass accreted by 2 m.y. after t<sub>0</sub> (*Dauphas*

*and Pourmand*, 2011). The early migration of Jupiter would conflict with the estimated 2.5–4-m.y. accretion ages of most carbonaceous chondrites, since in the Grand Tack model they must predate the onset of giant planet migration.

In the model of *Izidoro et al.* (2014), the small mass of Mars resulted from a local depletion in the solar nebula density, and giant planet migration was not involved (see also *Jin et al.*, 2008). Therefore this model predicts accretion of dry and wet asteroids close to their current locations, i.e., in the main asteroid belt. Finally, in the “standard” (without giant-planet migration) model of *Fischer and Ciesla* (2014), a Mars-sized object forms in ~5–10% of simulations. In this case, the architecture of the inner solar system is simply an unusual (but not rare) outcome of a stochastic process.

According to the Nice model, proposed to explain the current solar system architecture, including the giant-planet orbits, Trojan asteroids, and origin from late heavy bombardment (*Gomes et al.*, 2005; *Morbidelli et al.*, 2005; *Tsiganis et al.*, 2005; *Levison et al.*, 2011), additional implantation of transneptunian objects (spectrally D- and P-types) into the main asteroid belt took place at ~4 Ga, when the orbits of the giant planets became unstable (*Levison et al.*, 2009).

## 8.3. Cosmochemical Constraints on Accretion Regions of Chondrite Parent Bodies

The estimated oxygen- and hydrogen-isotopic compositions of chondrite water ice, and the chondrite accretion ages combined with the inferred water/rock ratios on the aqueously altered chondrite parent bodies, can potentially be used for constraining the disk regions where these bodies accreted and therefore for testing the predictions of the dynamical models of solar system evolution.

**8.3.1. Oxygen isotopes.** Making the assumption that oxygen-isotope exchange between aqueous solutions and anhydrous silicates during alteration of chondritic meteorites was insignificant, the inferred oxygen-isotope compositions of chondritic water are close to Earth’s ocean,  $-4\text{\textperthousand} < \Delta^{17}\text{O} < +4\text{\textperthousand}$  (Figs. 15, 16). The oxygen-isotope compositions of water ice in the outer part of the solar system are hypothesized to be significantly heavier, with  $\Delta^{17}\text{O} \sim +100\text{\textperthousand}$  (*Yurimoto and Kuramoto*, 2004). Although these observations can be interpreted as evidence for a local, inner solar system origin of chondritic water, they cannot be unambiguously used for constraining the chondrite accretion regions (inner vs. outer solar system) because (1) the extent of oxygen-isotope exchange during fluid-rock interaction is poorly constrained and model-dependent (e.g., *Clayton and Mayeda*, 1999; *Young et al.*, 1999; *Young*, 2001), (2) the evolution of the oxygen-isotope compositions of disk water is not well enough understood (e.g., *Lyons and Young*, 2005; *Yang et al.*, 2011), and (3) the uncertainties in the oxygen-isotopic compositions of OCC and JFC water are too large to be useful. For example, the  $^{18}\text{O}/^{16}\text{O}$  ratios of water measured for the OCCs 1P/Halley [ $(1.9 \pm 0.2) \times 10^{-3}$  (*Balsiger et al.*, 1995)] and C/2009 P1 (Garradd) [ $(1.9 \pm 0.3) \times 10^{-3}$  (*Bockelée-Morvan et al.*, 2012)] cannot be distinguished from the standard mean

ocean water (SMOW) value of  $2.01 \times 10^{-3}$ ;  $^{17}\text{O}/^{16}\text{O}$  ratios were not measured. Both  $^{18}\text{O}/^{16}\text{O}$  and  $^{17}\text{O}/^{16}\text{O}$  ratios of water have been reported for the JFC 67P/Churyumov-Gerasimenko (*Altwegg et al.*, 2014),  $(1.8 \pm 0.2) \times 10^{-3}$  and  $(3.7 \pm 0.9) \times 10^{-4}$ , respectively; however, they also cannot be distinguished from the SMOW values ( $^{17}\text{O}/^{16}\text{O}_{\text{SMOW}} = 3.8 \times 10^{-4}$ ). More precise measurements of oxygen isotopes in the water ice of primitive bodies are required in order to deconvolve the birth regions of comets and asteroids.

**8.3.2. Hydrogen isotopes.** Comparison of the inferred D/H ratios of chondritic water (*Alexander et al.*, 2012) with the ratios reported for the OCC and JFC water provide a hint for a possible linkage between CR chondrites and comets; no such connection can be inferred for the CIIs, CMs, and ungrouped carbonaceous chondrite Tagish Lake, which all had water ice with lower D/H ratios than comets measured so far [Fig. 14; but see *Moores et al.* (2012)]. However, there are only a limited number of comets with the measured D/H ratio of water ice, and even among these there are large variations (*Hartogh et al.*, 2011; *Bockelée-Morvan et al.*, 2012; *Lis et al.*, 2013; *Altwegg et al.*, 2014). As a result, a direct comparison of the inferred D/H ratio of chondritic water with the measured D/H ratios of cometary water to constrain the accretion regions of the chondrite parent bodies (*Alexander et al.*, 2012) may be inconclusive; understanding of the temporal and spatial evolution of hydrogen-isotope compositions of the protoplanetary disk water is required. The inferred hydrogen-isotopic evolution of the disk water, however, is model-dependent (e.g., *Drouart et al.*, 1999; *Mousis et al.*, 2000; *Hersant et al.*, 2001; *Yang et al.*, 2011, 2013; *Jacquet and Robert*, 2013), and cannot be unambiguously used for constraining the chondrite-accretion regions. To further test the Grand Tack model, direct hydrogen-isotope measurements of water ice in asteroids, including main-belt comets (*Jewitt*, 2012; see also the chapter by *Jewitt et al.* in this volume) are required. If some of the wet asteroids are in fact implanted comets, their water ice may have D/H ratios similar to those reported for comets. Additional measurements of D/H ratios in water of OCCs and JFCs would be also important.

**8.3.3. Chondrite-accretion ages, water/rock ratio, and position of the snow line.** The majority of hydrated chondrite parent bodies accreted  $\sim 2\text{--}4$  m.y. after CV CAIs and had W/R mass ratios significantly lower than the solar value,  $<0.1\text{--}0.6$  (see section 3) vs. 1.2 (*Lodders*, 2003), respectively. Members of the same chondrite group often experienced quite different degrees of aqueous alteration. This, in combination with the apparently isochemical nature of the alteration (*Bland et al.*, 2005) and the low fluid permeability of chondrites (*Bland et al.*, 2009; see the chapter by *Wilson et al.* in this volume), might indicate heterogeneous accretion of chondrite water ice. If correct, one explanation for these heterogeneities and the low inferred W/R ratios would be that chondrite parent bodies accreted close to the snow line, possibly slightly inside it, where only relatively large water-ice-bearing particles could have avoided instantaneous evaporation and survived prior to accretion (*Cyr et al.*, 1998). However, it should be born in mind that there are alternative explanations for the

variation in the degree of alteration within chondrite groups that invoke fluid flow (e.g., *Young et al.*, 1999; *Young*, 2001).

The location of the snow line in the solar nebula is uncertain, and depends on the mechanisms responsible for depositing heat in the disk. The snow line likely did not reside at a single location in the solar nebula, but rather migrated with time as the luminosity of the pre-main-sequence star, mass transport rate through the disk, and opacity of the nebula all evolved with time. In viscous disks, where mass accretion occurs throughout the disk, energy from internal dissipation can keep the inner disk warm for much of the lifetime of the disk. As mass-accretion rates diminished with time, the viscous dissipation would slow, causing the snow line to migrate inward with time. While specific details vary with the assumed disk structure and viscosity, models suggest that the snow line would be located beyond 5 AU early in disk evolution, but is likely to have been present at 2–3 AU 2–4 m.y. into the lifetime of the disk (e.g., *Ciesla and Cuzzi*, 2006; *Kennedy and Kenyon*, 2008; *Min et al.*, 2011; *Martin and Livio*, 2012), when most chondrite parent bodies accreted (see section 6). If viscous dissipation was not strong or was limited to the surface of the disk, the temperature structure of the disk would have been determined solely by radiative heating from the young Sun, which would have put the snow line at no further than 1–2 AU during the accretion of chondrite parent bodies (*Sasselov and Leclar*, 2000; *Kennedy and Kenyon*, 2008; *Martin and Livio*, 2012).

If the snow line for a 2–4-m.y.-old protoplanetary disk was at  $\sim 1\text{--}3$  AU from the Sun, then most of the hydrated asteroids could have formed in the main asteroid belt and need not have been implanted from the outer solar system, as predicted by the Grand Tack model. Based on these observations, we suggest that the majority of hydrated chondrite parent bodies sampled by meteorites (CM, CO, CV, CK, H, L, LL, R) accreted in the inner solar system, close to the main asteroid belt, consistent with the conclusion of *Alexander et al.* (2012). Therefore these chondrite groups provide no support for the predictions of the Grand Tack and Nice dynamical models that hydrated asteroids formed between and beyond the giant planets and were implanted into the main asteroid belt during migration of the giant planets. We cannot exclude the possibility that there are other types of hydrated or water-ice-bearing asteroids that were implanted into the main asteroid belt, but have not been sampled by the known meteorites (e.g., did not survive atmospheric entry).

Cosmochemical data identify CI chondrites as the best candidates for being cometary meteorites (*Gounelle et al.*, 2008). In contrast to the other chondrite groups, (1) CI chondrites provide the best match to the bulk chemical composition of the solar photosphere (*Palme et al.*, 2014); (2) high-temperature chondritic components — chondrules, which are commonly attributed to transient heating events in the inner solar system — are virtually absent in CI chondrites; (3) CI chondrites have the highest abundances of presolar grains that are resistant to aqueous alteration [e.g., SiC and graphite (*Huss and Lewis*, 1995)]; and (4) CI chondrites appear to have accreted the highest abundances of water ice.

These observations may indicate that CI precursor materials largely avoided thermal processing in the inner solar system and accreted further away from the Sun than other chondrite groups. Although CI chondrites may have accreted outside the snow line, it remains unclear whether they accreted inside Jupiter's orbit, in the outer part of the main asteroid belt, or they accreted outside Jupiter's orbit and were subsequently implanted into the main asteroid belt during migration of the giant planets. The inferred low D/H ratio of water in CI chondrites (Alexander *et al.*, 2012) provides no support for the latter scenario.

## 9. CONCLUSIONS

Most chondrite parent bodies accreted water ice together with anhydrous silicates, and subsequently experienced aqueous/hydrothermal alteration and fluid-assisted thermal metamorphism under variable conditions (e.g., temperature and W/R ratios) that resulted in the formation of a diverse suite of secondary minerals. There are significant variations in the degree of aqueous alteration within and between different chondrite groups. These observations in combination with the apparently isochemical nature of aqueous alteration and the low fluid permeability of chondrites may indicate heterogeneous accretion of water ice.

The aqueous activity in the carbonaceous chondrite parent bodies started almost contemporaneously, ~3.5–5 m.y. after CAIs, which is assumed to mark the time of formation of the solar system, consistent with  $^{26}\text{Al}$  being the major heat source of these bodies. The initial stages of aqueous alteration of ordinary chondrites appear to have predated those of carbonaceous chondrites, although the uncertainties are large.

The  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  ages of aqueous alteration, the  $^{26}\text{Al}$ - $^{26}\text{Mg}$  ages of chondrule formation, and the peak metamorphic temperatures reached by the ordinary and carbonaceous chondrite parent bodies suggest that they accreted ~2–4 m.y. after CAIs. The estimated water-ice-to-rock mass ratios in ordinary and carbonaceous chondrite parent bodies range from <0.1 to 0.6 (could be higher in CI chondrites), which is significantly lower than the solar value of 1.2. We suggest that ordinary and most carbonaceous chondrite parent bodies accreted close to the position of the snow line, possibly inside it. Because the position of the snow line in a 2–4-m.y.-old protoplanetary disk is estimated to be within 2–3 AU from the Sun, we infer that the majority of hydrated chondrite parent bodies sampled by meteorites (CI, CM, CO, CV, CK, H, L, LL, R) accreted in the inner solar system, close to the main asteroid belt. The estimated D/H ratios of water in CI, CM, CV, and CO chondrites are consistent with their accretion in the inner solar system. The estimated D/H ratio of water in CR chondrites is similar to the D/H ratio in some of the JFCs, but the accretion region of the CR parent body remains poorly constrained.

We conclude that most chondrite groups provide no evidence for the predictions of the Grand Tack and Nice dynamical models that hydrated asteroids formed between and beyond giant planets and were implanted into the main

asteroid belt during migration of these planets. We cannot, however, exclude the possibility that there are other types of hydrated or water-ice-bearing asteroids that may have been implanted into the main asteroid belt, but have not been sampled by the known meteorites (e.g., did not survive atmospheric entry). Additional studies of meteorites, asteroids, and comets are required to confirm or refute the Grand Tack model, including *in situ* measurements of hydrogen- and oxygen-isotopic compositions of water ice in the main-belt asteroids and comets, along with sample return missions to comets and asteroids.

Continued exploration of the diversity of primitive bodies in the early solar system and the processes that shaped the minerals they contained, coupled with detailed predictive models for the dynamic evolution of the main asteroid belt, will allow us to better refine our understanding of the processes that shaped the solar system we see today.

# Global-Scale Impacts

Erik Asphaug

*Arizona State University*

Gareth Collins

*Imperial College, London*

Martin Jutzi

*University of Bern*

---

Global-scale impacts modify the physical or thermal state of a substantial fraction of a target asteroid. Specific effects include accretion, family formation, reshaping, mixing and layering, shock and frictional heating, fragmentation, material compaction, dilatation, stripping of mantle and crust, and seismic degradation. Deciphering the complicated record of global-scale impacts in asteroids and meteorites will lead us to understand the original planet-forming process and its resultant populations, and their evolution in time as collisions became faster and fewer. We provide a brief overview of these ideas, and an introduction to models.

## 1. INTRODUCTION

The most important parameter governing the global extent of an impact is the mass ratio of the projectile to the target,  $\gamma = M_2/M_1$ . In the case of a cratering event this ratio is small, and there is a well-defined geometric locus. Crater scaling then becomes a powerful tool (e.g., *Housen et al.*, 1983) that allows simple analytical approaches to be applied to determine whether an impact “goes global”—for instance, whether the surface is shaken everywhere to the escape velocity, or whether the target is shattered or melted.

At the other extreme, as  $M_2 \rightarrow M_1$ , there is no impact locus, so the mechanics and dynamics are complex (*Asphaug*, 2010). Crater scaling does not apply, even though the impact physics are fundamentally the same. By definition, these similar-sized collisions (SSCs) are global events. Unlike most cratering impacts, they involve substantial downrange or even escaping motion of the projectile  $M_2$ , depending on the impact velocity  $v_{\text{imp}}$  and the impact angle  $\theta$ .

Impact velocity is the next most important parameter, because of its dynamical and thermodynamical consequences. In order for an asteroid to be eroded in a cratering impact, for example, one projectile mass of material must be ejected to  $v_{\text{ej}} > v_{\text{esc}}$ , where  $v_{\text{ej}}$  is the ejecta velocity and  $v_{\text{esc}}$  is the escape velocity described below. The ejection velocity in turn scales with  $v_{\text{imp}}$ , so that a cratering projectile has to strike at a few times  $v_{\text{esc}}$  in a competent rocky target if it is to cause net escape of material, and an order of magnitude faster to cause net mass loss from a highly porous target

(*Housen and Holsapple*, 2011). This implies a very different impact evolution depending on porosity.

Impact velocity also represents a specific collisional kinetic energy  $Q = \frac{1}{2}(M_1 v_1^2 + M_2 v_2^2)/(M_1 + M_2)$  where  $v_1 < v_2$  are the velocities of the target and projectile in the center of mass frame. If the energy is sufficiently intense,  $Q > Q_S^*$ , then shattering occurs, breaking the solid bonds of the asteroid into pieces no larger than  $M_1/2$ . If gravitationally bound (ejected at  $< v_{\text{esc}}$ ) then shattering produces a rubble pile as defined below; otherwise, if fragments are escaping, the result is a collection of new asteroids. This is the classic example of hitting something so hard that you break it. Catastrophic disruption requires a collision of greater energy  $Q > Q_D^* > Q_S^*$ , to break any solid bonds and also to overcome internal friction (see below), and to exceed the gravitational binding energy, thereby dispersing the fragments to  $v_{\text{ej}} > v_{\text{esc}}$ . For massive bodies, intermediate energy collisions  $Q_D^* > Q > Q_S^*$  can lead to complicated (altered and reassembled) geologies.

These are idealizations because impact energy is not deposited uniformly inside a target. Much of this chapter is to study how this deposition occurs, and what it does. The impact angle  $\theta$  is especially important in this regard, especially for similar colliding masses, since only a limited amount of angular momentum can be accreted in a collision, and because objects of comparable diameter tend to suffer grazing collisions more often than not. And finally, two asteroids of masses  $M_1$  and  $M_2$  cannot be thought of as colliding in isolation, even if one ignores all the other asteroids and planets: Both bodies orbit the Sun and their

fragments continue orbiting on intersecting orbits, so their interaction extends long after the original collision.

### 1.1. Mass Effects

Generally speaking, impacts slower than  $v_{\text{esc}}$  cause accretion, and impacts faster than  $v_{\text{esc}}$  cause erosion, with the specific boundary depending on the impact angle  $\theta$ . This is effectively the case for cratering impacts and for similar-sized collisions, so we consider the governing parameter  $v_{\text{imp}}/v_{\text{esc}}$ . But  $v_{\text{imp}}$  can be no slower than  $v_{\text{esc}}$ , the impact velocity of two spheres falling from infinity with initial relative velocity  $v_{\text{rel}} = 0$

$$v_{\text{esc}} = \sqrt{2G(M_1 + M_2)/(R_1 + R_2)} \quad (1)$$

where  $R_1$  and  $R_2$  are the corresponding radii. As a rule of thumb,  $v_{\text{esc}} = R_{\text{km}}/t$ , in meters per second, where  $R_{\text{km}}$  is the radius of a spherical asteroid in kilometers; this holds exactly true for bulk density  $\rho = 1.9 \text{ g cm}^{-3}$ .

For a two-body encounter in the absence of gas or other drag effects, conservation of energy implies that

$$v_{\text{imp}} = \sqrt{v_{\text{rel}}^2 + v_{\text{esc}}^2} \quad (2)$$

Concerning accretion and erosion, whether by cratering or SSC, it is consequently this relative velocity above  $v_{\text{esc}}$  that matters most

$$\phi = v_{\text{rel}}/v_{\text{esc}} \quad (3)$$

The magnitude of  $\phi$  defines the dynamical “kick” that drives material out of the gravitational potential of the target.

Dynamical studies of planet formation have tended to ignore the substantial differences between a collision (two objects’ radii intersecting) and an accretion. A collision at  $v = v_{\text{imp}}$  at a separation distance  $r < R_1 + R_2$  at contact angle  $\theta$  is a geophysically and astrophysically complicated event, so that even the slowest merger ( $v_{\text{imp}} \sim v_{\text{esc}}, \phi \sim 0$ ) is an imperfect accretion. Yet most N-body simulations to date implicitly assume that whenever two planetary bodies touch each other, they become a single object orbiting the Sun. This is generally an invalid assumption (Agnor *et al.*, 1999).

Accretion efficiency  $\xi$  is defined as the fraction of the projectile mass  $M_2$  acquired by the target  $M_1$ . Perfect accretion  $\xi = 1$  makes a final merged body  $M_F = M_1 + M_2$ , so in general

$$\xi = (M_F - M_1)/M_2 \quad (4)$$

Accretion efficiency is always a few percent less than 1, even in  $v_{\text{rel}} = 0$  collisions, because mergers release a substantial fraction of the gravitational binding energy compared to two contacting spheres. Mass is further lost by angular momentum redistribution, flung out by the spiraling, merging protoplanets. Mass loss in otherwise “perfect mergers” can lead to satellite formation (e.g., Canup, 2004) and percentage

losses of escaping remnants (Asphaug and Reufer, 2013).

In cratering collisions,  $\xi(\phi)$  is a relatively smooth function, becoming negative for  $\phi \sim 1$ , except in the case for highly porous bodies, where  $\xi$  may remain positive (accretionary) to velocities tens of  $v_{\text{esc}}$  in a process of compaction cratering (Housen and Holsapple, 2011). Similar-sized collisions ( $\gamma \geq 0.03$ ) are substantially different because of geometrical effects, and this leads to generally low accretion efficiency. For SSCs, accretion efficiency is a sensitive function of velocity  $\xi(\phi)$  that starts near  $\xi(\phi) \leq 1$ . At moderately off-axis angles (only  $\sim 15^\circ$ – $30^\circ$ ) SSCs are grazing, in the sense that most of the colliding material does not physically intersect. The colliding bodies can “bounce,” with outcomes very sensitive to  $\phi$  and  $\theta$ .

As reviewed by Asphaug (2010), there is an abrupt transition in accretion efficiency from  $\xi(0) \sim 1$ , to  $\xi \approx 0$  (little mass change to the target, but huge transformation to the impactor) over the velocity range  $1.2 \leq \phi \leq 2$ – $3$ . We call these “hit-and-run” collisions (see the chapter by Scott *et al.* in this volume). And finally, erosion and disruption ( $\xi < 0$ ) occur over the range  $\phi \geq 2$ – $3$ . The exact boundaries of these curves depend on the composition and degree of differentiation of the colliding bodies, as explored in further detail by Stewart and Leinhardt (2012).

One of the major unknowns of planet formation is the kind of collision that dominated the accretion of mass by asteroid parent bodies. If it was accretion of myriad much smaller objects (cratering,  $\gamma \rightarrow 0$ ), then effective compaction might facilitate accretion, with highly porous planetesimals acting as “sponges” to sweep up much smaller objects. Truly primitive bodies would contain a record of compaction events (e.g., Belton *et al.*, 2007). If SSCs dominated ( $\gamma \rightarrow 1$ ), then small planetesimals would be unlikely to accrete further once random velocities were excited to faster than  $v_{\text{esc}}$ . Turbulent stirring of the nebula would lead to their disruption (Benz, 2000), one of several “size barriers” to primary accretion (Weidenschilling and Cuzzi, 2006).

One possible solution is to bypass these bottlenecks during the gas phase, for example, by streaming instabilities followed by pebble accretion as described in the chapter by Johansen *et al.* in this volume. Such models indicate the rapid formation of  $\sim 100$ – $1000$ -km-diameter asteroid progenitors in the presence of the nebula. These bodies would be well sorted by mass, so that their further collisional interaction would be dominated by SSCs. Another implication is that many of these bodies (those containing chondritic abundances of active radiogenic  $^{26}\text{Al}$ ) would likely be melted by radionuclide decay during the timeframe of their collisional interaction. The surviving original bodies would include a preponderance of hit-and-run relics according to Asphaug and Reufer (2014), by the attrition of a population that is mostly accreted into growing planets.

### 1.2. Thermodynamical Effects

Impact heating is also sensitively dependent on velocity. In addition to radiogenic heating, shock and frictional heat-

ing were common throughout early solar system history, as recorded in meteorites, with shocks being particularly (but not uniquely) effective at dissipating impact kinetic energy  $Q$  into heat (Ahrens and O'Keefe, 1994; Melosh, 1989).

Shocks are produced when the impact velocity exceeds the sound speed,  $v_{\text{imp}} \geq c_s$ . Essentially, impact momentum is added to the medium faster than it can be transported away as a pressure wave, leading to a discontinuous “jump” that causes irreversible thermodynamical effects (heating, compression, momentum deposition). Because impacts are generally faster than  $v_{\text{esc}}$ , this means that planet-scale collisions always involve shocks ( $v_{\text{esc}}$  of tens of kilometers per second), whereas asteroid-scale impacts must be stirred up externally to high random velocity to produce shocks.

Random velocities in the main belt are excited by gravitational interactions with the terrestrial and giant planets, to velocities that are typically  $v_{\text{rel}} \sim 2\text{--}8 \text{ km s}^{-1}$ , exceeding  $v_{\text{esc}}$  by orders of magnitude. Although we have no direct measurements of asteroid sound speed, an upper limit is probably that of the lunar mantle,  $c_s \sim 7\text{--}8 \text{ km s}^{-1}$ . A more representative sound speed may be that measured by Flynn (2005) and others for competent fragments of chondrite meteorites,  $c_s \sim 1\text{--}3 \text{ km s}^{-1}$ . Thus a great deal of shock processing occurs on small bodies in the evolving and modern solar system. But unlike planet-scale collisions that retain their shock-melted materials, the shocked ejecta in asteroid-asteroid collisions are generally lost as interplanetary dust.

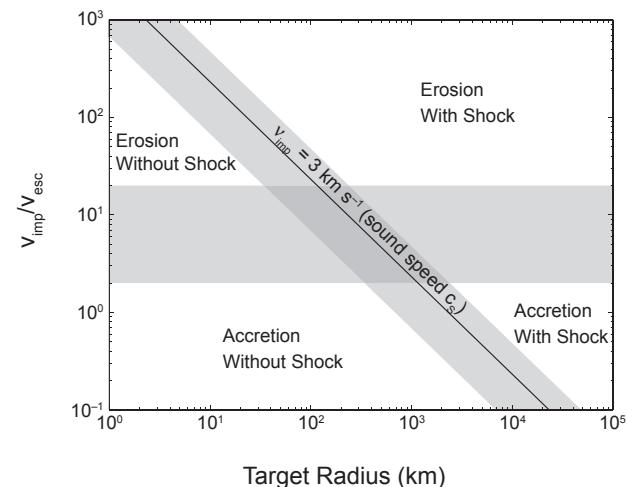

The sound speed is much slower in rubble piles and near-surface regoliths, perhaps only on the order of  $\sim 100 \text{ m s}^{-1}$ , so in this crushable zone it is possible to form melted materials that could be retained in place, or at least, be ejected at  $< v_{\text{esc}}$ . Housen and Holsapple (2011) find that crater ejection velocities in highly porous silicate material can be more than an order of magnitude slower than crater ejection velocities in competent materials. This means that in addition to being more prone to shock melting and compaction melting, the melted material may be less prone to escaping on highly porous bodies.

### 1.3. Velocity Relationships

Impact velocity relative to escape velocity,  $v_{\text{imp}}/v_{\text{esc}}$ , governs accretion efficiency and its mass effects, while impact velocity relative to sound speed,  $v_{\text{imp}}/c_s$ , governs the formation of shocks and its thermodynamical effects. Accordingly, there are four quadrants of global-scale impacts, as summarized in Fig. 1.

Shock-forming impacts are to the right of the diagonal band, represented here by a wide possible range  $0.5 \text{ km s}^{-1} < v_{\text{imp}} < 8 \text{ km s}^{-1}$ . Mass loss and catastrophic disruption ( $\xi < 0$ ) occur above the horizontal band, broadly the range  $v_{\text{imp}} \geq 2$  to  $20 v_{\text{esc}}$  (competent or highly porous target; cratering or SSC). Asteroid family formation, reviewed in the chapter by Michel et al. in this volume, occupies the upper right quadrant, while parent-body accretion occupies the lower left.

The transitions across quadrants (gray shaded zones) are just as important as the end-member scenarios, perhaps

**Fig. 1.** Global-scale impacts span four quadrants in a graph of impact velocity normalized to target escape velocity,  $v_{\text{imp}}/v_{\text{esc}}$ , vs. target radius. The horizontal band marks the approximate transition from accretionary to erosive/disruptive impacts, a few times  $v_{\text{esc}}$ . The diagonal band defines impact speeds comparable to the sound speeds for a wide range of solar-system materials. Planetesimal-scale accretion (bottom left) does not involve shocks, while planet-scale accretion (bottom right) does. On small bodies, mass loss and disruption do not require shocks. Large  $v_{\text{imp}}/v_{\text{esc}}$  requires gravitational stirring by larger bodies, so that events to the right of the graph tend to be damped (no larger bodies; gravitational drag by smaller bodies), while events to the left tend to be excited, e.g., the modern main belt.

more so. Consider the horizontal band: Most collisions will have  $v_{\text{imp}}$  equal to a few times  $v_{\text{esc}}$  in a self-stirred population, because the random velocities grow to be proportional to the escape velocities of the largest members (e.g., Safronov, 1972).

As for the sound speed transition, it appears to be coincidence that the range of  $c_s$  for asteroid materials overlaps the expected collisional velocities. Random velocities are slower in the outer solar system,  $\sim 1\text{--}2 \text{ km s}^{-1}$ , but so is the sound speed of icy bodies. So in both regions, collisions are expected to occur on either side of the “shock zone,” at least in the present solar system.

During parent-body accretion, most events were at or near this line (low velocities) and toward the left (small sizes). As planets grew and stirred things up, events stayed near the line at large sizes, but rose to high above the line for small sizes, grinding down that population into today's generation of asteroids.

In the first 10–100 m.y. after dissipation of the dust and gas in the solar nebula, when collision probabilities were substantially higher than they are today, the average collision speed in the asteroid belt grew from  $< 1 \text{ km s}^{-1}$  to several kilometers per second. Hence, impacts straddled the shock transition zone when impacts were most influential in defining asteroid parent-body geology.

#### 1.4. Overlapping Timescales and Linked Models

Global-scale impacts involve a diverse range of overlapping processes and timescales, making it important to understand and utilize linked models. Because asteroidal targets vary from tens of meters to hundreds of kilometers in diameter, global-scale impacts can take place in less than a second, on the ballistic timescale

$$\tau_b \sim 2r/v_{imp} \quad (5)$$

where  $r$  is the radius of the projectile and  $v_{imp}$  is the impact velocity; or in seconds to minutes, on the stress propagation timescale

$$\tau_s \sim 2R/c \quad (6)$$

where  $2R$  is the target diameter and  $c$  is the sound speed (or shock speed); or in hours to days, on the gravity timescale

$$\tau_g \sim \sqrt{3\pi/G\rho} \quad (7)$$

where  $G$  is the gravitational constant and  $\rho$  is the asteroid bulk density.

In the end-member regimes (e.g., self-gravitating planets without strength, or monolithic rocks without gravity) key variables can be eliminated and simple models or scaling predictions can be viable. Similarly, if one can bypass a complex phase or timescale of a collision using an effective approximation, then a simpler analysis can be available — for instance, skipping the self-gravity phase by applying an escape-energy approximation, or replacing the hypervelocity impact calculation with a “z-model” velocity field derived from impact-cratering experiments (cf. Melosh, 1989). It is an open question whether these and other simplifications are well justified for modeling global-scale asteroid impacts, when the balance of force is so subtle.

Another approach is to use end-to-end linked numerical models. For asteroids up to tens of kilometers in diameter,  $\tau_b$ ,  $\tau_s$ ,  $\tau_g$  are distinct, making it possible to consider three separable regimes of impact, using one calculation as input for the next. This of course makes the assumption that not a lot of physics happen in the intermediate regimes, which as we shall see is not always the case.

Consider the example of forming an ~10-km crater on an ~20-km-diameter asteroid [e.g., Stickney on the martian satellite Phobos, or Shoemaker on asteroid (433) Eros]. Here  $\tau_b \sim 10^{-2}$  s,  $\tau_s$  is seconds, and  $\tau_g$  is hours. An impact hydrocode (Anderson, 1987) is a versatile simulation tool (see below and the chapter by Jutzi et al. in this volume) that can be run for several  $\tau_b$  to compute the shock pressures, energies, and temperatures and the initial momentum distribution emplaced by the projectile. The accuracy of this step is limited by our understanding of asteroid target geology, which in even the best codes is represented simplistically (equations of state and crush models). For example, rate-dependent effects are not typically included in hydrocodes.

After the impact-coupling phase is complete, shock pressures and stress states can be evolved using a wave propagation code (e.g., Richardson et al., 2004; Blitz et al., 2009), or using the hydrocode itself within the limitations and caveats discussed below. Hydrocodes are not generally designed for seismic-wave propagation, although as discussed further below, the most modern codes are beginning to do a good job on the equation of state (EOS) aspects of the problem, and the fracture mechanics parts of the problem, and also the granular physics, which is intimately connected to the acoustics and flow of disrupted material. Simpler approaches are also feasible, and sometimes recommended, especially those that are anchored in laboratory and field data. A power law of stress attenuation with distance (Cooper and Sauer, 1977) can be applied (e.g., Ryan and Melosh, 1998; Asphaug, 2008), as well as direct comparison with nuclear explosions (Asphaug and Melosh, 1993).

If  $\tau_g$  is orders of magnitude longer than the other timescales, then the earlier phases of a collision, establishing the pressure evolution, can be calculated with no gravity at all, or with gravity expressed as an overburden term and constant gravity. The largest-scale events conclude with a gravitational and rotational-mechanical evolution over several  $\tau_g$ , as modeled by Michel et al. (2003), Durda et al. (2004), Leinhardt and Stewart (2012), and others; see the chapter by Michel et al. in this volume.

While gravity can be ignored below some small size, it is not clear what size this is — gravity being a long-range force and strength, friction, and cohesion being short-range forces. The escape velocity of a 100-m-diameter rubble pile is a few centimeters per second, so massive debris evolution on a small asteroid can perhaps be astrophysically similar to much-larger-scale events.

On the other hand, the central pressure inside a 100-m asteroid is only ~1 Pa (10 dyn cm<sup>-2</sup>), and while not zero, it is 100× smaller than the cohesions measured for the upper lunar regolith. That is, granular cohesion may well dominate over gravity, inside of asteroids up to kilometers in diameter, as discussed further in the chapter by Scheeres et al. in this volume.

To make matters worse, granular materials can be cohesive in the absence of internal vibrations, and fluidized by the acoustic energy of a global-scale collision, respond like a mobilized global landslide (e.g., Collins and Melosh, 2003). Anyone who has played with sand is familiar with the solid liquid behavior of granular media. Models are just barely catching up to our awareness of the complex physics that can be at play in a global-scale asteroid collision.

#### 1.5. Small Giant Impacts

For large planetary collisions a separation of timescales is generally not possible. In the Moon-forming giant impact,  $\tau_b$ ,  $\tau_s$ ,  $\tau_g$  are all ~10<sup>3</sup> s, so all processes must be calculated simultaneously. Fortunately, giant-impact computations are greatly simplified by two facts: Planets can be treated as idealized fluids on these timescales, and the computational

timestep  $dt$  can be long, requiring fewer hydrocode iterations, as described in section 2.

For numerical accuracy,  $dt$  must be substantially shorter than the wave-crossing-timescale  $dx/c_s$ , where  $dx$  is the spatial resolution and  $c_s$  is the sound speed; or in the case of shock-forming impacts,  $dx/v_{imp}$ . Otherwise, information travels faster than the physical propagation velocity in a computation. In medium-resolution simulations of the Moon-forming giant impact  $dt \geq 10$  s, which is large enough that an all-in-one three-dimensional hydrocode approach is feasible for the phases leading to the capture of protolunar materials.

Although we do not consider giant impacts in this chapter, we do consider what might be called “small giant impacts,” i.e., planetesimal-scale SSCs at speeds proportional to the bodies’ mutual escape velocity. Like giant impacts, these straddle the erosion-accretion transition in Fig. 1. This is thought to be the regime where the parent bodies of asteroids were accreted (see the chapter by Johansen et al. in this volume). Modeling small giant impacts is most challenging computationally, because of the short timestep combined with complex physics. Consider a three-dimensional impact simulation of 10-km planetesimals colliding;  $dt < 0.1$  s so that it requires  $\geq 100\times$  more computational effort than a comparable Moon-forming calculation. For well-subsonic collisions the timestep can be sped up by artificially softening the EOS, thus reducing the sound speed (cf. Asphaug et al., 2011) while not greatly changing the response so long as the collision remains subsonic.

Although similar in scale to giant impacts, there is usually no shock when the colliding bodies are smaller than about 1000 km in diameter (Asphaug and Reufer, 2014). This makes the physics quite different, although there is still substantial heating, shear alteration, and melting, all ultimately compensating for the loss of gravitational binding energy. The slowest possible collisions between  $\sim 100$ -km planetesimals occur at  $\sim 100$  m s $^{-1}$ , like two high-speed trains colliding, so friction and compaction do a great amount of work. It is a cutting-edge problem in computational modeling, one that cannot easily be remedied using linked models on separate timescales, and therefore is in need of experimental work on representative bodies.

## 1.6. Rubble Piles

The consequences of accretionary collisions may thus dominate the geologic records of the largest asteroids and primary planetesimals. In small asteroids, on the other hand, this record has probably been beaten down. Because their relative collisional energies are more disruptive, compared to their binding energies (larger  $Q$ , stirred up by planets), they are second generational or further, as represented by asteroid family formation (see the chapter by Michel et al. in this volume).

Today most asteroid mutual collisions are erosive or disruptive,  $v_{rel} \gg v_{esc}$ . Impacts produce craters, sometimes with hemispheric morphologies (megacraters). If cratering “goes global,” as discussed below, the result is global-scale resur-

facing of the asteroid, by ejecta deposition and by shaking down of preexisting topography. And of course, impacts contribute great energy from heating, melting, fragmentation, and other forms of material transformation.

Strength is partly a material property, and partly a property of the scale and the dynamics of the collision (Holsapple, 2009). Size- and rate-dependent dynamic strength effects (Grady and Kipp, 1980; Melosh et al., 1992; Housen and Holsapple, 1999) make large bodies much easier to destroy, mechanically, than smaller ones. However, gravitationally large objects are harder to destroy. This means that it is much easier to create a rubble pile, breaking rocks to pieces, than to destroy it, sending half of its mass onto escaping trajectories (reviewed in Davis et al., 2002). In the 1990s it was demonstrated in computer simulations (e.g., Benz and Asphaug, 1999) that asteroids larger than a few hundred meters in diameter are likely to be pulverized completely, several times over, before they are likely to be destroyed. But as noted by Davison et al. (2013), this does not mean that a given subcatastrophic event is inevitable — just that comminution is much more likely than disruption,  $Q_S^* \ll Q_D^*$ .

According to this analysis, asteroids larger than a few hundred meters in a collisionally evolved population become rubble piles. How rapidly or completely they do so is an open question. It does not mean that asteroids larger than 100 m can be treated as liquid bodies in simulations, or that smaller asteroids are necessarily hard rocks (Holsapple, 2009). Indeed, it has become obvious in recent years that there is a broad transition regime, rather than a transition size, that spans perhaps  $\sim 0.1$ –100 km diameter, where mechanical, gravitational, and impact momentum stresses need to be calculated simultaneously altogether. This includes all but the very smallest asteroids.

## 1.7. Giant Craters

Giant craters are principal probes of interior geology. They excavate deep inside the asteroid and produce reverberating stresses that cause global surface modification, massive faulting, and overturn. Asteroids with giant craters (most of the  $\sim 10$ -km ones evidently) must be “strong” in some sense, in order to survive the megacratering events themselves. On (253) Mathilde, several hemisphere-sized simple craters were excavated [or crushed (Housen and Holsapple, 1999)] without destroying the preexisting craters, not even their steep walls and rim structures (so far as we can tell at flyby resolution; Fig. 2). For an unconsolidated material one might expect sustained reverberations that would trigger an asteroid to relax into a spheroid, but Mathilde did not; this large asteroid retained some of the most spectacular topography in the solar system.

To sustain this kind of dramatic topography, one might expect that a solid target structure is required. But this presents a paradox: Breaking holes this large into a competent asteroid will catastrophically disrupt the asteroid, according to strength-scaling rules and hydrocode models with strength (Melosh et al., 1992). So we get backed into a corner, in that

**Fig. 2.** NASA's NEAR Shoemaker mission obtained flyby images of the 50-km-diameter asteroid (253) Mathilde (Veverka *et al.*, 2000). The image at left was obtained as the spacecraft approached in the direction of the Sun; the image on the right is from greater distance at much lower phase angle (43°). Mathilde is a great puzzle for the study of global-scale impacts: Each giant crater should have reset the asteroid's global shape, according to simulations. Instead, each crater seems to have formed in isolation, without degrading the preexisting craters. If coming in at random angles, these successive global scale impacts would have spun Mathilde into fast rotation, if even a fraction of the incoming momentum was accreted (Asphaug *et al.*, 2002). But the asteroid is one of the slowest-rotating bodies in the solar system,  $P_{\text{rot}} = 418$  h.

these large craters cannot have formed in the strength regime. This does not automatically mean they are gravity-regime craters, as we shall see.

Of known asteroid craters, only Rheasilvia and Veneneia, the two largest on (4) Vesta (Schenk *et al.*, 2012; see also the chapter by Russell *et al.* in this volume) show clear evidence for gravitational rebound and central peak formation. These two giant basins overlap in Vesta's southern hemisphere, the ~500-km-diameter Rheasilvia basin overprinting the earlier ~400-km Veneneia, offset by some 40°, on an asteroid only somewhat larger (~530 km average diameter). Like Mathilde, Vesta provides an example of the interaction of younger and older giant craters overlapping, but in this case their interaction is notable. Unlike Mathilde, it is easy to recognize the sequence of events, in part because of the much more detailed global imaging, but also due to the fundamentally different cratering mechanics on a body 10× larger.

A number of past (Asphaug, 1997) and recent (Jutzi and Asphaug, 2011; Ivanov and Melosh, 2013; Bowling *et al.*, 2013; Stickle *et al.*, 2015) numerical impact modeling studies of Vesta have investigated the formation of its megacraters and their resulting global effects, and the potential for producing ejecta [the V-type asteroids (Binzel and Xu, 1993)]. Modeling two overlapping megacraters is challenging, and scientifically interesting, because of Vesta's nonspherical shape and gravity potential, rapid rotation, and differentiated structure. In addition, a three-dimensional approach is required, since the problem is strongly non-axisymmetric.

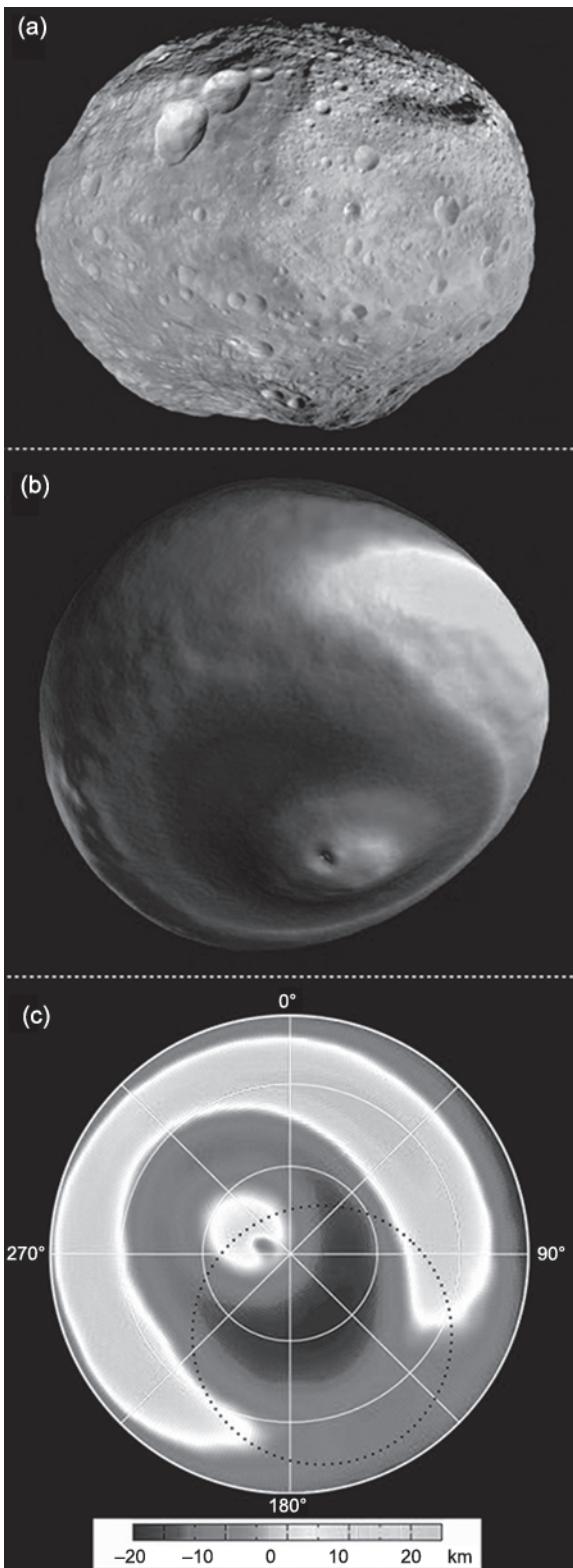

Jutzi *et al.* (2013) studied the sequential formation of Veneneia followed by Rheasilvia using a three-dimensional smooth particle hydrodynamics (SPH) impact code described below. The goal of these simulations was to start with a non-rotating differentiated  $d = 550$ -km sphere, impact it once (to form Veneneia), then place the resulting megacrater on axis, spin it to period  $P_{\text{vesta}} \sim 5.3$  h, and finally impact the rotating cratered body 40° off-axis to end up with the observed topography of Vesta. Thus Vesta's topography is created by a complex process of ejection and deposition, requiring a realistic treatment of the ejecta gravitational dynamics and the post-impact rheological response. A pressure-dependent strength model, a tensile fracture model, a friction model, and self-gravity were included. Finally, to "freeze in" the central peak structures, a block-model approximation of acoustic fluidization was used. The result (Fig. 3) is in good agreement with the shape and topography of Vesta (see the chapter by Russell *et al.* in this volume).

Understanding the formation of Vesta's giant craters and the provenance and specific distribution of ejecta is key to understanding the observed properties of Vesta, such as the topography and the surface mineralogy. The proper interpretation of surface materials [and exhumed V-type asteroids and howard-eucrite-diogenite (HED)-type meteorites] lead to important constraints on models of internal structure (McSween *et al.*, 2013; Clenet *et al.*, 2014). Jutzi *et al.* (2013) found that a significant fraction of the rocks exposed in the south pole region should come from >50 km deep, and up to ~60–100 km deep in the central mound of Rheasilvia and in the region where the two basins overlap. Also, according to the model, a significant fraction of the material that escapes Vesta during the more recent impact, which would be the dominant source for HEDs, comes from greater than 40 km deep (Clenet *et al.*, 2014). This is puzzling because olivine-rich mantle rock has not been detected in the Veneneia/Rheasilvia region on Vesta, and there is also a lack of mantle samples among the HED meteorites.

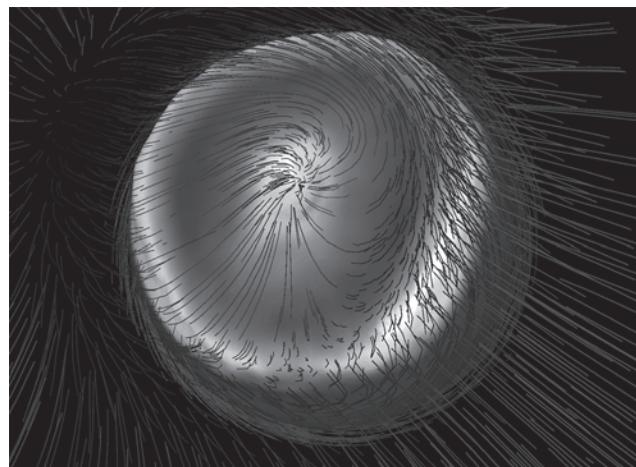

The rapid rotation of Vesta and other asteroids can lead to curious megacratering results. In the course of reproducing Rheasilvia on an already-spinning Vesta, Jutzi and Asphaug (2011) found that ejecta from megacraters would be draped back on the asteroid in complex overlapping lobes, falling back in the rotating frame. Since for Vesta the crater rebound timescale is comparable to the rotation timescale, the Rossby number of the flow  $R_o \sim 1$ , and the result is actually "Coriolis topography" as shown in Fig. 4 — i.e., crater-rebound morphologies that form a spiral pattern relative to the impact locus. This provides a potential window to further explore megacratering mechanics, especially in materials not covered beneath impact melt (Schenk *et al.*, 2012).

### 1.8. Seismic Erasure

There is a strong correlation between the normalized diameter of the largest undegraded crater  $D_{\max}$  seen on an asteroid, and the diameter  $D$  of the asteroid.  $D_{\max}$  is well defined for most imaged asteroids, and for a number of

**Fig. 3.** (a) Asteroid Vesta as seen by Dawn. Credit: NASA/JPL/UCLA/MPS/DLR/IDA. (b) Final result of the simulation of two large impacts in the southern hemisphere. (c) Lambert azimuthal projection (equal area) of the southern hemisphere in the model. Shading indicates the elevation (in km) with respect to a reference ellipsoid; for color see Jutzi et al. (2013).

**Fig. 4.** Simulating the opening and collapse of the Rheasilvia complex crater on asteroid Vesta; from Jutzi et al. (2013). The rapid rotation of the asteroid leads to strong Coriolis forces in the rebounding ejecta, as indicated by the vectors and in agreement with the patterns on the crater floor. Outward vectors plot the distant and escaping ejecta.

the best-resolved radar-imaged asteroids (see the chapter by Benner et al. in this volume). Define  $\chi = D_{\max}/D$ . The smallest asteroid seen up close in high detail, Itokawa (mean diameter  $D = 330$  m) has a largest crater  $D_{\max} \sim 30$  m, i.e.,  $\chi \sim 0.1$ . The crater is not obvious to see. For (253) Mathilde ( $D \sim 53$  km),  $\chi \sim 0.6$  — and is reasonably well determined even from medium-resolution images. For (433) Eros ( $D \sim 20$  km),  $\chi \sim 0.4$ . The trend of  $\chi$  varying inversely with  $D$  appears to generally hold (Asphaug, 2008). Either global-spanning craters do not form on small asteroids, or they are unable to retain them.

Shoemaker Crater on Eros shows a different kind of evidence (and so perhaps would Mathilde if imaged at good resolution). The formation of this 7-km recent basin appears to have shaken down regional preexisting ~100-m-scale topography, both next to and opposite the crater (Thomas and Robinson, 2005). The seismic erasure may have been impulsive (as seems to be the evidence), taking seconds to minutes as the initial pulse radiated from the impact, or else diffusive, as acoustic energy remained trapped inside the asteroid for many  $\tau_s$ .

If seismic erasure is efficient, then why has wholesale seismic degradation not shaken down the early giant craters of Mathilde? One approach (Asphaug, 2008) is to define a self-consistent critical crater diameter  $D_{\text{crit}}$  for which the above is true, and to show that  $D_{\text{crit}}$  increases with asteroid diameter  $D$ . Craters larger than  $D_{\text{crit}}$  shake down all preexisting topography smaller than  $D_{\text{crit}}$ . The giant crater that is forming continues its excavation long after the seismic impulse attenuates, at least in this scenario, because the crater-formation timescale in the gravity regime is many times  $\tau_s$ . A crater forms as a solitary feature if it has shaken down preexisting craters of its size. Craters smaller than  $D_{\text{crit}}$

do not cause global resurfacing at their own scale. Craters larger than  $D_{\text{crit}}$  stand out as solitary undegraded craters. In this framework one can interpret that  $D_{\text{crit}}$  has never been achieved on Mathilde (there is no one solitary crater), and that  $D_{\text{crit}}$  would require something larger than Shoemaker Crater to globally erase the craters of that scale on Eros.

A normalized critical crater diameter  $\chi_{\text{crit}} = D_{\text{crit}}/D$  can be solved as a function of asteroid diameter and target properties [gravity, density, and scaling constants (cf. *Housen et al.*, 1983)]. Assume that the seismic impulse created by an impacting projectile decays in amplitude with distance  $r$  from the impact. This impulse is required to shake down topography to a scale equal to the diameter of the crater that is forming,  $D_{\text{crit}}$ , out to a maximum distance  $r = D$ . If seismic decay with distance takes the form of a simple power law (e.g., *Cooper and Sauer*, 1977), then particle velocity  $v_p \propto r^{-\beta}$ . Crater diameter  $D_{\text{crit}}$  is then calculated (*Asphaug*, 2008) according to gravity-regime crater scaling, and is substituted into the above, thus solving for  $\chi_{\text{crit}}$ .

For physically reasonable target parameters,  $\chi_{\text{crit}}$  is proportional to  $D$ , accounting for the trend in crater sizes. On a case by case basis, matching the largest undegraded craters observed on spacecraft or radar-imaged asteroids to their theoretical maximum does a good job at fitting the data if one assumes a seismic attenuation with distance  $\beta \sim 1.2\text{--}1.3$  for most asteroids. While a power-law attenuation is only an approximation to seismic dissipation, this value is comparable to seismic attenuations of  $\sim 0.1\text{--}10\text{-m s}^{-1}$  particle velocities in unconsolidated terrestrial materials.

For Mathilde-sized asteroids, the predicted  $D_{\text{crit}}$  is larger than the asteroid, consistent with the handful of non-interacting craters greater than half the asteroid diameter. For (25143) Itokawa, assuming the same seismic attenuation as Mathilde, it turns out that  $\chi_{\text{crit}} = 0.1$  — the small crater seen on Itokawa would have resurfaced the asteroid down to that scale. It is an inexpensive if approximate kind of seismology: An Itokawa-sized asteroid exhibiting larger craters would have substantially greater seismic attenuation. The different behavior is in this case not because of material differences, but because of the differences in scale: Itokawa next to Mathilde would be analogous to a refrigerator next to the Empire State Building.

## 2. NUMERICAL MODELING OF GLOBAL IMPACTS

When extrapolations lead to curious results, one turns to direct experimentation; when that is unavailable, one resorts to the brute force of computer simulations. These techniques are featured in the chapter by Jutzi et al. in this volume, and their application to global-scale impacts is summarized here. These techniques include hydrocodes (reviewed in *Anderson et al.*, 1987), particle codes (e.g., *Richardson et al.*, 2002), and linked models. These codes rely on models, implemented as part of a time-stepped evolution, describing the material behavior — such as friction, compaction, viscoelastic properties, and EOS.

Hydrocodes integrate the hydrodynamic equations describing the conservation of mass, momentum, and energy. They relate intrinsic scalar variables — the density  $\rho$ , internal energy  $U$ , and pressure  $P$ , at position  $x, y, z$  — to the velocity field  $v_x, v_y, v_z$  as determined by accelerations (forces). They integrate a time-evolving solution to a set of partial differential equations. If deviatoric stresses are considered, then body forces are evolved according to the stress tensor, introducing six additional variables in three dimensions; in practice a simplified approach is often made.

The resulting partial differential equations are integrated forward in time (*Benz*, 1990; *Collins et al.*, 2013) according to accuracy requirements on the spatial resolution and the timestep  $dt$ . Time-evolution is cast in either a Lagrangian reference frame, which follows the material, or in an Eulerian frame that is fixed in space, advecting material properties (density, momentum, energy, composition) through a grid. These have advantages and disadvantages; for more detailed background and benchmark comparison see *Pierazzo et al.* (2008).

### 2.1. Smooth Particle Hydrodynamics

In smooth particle hydrodynamics (SPH) the continuous fluid is represented as a Lagrangian set of particles (*Benz*, 1990; *Monaghan*, 2012) that move with the flow. The properties at particle  $i$  are averaged over its  $\sim 50$  nearest neighbors, weighted according to their distance from particle  $i$  relative to the smoothing length  $h$ . So  $h$  is the grid resolution. Particle density, for example, is the weighted contribution of mass over its neighbors (hence “smoothed”). The mass and momentum conservation equations are approximated to second order as kernel sums. The most commonly used SPH code in asteroid research is by *Benz and Asphaug* (1994, 1995); this includes elastic strength and fracture damage in addition to the hydro-equations. This code has been modified by *Jutzi et al.* (2008, 2013) to include friction and compaction.

The SPH method is mostly applied in three dimensions, requiring million-particle calculations to resolve colliding bodies  $\sim 100$  particles across. A fast parallel cluster is needed for production investigations. Nonetheless, SPH is popular because it is relatively simple and numerically robust. It is straightforward to add new physics, and the purely Lagrangian description (all variables co-located at particle centers, co-moving with the fluid) makes it easy to hand off to other codes, visualizations, and analytical reductions. Unlike the grid-based codes described below, the problem domain is completely described by the particles themselves, so there is no need to grid up empty space into which the problem can evolve.

### 2.2. Grid-Based Codes

For computation of shocks, and for resolving boundary conditions and abrupt material contrasts, a grid-based calculation generally has greater fidelity than a particle mesh. However, in grid-based Lagrangian hydrocodes mesh entanglement can result. Eulerian hydrocodes avoid mesh

entanglement by maintaining a fixed grid, optimized for the problem. Each timestep advects density, internal energy, momentum, and material type from cell to cell, according to the velocity and pressure differential. Material histories and interface positions are recorded using “tracer particles” whose position moves with the mass flux from cell to cell.

Advection of material type is problematic. Imagine iron flowing into a pure olivine cell, whose composition has just become 1% iron. What EOS do we use in the next timestep? It is not trivial; e.g., what if one material is vapor at the computed pressure and temperature, and the other is liquid? There are many approaches to handling mixed materials in a cell. As for the mass flux from a mixed cell, do we assume 1% iron applies instantaneously everywhere in the cell (faster than any physical velocity), or do we concentrate iron near the donor cell, holding it “upstream” according to some criterion? Eulerian codes usually require techniques for limiting this artificial diffusion.

Grid-based codes have one overwhelming advantage compared to SPH: They allow accurate calculations in two-dimensional (axisymmetric or planar) or one-dimensional (planar or spherical) symmetrical geometries. High-definition two-dimensional computations, for instance, where a spherical asteroid is impacted on axis, can be done on a modest workstation, enabling careful research exploring many kinds of hypotheses. Parameter exploration in three dimensions is much more limited.

One popular grid-based code for asteroid collisional modeling is iSALE (Collins et al., 2004; Wünnemann et al., 2006), the successor to SALE (Amsden et al., 1980; Melosh et al., 1992; Ivanov et al., 1997). This code is maintained in a community forum, and includes both two-dimensional and three-dimensional versions and associated analytical and visualization tools, as well as several of the most relevant EOS models. Another popular code is CTH (McGlaun et al., 1990; Crawford et al., 2006), although like other sophisticated defense-related packages, its foreign access restriction can limit its utility in academic collaborations.

Which hydrocode to use depends on the problem. An intrinsically axisymmetric problem, such as impact cratering within about 45° of vertical, can be prototyped in a two-dimensional code before serious computer effort is expended looking at the three-dimensional details. If projectile-target contact and compression are of greatest interest, then a two-dimensional or even one-dimensional planar calculation will allow for the highest resolution. If the downrange momentum of massive ejecta is of key interest, then an axisymmetric model at any resolution is almost useless.

To study the long-term self-gravitational interaction following megacratering or disruption, the hydrocode simulation can be handed off to a particle method such as we now describe.

### 2.3. Discrete-Element Models

At low velocity, impacts can be modeled approximately according to Newton’s laws using discrete-element methods

(DEMs). These do not model shocks or stress waves, but represent collisions by piles of immutable, self-gravitating, idealized solids with contact and restitutive forces [e.g., PKDGRAV (Stadel, 2001; Richardson et al., 2002)]. Soft-sphere codes (Sanchez and Sheeres, 2011; see the chapter by Murdoch et al. in this volume) further represent contact forces according to a viscoelastic “dashpot” model (not to be confused with SPH).

Resolution in a DEM does not mean the same thing as it does in a hydrocode. In a hydrocode, the finer the resolution, the more accurate the solution. In a DEM there is a correct resolution for the problem, because every element represents a discrete body. Infinitesimal particle size in a DEM results in infinite strength, and for physical reasons: Fine powders are strongly cohesive due to their high specific contact area. In practice, however, DEMs struggle to resolve the physical scale; a 10<sup>6</sup> element simulation of Itokawa would have a finest block size of several meters. While sufficient to mimic the granular nature of a rubble pile, the contact area per unit volume is a billion times less than if we had a finest block size of centimeters, meaning that we must represent the surface physics parametrically.

Polyhedral rubble-pile codes (Korycansky and Asphaug, 2006; Movshovitz et al., 2012) are more challenging to implement than sphere-based DEMs due to the complexity of contact detection and the variety of contacts (face, vertex, edge), and they have even worse resolution. But the physical insights are important. Polyhedral DEMs exhibit substantially different behavior than sphere-based DEMs because of the dilatancy and grain-locking effects that are only partially captured by sphere-based approaches. For example, Korycansky and Asphaug (2009) find a systematically higher value of  $Q_D^*$  in planetesimal collisions at tens of meters per second, compared with results derived using sphere-based DEMs (Leinhardt and Stewart, 2009).

For collisions faster than ~10 m s<sup>-1</sup>, DEMs are not appropriate without special handling, because they do not account for realistic mechanical behavior and thermodynamic effects. Comparable to a train wreck, or the collapse of a skyscraper, large planetesimal collisions are transformative events involving fragmentation, crushing, shear friction, and shocks — they are not piles of bouncing marbles.

Although the science is still in its early stages, a linked model (e.g., Michel et al., 2003; Leinhardt and Stewart, 2012) has proven versatile, where SPH (or another hydrocode) evolves the high-velocity collision for a few  $\tau_s$ , which is handed off as particle positions and velocities to a DEM. But even if the handoff is perfectly achieved, we caution, as shown below, that the result may depend on unknown aspects of asteroid dynamical rheology.

### 2.4. Strength and Damage

Strength describes a material’s response to volume-conserving deformation and to tensile pressure. Volumetric compaction is included in the EOS and the porosity model, described below. The strength model can be simple,

requiring no material history, or can be a complicated evolution of strain, strain rate, temperature, and pressure.

Asteroid strength modeling used to be based around concepts of brittle fragmentation and fracture damage. While these approaches are still valuable, asteroid strength modeling now revolves more around concepts of cohesion, friction, and compaction — the subtle strengths of granular rubble piles and regoliths, in microgravity.

A small strength or cohesion can exert a major influence on the asteroid impact process, especially during the final stages, which govern how the feature will appear geologically in spacecraft images. Cohesion as small as that of fresh dry snow can dominate global-scale events on ~100-m asteroids, making the difference between a cratering event “going global” or remaining local.

A shear-strength model dependent on confining pressure  $P$  is employed in iSALE (Collins *et al.*, 2004) and in SPH (Jutzi *et al.*, 2013; Jutzi, 2015). In this simple approach the shear stress is limited by a yield stress, which increases with  $P$  due to grain interlocking and friction

$$Y_i = Y_0 + \frac{\mu_i P}{1 + \mu_i P / (Y_M - Y_0)} \quad (8)$$

where  $Y_0$  is the shear strength at  $P = 0$  (measured in the lab),  $Y_M$  is the asymptotic shear strength at infinite pressure (the Hugoniot elastic limit), and  $\mu_i$  is the coefficient of internal friction.

In elastic solid materials, a damage  $D$  can be accumulated either as a tensor  $D_{ij}$  or a scalar (isotropic damage). Damage reduces the deviatoric stress, leaving behind (when  $D = 1$ ) only the granular cohesive properties. To account for thermal softening,  $Y$  may be further reduced by a factor  $1 - U/U_{melt}$  where  $U_{melt}$  is the specific melting energy, so that a molten material has zero strength.

An approach used in iSALE is to accumulate shear damage as a nonlinear function of the equivalent plastic strain (Collins *et al.*, 2004). There is no rate dependence to this function; rate-dependent fragmentation requires a dynamic fracture model (Melosh *et al.*, 1992; Benz and Asphaug, 1994, 1995).

Completely damaged material has some cohesion; lunar regolith has  $Y_0 \sim 10^3$  Pa. Cohesion of only tens of pascals can dominate the structural geology of small asteroids (Asphaug, 2009; Holsapple, 2009; Sanchez and Scheeres, 2011). This cohesion can be further weakened by granular dynamical processes, as discussed in the chapter by Jutzi *et al.* in this volume.

Acoustic fluidization has been simulated using a block model (Melosh and Ivanov, 1999) to freeze in the central peaks of the largest craters on Vesta (Jutzi *et al.*, 2013). Although it has not yet been implemented so far for small asteroid collisions, the attenuation of random motions responsible for fluidization might lock in global-scale shapes and structures of rubble-pile asteroids.

## 2.5. Size and Rate Dependence

The number of flaws  $n$  per unit volume  $V$  in a solid is often described as a power law

$$n(\varepsilon) = k\varepsilon^m \quad (9)$$

In this equation a few flaws  $n$  will become active in  $V$  for a given volumetric strain  $\varepsilon$ . There will be one single weakest flaw,  $\varepsilon_{min} = kV^{-1/m}$ , so that an asteroid’s strength decreases with size, as the power  $R^{-1/2}$  (Farinella *et al.*, 1982) for  $m \sim 6$  (a typical value). This is the static threshold, but dynamic strength increases with strain rate in a closely related manner. The overall effect is a negative slope when plotting  $Q_S^*$  vs.  $R$ , where  $R$  is asteroid radius — larger asteroids are weaker.

On the other hand, larger asteroids are harder to disrupt, because the gravitational binding energy per unit volume (equivalently, the internal hydrostatic pressure  $\sim G\rho^2R^2$ ) is proportional to the escape velocity squared. Setting gravitational binding energy equal to the rock strength  $Y$  gives a transition diameter above which it is more likely for an asteroid to be beaten into rubble many times over, than to be dispersed.

One of the remarkable discoveries of the previous decade was that the strength-gravity transition would occur around 100–300-m-diameter asteroids. This result was predicted in simple analyses and is confirmed in advanced numerical models, but the implications are still the subject of considerable debate, as reviewed in the chapter by Michel *et al.* in this volume.

## 2.6. Equations of State

The hydro-equations are closed using an EOS relating energy, density, and pressure. For impact modeling, the EOS defines the material response to changes in volume, often in collaboration with a porosity model. The EOS is called by the hydrodynamics integrator (sometimes iteratively) as  $P(\rho, U)$  to obtain the “righthand side” terms that drive evolution of the momentum equation.

One popular model is ANEOS (Thompson and Lauson, 1972; Melosh, 2007), whose thermodynamics variables are derived from the Helmholtz free energy. As a result, all data in an ANEOS table are thermodynamically consistent, something that is especially important in the detailed modeling of shocks. ANEOS returns temperature, pressure, and state of the material, mapping polymorphic and liquid/solid-phase transitions, specific heats, and vapor/liquid fraction. But thermodynamical consistency is not the same as accuracy, and Kraus *et al.* (2012) find that the shock vaporization energy of silicate rocks may be a factor of 2–3 lower than reported by ANEOS, of fundamental importance to the study of high-velocity events and giant impacts.

Another popular EOS model is that of Tillotson (1962), effectively a stitched-together polytrope defining a cold condensed state and a hot expanded state. With only five parameters Tillotson is easily modified to new materials; one

avoids the tabular precomputations and interpolations and possible version-inconsistencies that can plague calculations. Tillotson is poorly suited to problems where vapor-melt interactions are expected to dominate, such as the post-impact protolunar “flying magma ocean” (Stevenson, 1987). Even so, Canup (2004) finds that Tillotson gives comparable results to more sophisticated EOS models for the initial characteristics of the protolunar disk.

There is a practical advantage to Tillotson: It is simply defined, easily computed, and easily understood in a calculation. Because it derives from the particle-velocity shock-velocity relation (Melosh, 1989), it is highly suitable to producing the post-shock particle velocities, and that is what is most important in most asteroid collisions. Melt is not produced in Tillotson (there are no “phases”), but melt and vapor produced in asteroid collisions are usually ejected to escaping velocity anyway, as discussed further below.

## 2.7. Porosity

The realization that asteroids and planetesimals contain a large volume of pore space (e.g., Housen and Holsapple, 1999; Consolmagno and Britt, 1998) has driven a recent advance in modeling dissipative properties of porous media (e.g., Wünnemann et al., 2006; Jutzi et al., 2008; Collins et al., 2011). To the extent that resolution allows, macroporosity can be modeled explicitly using solid materials described above, as cavernous voids (Asphaug et al., 1998; Jutzi et al., 2008). But the idea of a loosely packed dust rich structure for asteroids (Asphaug, 2009) requires porosity to be modeled at the subresolution, in addition to the compressibility of a fully compacted material that is defined by the EOS.

Porosity is associated with a crushing strength. One approach [the P- $\alpha$  model (Herrmann, 1969; Carroll and Holt, 1972)] computes a distention  $\alpha = \rho_s/\rho$ , where  $\rho$  is the bulk density of the porous material and  $\rho_s$  is the density of the nonporous matrix corresponding to the EOS. The pressure  $P$  and internal energy  $U$  in the porous material, at the grid resolution, is what is needed by the hydrocode, but the EOS only knows how to compute these for the nonporous material,  $P_s$  and internal energy  $U_s$ .

The P- $\alpha$  model uses the approximation

$$P = \frac{1}{\alpha} P_s (\rho_s, U_s) = \frac{1}{\alpha} P_s (\alpha \rho, U) \quad (10)$$

In this manner the EOS model for nonporous rock is converted into an EOS model for porous rock, whose pressure gradients at the grid scale then drive material accelerations and shocks. The distention varies with pressure according to a “crush curve” derived from uniaxial laboratory experiments, as described in the chapter by Jutzi et al. in this volume.

## 2.8. Self-Gravity

For modeling global-scale impacts into small asteroids, self-gravity can be neglected during the impact phase and

applied later, since  $\tau_g \gg \tau_s$ . Otherwise, self-gravity can be approximated using a constant radial gravity field inside a spherically symmetric asteroid. The modern hydrocodes described above can also calculate gravity explicitly (e.g., Jutzi et al., 2013; Davison et al., 2013), although this adds considerably to the computational expense.

Precompression must be included along with self-gravity, otherwise the first phenomenon is the asteroid shrinking and overshooting its central pressure. For small asteroids an analytical precompression is acceptable (Asphaug and Melosh, 1993). For larger asteroids or more sensitive studies, gravitational stresses must be iteratively solved prior to the impact simulation.

Following a global-scale collision, gravitational evolution must be computed over the orbital timescale of days. This is many thousands of hydrotimescales at the resolution of an asteroid, and thus prohibitive. This evolution is best computed after pressures and velocities have equilibrated, by mapping the hydrocode results into N-body codes or self-gravitating DEMs as described above.

## 3. THERMAL EFFECTS

Following its accretion in the first few million years, a typical  $\approx 200$ -km-diameter meteorite parent body likely experienced several hundred impacts by asteroids larger than 300 m during the first 100 m.y. of solar system history. This is about half the impacts expected during its lifetime (Davison et al., 2013). Over the same period, impact speeds increased from an average  $< 1$  km s $^{-1}$  to as fast as  $\sim 10$  km s $^{-1}$  (O’Brien and Greenberg, 2005).

According to Davison et al. (2013), post-accretion collisions were only capable of catastrophically destroying at most a few percent of the finished asteroids. Of the remainder, most were subjected more than one collision with an object one-twentieth its diameter, and a few percent experienced a collision with an object one-fifth its diameter.

It is therefore no surprise that evidence for impact processing is common in meteorites (e.g., Sharp and DeCarli, 2006), including shock effects, compaction, and frictional heating. However, as we now review, impact heating appears to be inefficient at the global parent-body scale, because the same violent impact that heats and melts the material ultimately causes the asteroid to disperse ( $Q > Q_D^*$ ). The fate of dispersed shocked material is another question — whether it finds its home back to the target asteroid, or another asteroid, or becomes ground into fine dust and disappears, or is sampled as meteorites.

### 3.1. Global Impact Heating of Asteroids

Widespread heating and melting of asteroids is evident in meteorites (e.g., Bizzarro et al., 2005) and one of the primary debates has been whether the source of this heating is by early accretion of radiogenic  $^{26}\text{Al}$  or by impact processes.

Keil et al. (1997) combined simple theoretical arguments with observational evidence and numerical impact

simulations to conclude that the globally averaged effect of impact heating on a nondisrupted asteroid was equivalent to a global temperature increase of less than a few degrees. Others (e.g., Rubin, 1995) maintained that shocks from high-velocity collisions, especially into porous primitive targets, could be the source of melting, and that the meteorite collection itself would be biased to include the more highly shocked and melted surface materials.

Davison *et al.* (2013) revisited the question of impact heating, using a Monte Carlo simulation that accounted for the effect of asteroid porosity and impact velocity on the disruption threshold (Jutzi *et al.*, 2010; Housen and Holsapple, 1990) and for the evolving impactor size- and velocity-frequency distribution (using a simulation by O'Brien and Greenberg, 2005). For a 200-km-diameter, 20% porous asteroid, Davison *et al.* (2013) found that the maximum specific impact energy that could be imparted, without disrupting the target, is  $\sim 0.1\text{--}0.7 \text{ MJ kg}^{-1}$ . This corresponds to a globally averaged temperature increase of 100–700 K, depending on the impact velocity, substantially greater than the Keil *et al.* (1997) estimate.

However, an impact just below the catastrophic threshold is not representative of the largest collision that is expected. This just gives the maximum heating that is theoretically possible, without also dispersing the heated mass. Davison *et al.* (2013) followed the collisional evolution during the first 100 m.y. of solar system formation, assuming an approximately inverse square size-frequency distribution of impactors. They found that in most cases, the most energetic impact experienced by a 200-km-diameter asteroid that was not disrupted was only a few percent of  $Q_D^*$ . They concluded that significant impact heating on an  $\sim 200$ -km-diameter parent body is unlikely, and in the end obtained a result similar to Keil *et al.* (1997), that in the most typical scenario the maximum specific impact energy delivered to a nondisrupted asteroid amounts to a globally averaged temperature increase of only a few degrees.

Larger asteroids have much greater specific binding energy and can therefore withstand collisions that deposit far more heat. An analogous situation is true of planetary cratering, where the largest craters are the most melt rich. But a maximal event is less likely to occur on a larger target than on a smaller target, for an approximately inverse square size distribution. On this basis, Davison *et al.* (2013) found that both the maximum specific impact energy and the total impact energy were rather constant for asteroids 100–500 km in diameter, a few tens of degrees of heating at most. These estimates assume that all the heated materials of impact are retained in the nondisrupted asteroid. A fraction of the hottest material actually escapes the asteroid, so that these global heating estimates are upper limits.

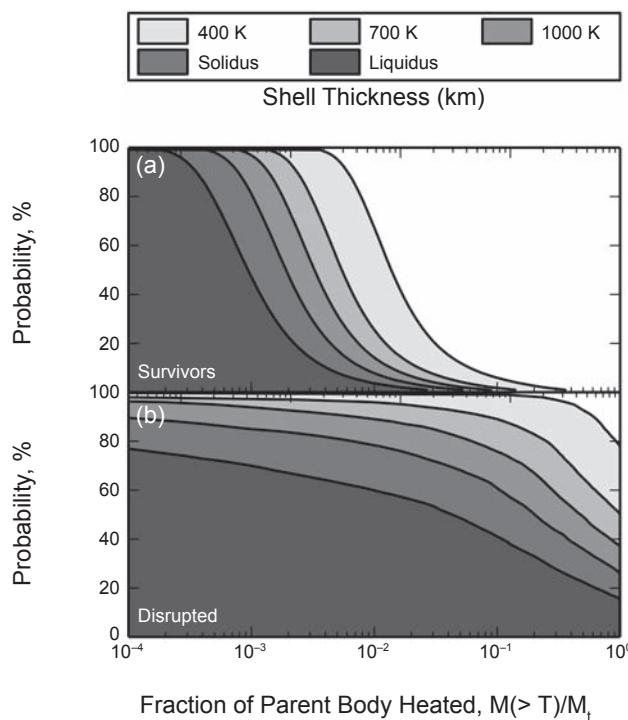

### 3.2. Localized and Buried Heat

These globally averaged estimates suggest that short-lived radionuclide decay ( $^{26}\text{Al}$ ) was a far more effective global heat source than impact. However, impact heating is trans-

sient, local, and non-uniform. In events where the projectile is much smaller than the target, impact energy is converted into heat within the proximal, near-surface volume that is highly shocked, a few projectile radii, and zero appreciable heating occurs far from the impact. For small asteroids with low escape velocity, much of this melted material escapes, while on large asteroids it can be retained, requiring a different sort of calculation.

Temperature increases attenuate with shock pressure, rapidly with distance, and so do ejection velocities. Only in rare, disruptive collisions between objects of similar mass can impact heating be considered to be nearly uniform (Davison *et al.*, 2010). The accretionary collisions described above (“small giant impacts”) are global in consequence, but too slow to result in shock heating. Frictional and compaction heating during early accretion (the first  $\sim 3$  m.y.) may be of global consequence, but are thought to be insignificant in magnitude compared to the prevalence of  $^{26}\text{Al}$ .

Using the same dynamical and population framework described above, Davison *et al.* (2013) computed the volumetric significance of impact heating on 200-km-diameter meteorite parent bodies during the first 100 m.y. of solar system history (Fig. 5). Less than 1% by mass of a typical undisrupted parent body experiences heating of more than a few hundred Kelvins, volumetrically equivalent to a surface layer  $<300$  m thick. However, of the few percent of asteroids

**Fig. 5.** The probability that a given mass fraction of a meteorite parent body will be heated to a range of temperatures, for (a) those asteroids that survive the first 100 m.y. of solar system history without being disrupted and (b) those bodies that are disrupted. Modified from Davison *et al.* (2013).

that are disrupted, most experience a near-global temperature increase of a few hundred Kelvins, and one-fifth are expected to undergo (near) complete melting.

The main influence of asteroid porosity on impact heating is to modify the distribution of heat. Shock heating is more extreme, but much more localized, in porous-body collisions compared to impact on a nonporous body. More shock energy is absorbed close to the impact site on a porous asteroid by permanent crushing of pore space; the excess heating from pore collapse leads to higher proximal temperatures (Asphaug et al., 2002; Davison et al., 2010).

The localized heating by subcatastrophic collisions, and the distribution of heated materials beneath and around the crater, imply that a single impact can produce materials with a remarkable range in peak temperature and cooling rates. According to Davison et al. (2012), impacts on porous asteroids can produce large amounts of melting at speeds as low as  $4 \text{ km s}^{-1}$ , and material heated up to  $\sim 1200 \text{ K}$  (petrologic type 6) is expected for most impacts in the first 100 m.y. (Davison et al., 2013).

Numerical simulations of crater formation in large subcatastrophic impacts also suggest that heated impactor and target material, and exhumed hot material from the deep mantle, is rapidly buried beneath an insulating lens of porous breccia. The structure of these lobate/hemispheric deposits, for the specific case of the global-scale impacts Rheasilvia and Vennenia on asteroid (4) Vesta, is studied by Jutzi and Asphaug (2011) and Jutzi et al. (2013). Buried impact-heated or impact-exhumed material cools slowly, consistent with the wide range of metallographic cooling rates inferred for chondritic materials (Davison et al., 2012).

While the volumetric significance of impact-heated material appears to be consistent with the limited constraints on meteorite thermal metamorphism, compared to  $^{26}\text{Al}$  decay, it appears that localized impact heating is an important secondary effect, even when considering the cumulative effect of multiple impacts over the lifetime of a parent body. There is of course a bias, that the proximity of impact-heated material to the parent body's surface makes it most accessible for excavation and meteorite delivery by subsequent collisions.

### 3.3. Accelerated Cooling by Impact Overturning

If internal heating by short-lived radioactivity was dominant, then subcatastrophic collisions would have played an additional important role in regulating thermal evolution. Ciesla et al. (2013) showed how a single large impact can have an enormous influence on the cooling of planetesimals heated internally by radioactivity.

In their models (Fig. 6), hot, thermally softened material is brought up from the deep interior to flow out and over the surface of the planetesimal, turning the asteroid "inside out." The direct exposure to space of deeply exhumed molten silicates would lead to rapidly accelerated cooling and degassing; more generally, it is a considerable source of enthalpy for materials brought to the surface, something Asphaug et al. (2011) proposed as an origin of chondrules.

In general, a much larger fraction of an internally heated planetesimal experienced enhanced cooling than is heated by the impact, implying the non-intuitive result, that the major effect of subcatastrophic collisions was to accelerate the loss of heat, rather than to deposit heat (Ciesla et al., 2013).

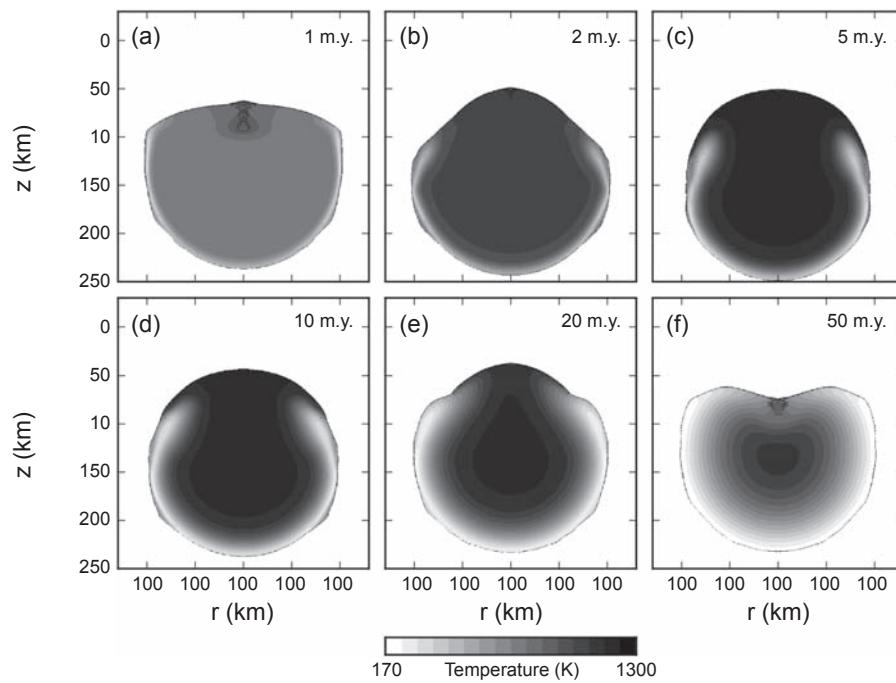

The rapid cooling of iron meteorites is a longstanding problem (e.g., Wood, 1964) that could perhaps be solved if melted core material buried deep inside a differentiated asteroid could be exhumed by this mechanism, so that the iron might cool rapidly. But from many simulations (Love and Ahrens, 1996, and thereafter) it appears that an iron core, once buried, is almost impossible to blast out by impact overturning. Furthermore, it would sink back to the core, cooling there instead of at the surface. So the above process, of "breaking open the pie crust," would affect mostly the thermodynamics of meteorites from the upper to mid-mantle of a melted planetesimal, not the core.

It is possible, on the other hand, to achieve greatly accelerated cooling of iron planetesimals if we consider the exhumation of the projectile rather than the target. As noted above, planetesimal projectiles (but not targets) during SSCs can be ripped apart into beads of iron-rich objects during hit-and-run collisions involving larger embryos (Asphaug et al., 2006; Asphaug, 2010). The mechanism of mantle stripping of hit-and-run projectiles is discussed in more detail in the chapter by Scott et al. in this volume, including its implications for the history and evolution of the asteroid-parent-body population.

While mantle stripping by hit and run has been simulated dynamically in a number of studies, the thermal consequences of abruptly exposing interior materials to space awaits the kind of detailed study that Ciesla et al. (2013) have given to large-scale cratering. Asphaug et al. (2011) consider exhumation in a more specific context to explain the cooling rates of chondrules, which are formed according to their model by inefficient accretion of incompletely differentiated melted planetesimals. For the general case, it is apparent that the accelerated-cooling scenarios defined above for megacratering would have comparable, more accentuated aspects if applied to the aftermath of hit-and-run collisions, which typically rip off half the mantle of a differentiated body without producing shocks (Asphaug, 2010). Yang et al. (2007) invoke hit-and-run mantle stripping to explain the rapid cooling rates of the IVA iron meteorites, in a scenario that requires almost complete mantle stripping to leave behind only a thin rind of insulating silicates. This would require repeated hit-and-run collisions while the body was still molten — something that Asphaug and Reufer (2014) argue would have been probable for at least a few of the unaccreted bodies that became the progenitors of asteroids.

## 4. RHEOLOGY AND DISRUPTION

One goal of current numerical modeling is a unified simulation of asteroid collision including fracture, crushing, dilatancy, friction, and debris flow. The physical modeling borrows equally from dynamics, seismology, geomorphology,

**Fig. 6.** Post-impact temperature distribution within planetesimals internally heated by radioactive decay of  $^{26}\text{Al}$  for a single impact that occurs at different times during thermal evolution. At early and late times, the impact occurs on a relatively cool planetesimal, resulting in a recognizable crater with a localized, impact-heated region at its center. In contrast, impacts that occur during the period of high internal temperatures ( $\sim 2\text{--}20$  Ma for this size planetesimal) result in uplift and overturn of deeply derived, hot and thermally softened material. From Ciesla *et al.* (2013).

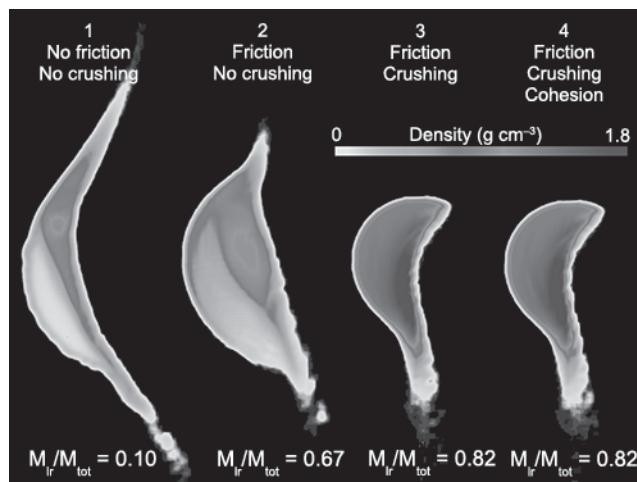

and impact cratering. Only recently has it been possible to look at the additional effects of friction, porosity, and cohesion, at least on a global scale, so this represents a frontier of computational geophysics.

Jutzi (2015) used SPH to model colliding bodies in an exploration of the threshold for catastrophic disruption. Below we show a subset of those calculations: colliding asteroids that are the same size in each simulation ( $R_t = 100$  km,  $R_p = 27$  km), and the same mass (initial bulk density  $\rho = 1.3 \text{ g cm}^{-3}$ ), and the same impact parameter ( $v_{\text{imp}} = 3 \text{ km s}^{-1}$ ,  $\theta = 45^\circ$ ). What is different between the four simulations in Fig. 7 are the material properties: (1) no friction, no crushing, no cohesion; (2) friction, no crushing, no cohesion; (3) friction and crushing, no cohesion; (4) friction, crushing, and cohesion.

For the two cases with crushing, a crush curve with parameters for pumice is applied (Jutzi *et al.*, 2009). For the case with cohesion, an internal friction  $\mu_i = 1.5$  and cohesion  $Y_0 = 100 \text{ MPa}$  are applied, which is reduced to  $Y_0 = 0$ ,  $\mu_d = 0.8$  and  $Y_m = 3.5 \text{ GPa}$  following damage. The first case in Fig. 7 is a fluid, the second is a fluid resisted by friction, the third is a crushable fluid resisted by friction, and the last is a cohesive porous body like pumice.

Based on a suite of such models, Jutzi (2015) found the catastrophic disruption energy  $Q_D^*$  to be  $\sim 5\text{--}10\times$  higher when friction is included. The disruption threshold further

increases by a factor of  $\sim 2\text{--}3$  when the energy dissipation by compaction (pore crushing) is taken into account. (Surprisingly, there is not much difference between the cases

**Fig. 7.** Cross-sections of four SPH simulations of collisions between targets  $R_t = 100$  km and projectiles  $R_p = 27$  km, at relative velocity  $3 \text{ km s}^{-1}$  and  $45^\circ$  impact angle. Four different rheologies are investigated. The degree of disruption, the size of the largest remnant ( $M_{lr} = M_{tot}$ ), and the increase in density strongly depend on the target properties. From Jutzi (2014).

with or without cohesion.) This implies that many events previously thought of as catastrophically disruptive are more likely global-scale impacts that leave behind a completely transformed asteroid, but do not disperse it.

These simulations are consistent with previous models, that cohesion and tensile strength are negligible in potentially disruptive impacts involving bodies larger than a few hundred meters in diameter. But it is a misnomer to speak of this as the “strength-gravity transition,” because gravity is not the controlling aspect for the response either. For example, collisions involving partially melted silicate targets up to  $\sim 1000$  km in diameter may be limited by viscosity (Asphaug et al., 2006). For solid asteroids and planetesimals up to hundreds of kilometers in diameter that have been beaten into rubble, friction and compaction are expected to dominate, according to these calculations. Although gravity cannot be ignored, there may be no simple “gravity regime” for asteroid impacts.

## 5. CONCLUSIONS

Global-scale impacts on asteroids and their parent bodies are in many respects similar to the giant impacts that created the terrestrial planets, and there is great scientific value in making the connection. But at asteroid scales, we cannot ignore the internal stresses and their associated rheological responses — the breaking of rock, the flow of rubble, the opening of faults, the seismological vibration — in addition to the self-gravitational complexities.

Gravity is subtle, and so are the other forces. Approximations or even small numerical errors can overwhelm the accurate calculation of an asteroid impact. In recent years computer modeling has begun to catch up with the physics, and progress on this front defines much of the modern science of global-scale impacts. In the coming decade, we can look forward to ever more sophisticated simulations; for now, it is too early to say whether the models are sufficient to be predictive.

Meanwhile, every new mission to an asteroid — and in particular, every new mission to a different size or class of asteroid — has revealed a solar system process not previously envisioned, and has turned our previous understanding of small bodies on its head. Flyby missions are of great value, as are the increasingly impressive radar shape models (Ostro et al., 2002) and adaptive optics models (see the chapter by Marchi et al. in this volume) obtained so far for dozens of near-Earth asteroids (see the chapter by Benner et al. in this volume). While lacking the fidelity of a spacecraft flyby, radar images are sufficiently detailed to play a fundamental role in resolving the geophysical debates that have been summarized in this chapter.

Rendezvous missions provide a much more thorough examination of a smaller subset — three asteroids so far, with three more on the near horizon: the sample return missions Hayabusa 2 and Origins Spectral Interpretation Resource Identification and Security-Regolith Explorer (OSIRIS-REx) to small near-Earth objects, and the Dawn mission continuing to Ceres. Hayabusa 2 will conduct the

first impact experiment on an asteroid, and although it is almost certainly too small in scale to result in any of the global-scale phenomena described above, it will no doubt shed light on some of the open questions concerning microgravity impact physics at several meters scale.

Efforts are ongoing to study the effect of a small spacecraft colliding into an asteroid using a mission approach like that of the Lunar Crater Observation and Sensing Satellite (LCROSS) (Colaprete et al., 2010), which depending on the asteroid could cause global accelerations greater than local gravity, rearranging the global topography. Such a mission would elucidate the many factors that dictate whether a cratering event has global consequences or is local to one hemisphere — an understanding that in turn will allow us to put the more readily attainable cratering observations from radar and flyby missions into context.

And the last front is meteorites, including the samples that are collected by missions. Meteorites have a way of presenting us with seemingly contradictory information, leading to a spectrum of contested hypotheses for their origin. But there is a chance, through collisional and thermal modeling and geochemistry, to understand their most basic physical properties and the processes they have experienced, from the formative collisions to the catastrophic disruptions that have populated the main belt and near-Earth space.

## *Color Section*

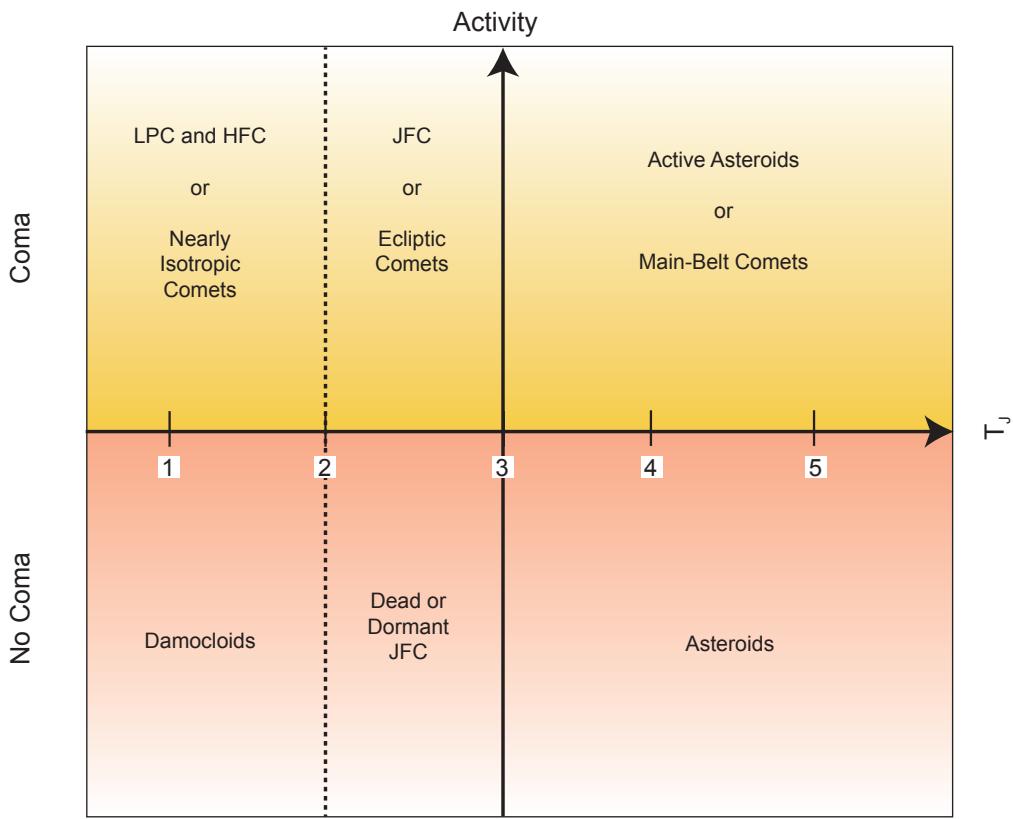

**Plate 1. (a)** Schematic model of an underdense, "fairy-castle" regolith on Trojan asteroids deduced from comparisons between MIR emissivity spectra of Trojans and laboratory measurements of powdered meteorites mixed with KBr. From Vernazza *et al.* (2012). **(b)** Evolutionary scenario that might produce salt-rich surfaces, in which embedded fine-grained silicate dust could explain measured MIR emissivity spectra of Trojans. From Yang *et al.* (2013).

Accompanies chapter by Emery *et al.* (pp. 203–220).

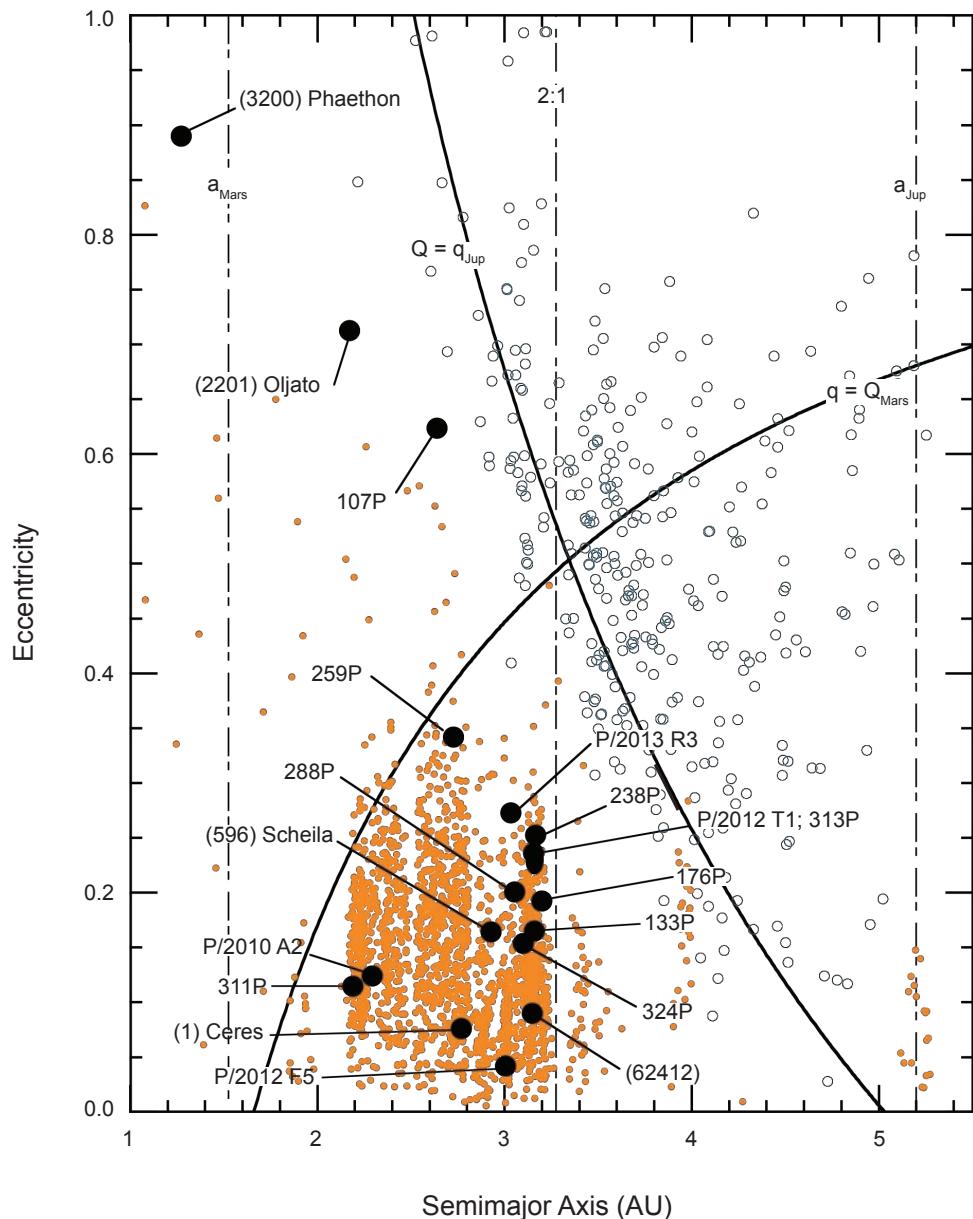

**Plate 2.** Diffusion map around  $L_4$  for an N-body model including the outer four planets. Blue indicates stable orbits while red corresponds to highly chaotic motion. The black zone marks trajectories that lead to ejection from  $L_4$  on a short timescale. From *Robutel and Gabern* (2006).

Accompanies chapter by Emery et al. (pp. 203–220).

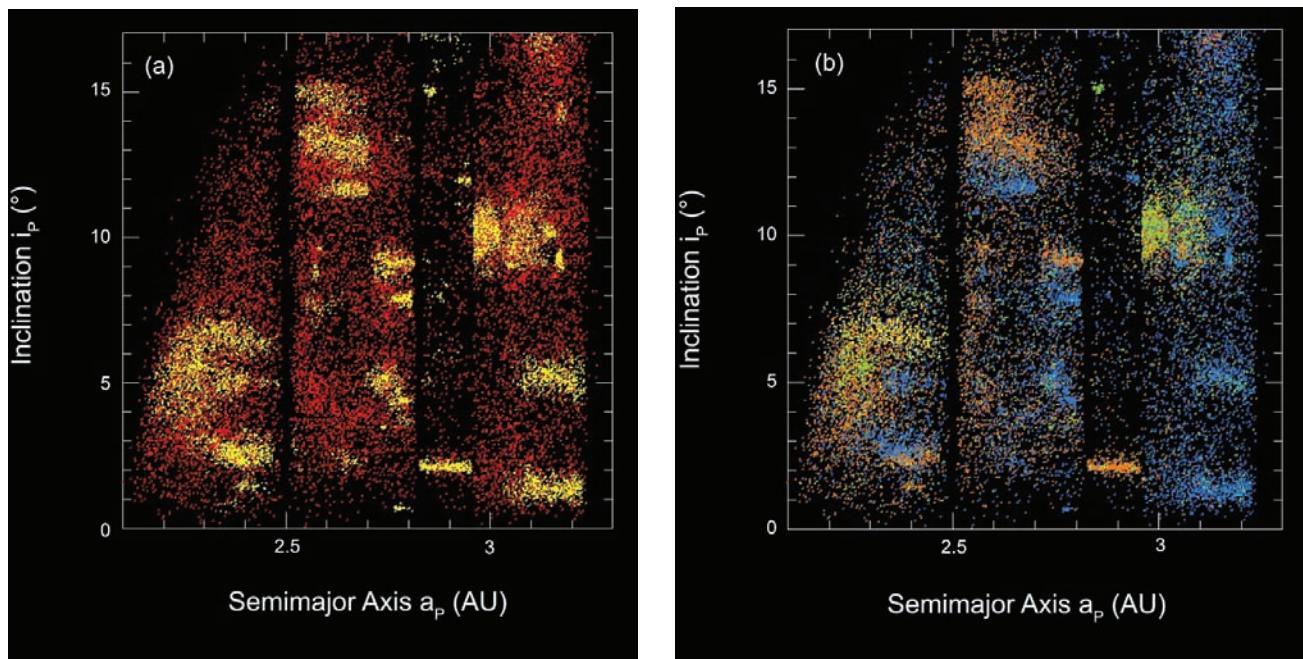

**Plate 3.** Empirical classification of small bodies based on the Tisserand parameter,  $T_J$  (x-axis), and the presence or absence of coma (y-axis). JFC, LPC, and HFC are the Jupiter-family, long-period, and Halley-family comet subtypes, distinguished by their dynamics. From Jewitt (2012).

Accompanies chapter by Jewitt et al. (pp. 221–241).

**Plate 4.** Distribution of the active asteroids in the semimajor axis vs. orbital eccentricity plane. Dynamical asteroids are shown as filled orange circles, comets as empty blue symbols, and the active asteroids as black circles, each labeled with the object name (cf. Table 1). Objects plotted above the diagonal arcs cross either the orbit of Mars or Jupiter.

Accompanies chapter by Jewitt et al. (pp. 221–241).

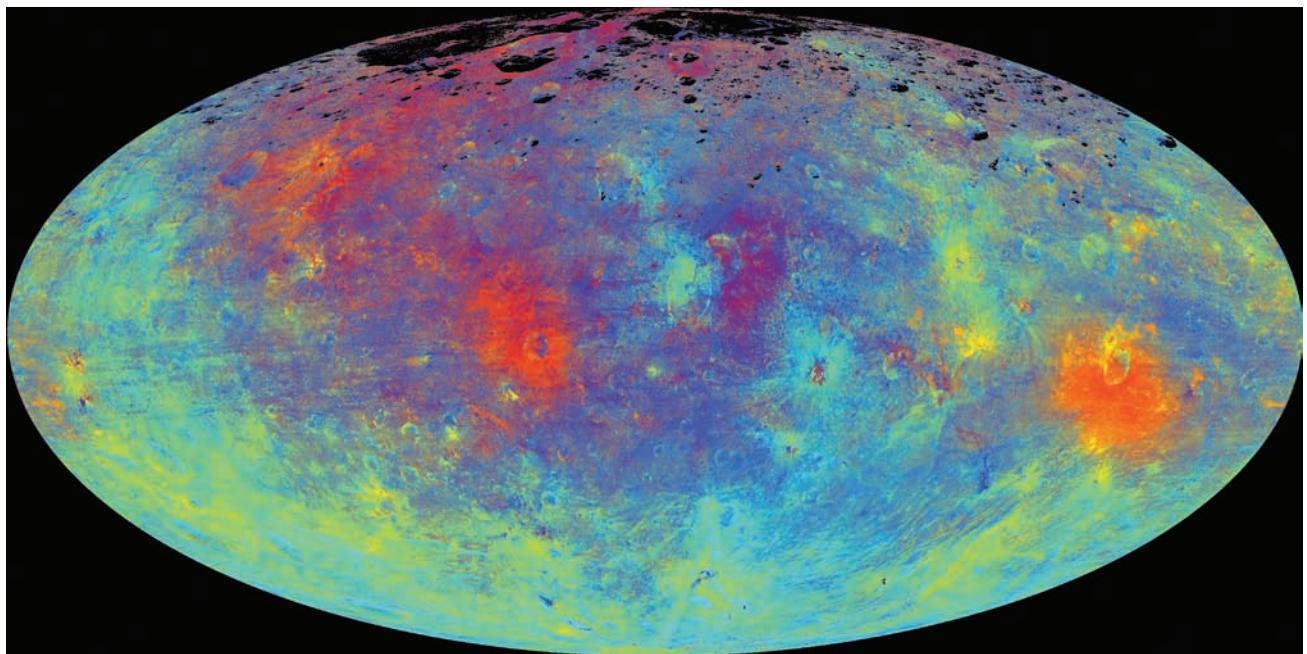

**Plate 5.** (a) Clustering algorithm applied to the asteroid belt separates dynamical families (yellow) from the background (red). (b) Variation in reflectance properties of main-belt asteroids. Here we plot  $\approx 25,000$  asteroids that were observed by both SDSS and WISE. The color code was chosen to highlight the albedo/color contrast of different families.

Accompanies chapter by Nesvorný et al. (pp. 297–321).

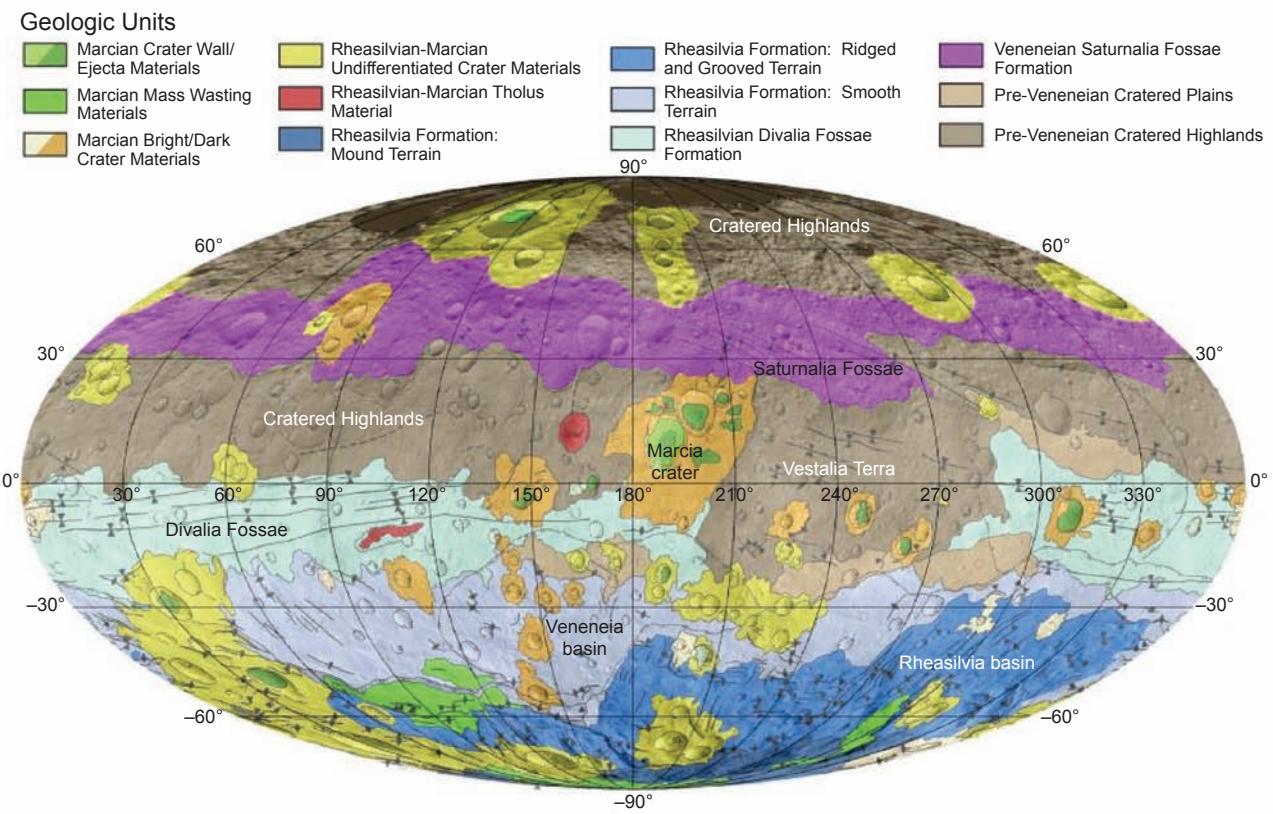

**Plate 6.** The Dawn spacecraft depicted as it left Earth on September 27, 2007.

Accompanies chapter by Russell et al. (pp. 419–432).

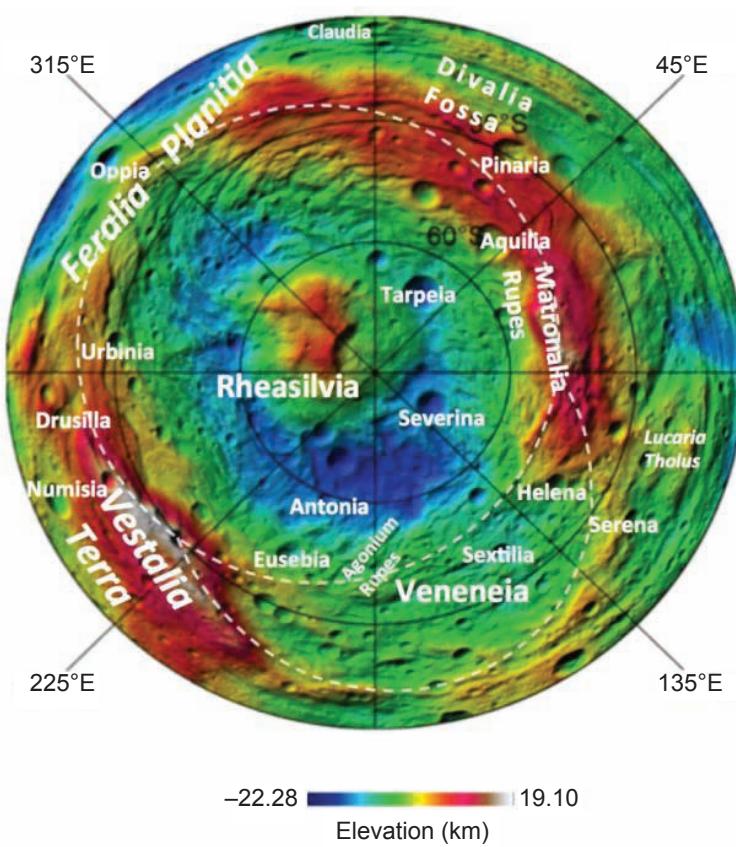

**Plate 7.** Mollweide projection of FC color mosaic using Clementine ratios (A. Nathues, personal communication, 2014).

Accompanies chapter by Russell et al. (pp. 419–432).

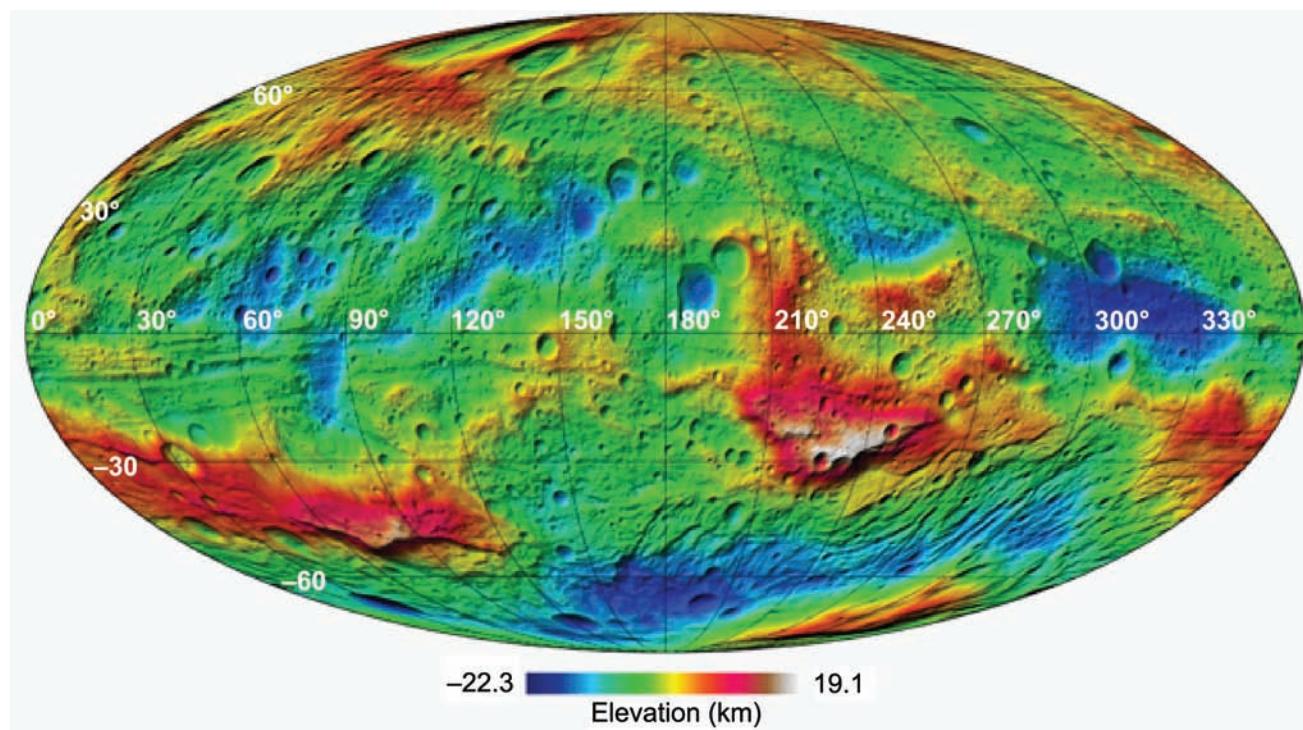

**Plate 8.** Geologic map of Vesta using Mollweide projection. Major terrains are identified here. From Jaumann *et al.* (2012) and Williams *et al.* (2014a).

Accompanies chapter by Russell *et al.* (pp. 419–432).

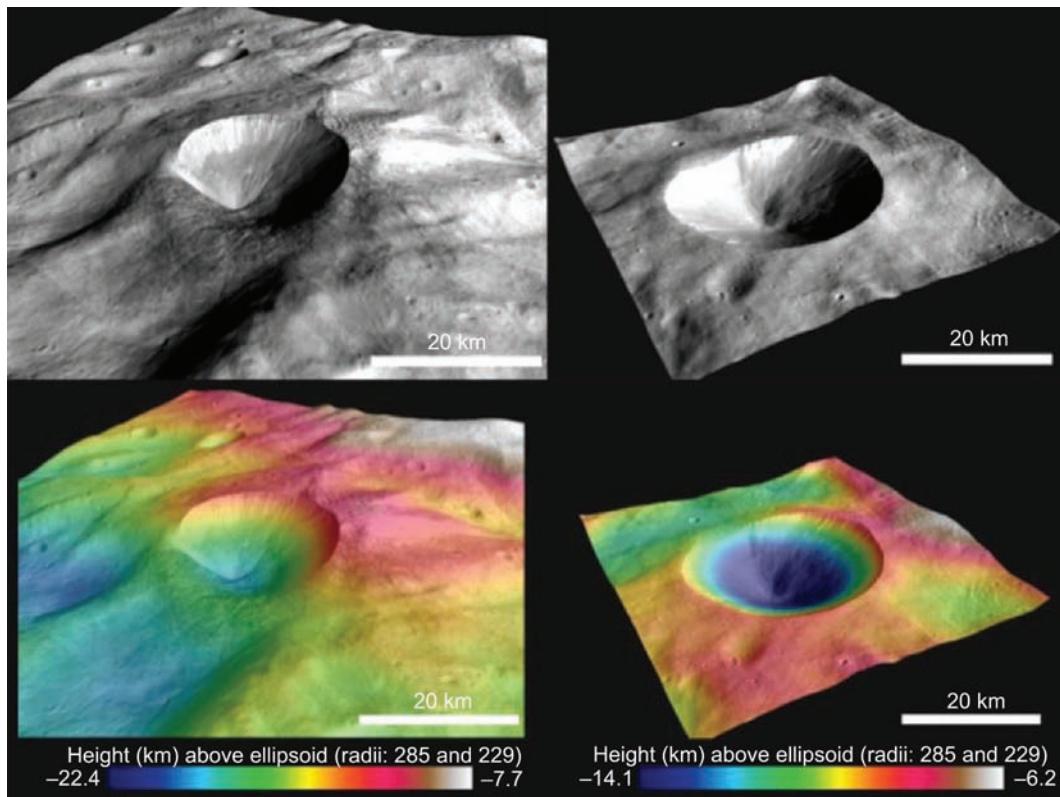

**Plate 9.** The Veneneia and Rheasilvia south polar basins and their geological environment. From Jaumann *et al.* (2012).

Accompanies chapter by Russell *et al.* (pp. 419–432).

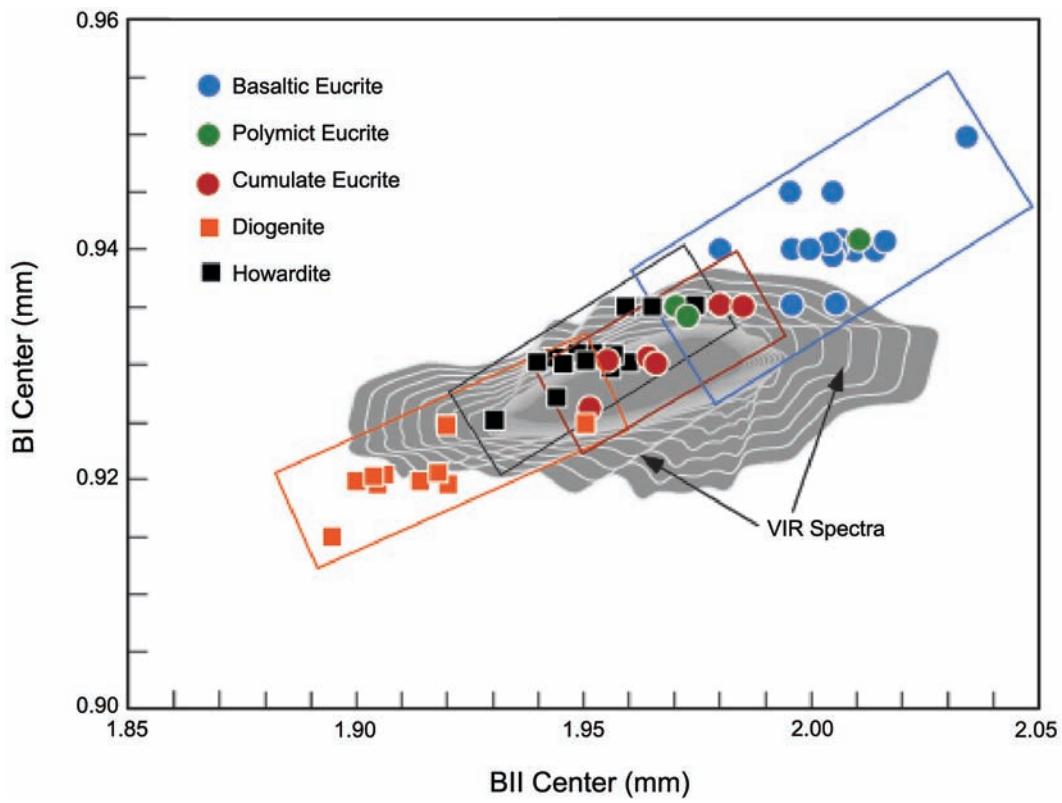

**Plate 10.** Mollweide projection of Dawn topography data.

Accompanies chapter by Russell et al. (pp. 419–432).

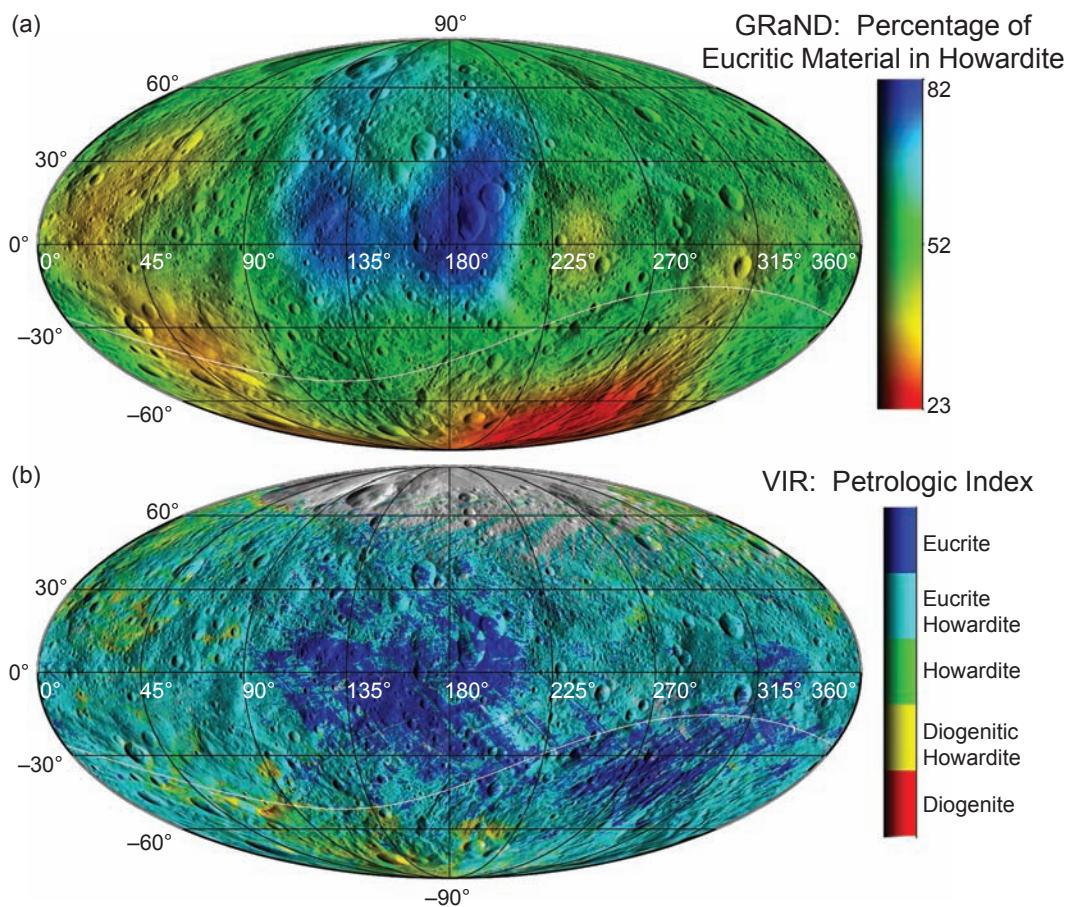

**Plate 11.** Typical impact crater on Vesta: Antonia ( $200.8^{\circ}\text{E}$ ,  $58.7^{\circ}\text{S}$ ; diameter  $16.75\text{ km}$ ) is an impact on a slope of asymmetric shape with the ejecta mainly concentrated downhill also covering the downslope crater rim; Sextilia ( $145.9^{\circ}\text{E}$ ,  $39^{\circ}\text{S}$ ; diameter  $19.48\text{ km}$ ) is of approximately the same size, located on a more gentle slope, and circular in shape but exposing significant mass wasting inside the crater on the uphill rim (Jaumann *et al.*, 2012; Krohn *et al.*, 2014b).

Accompanies chapter by Russell *et al.* (pp. 419–432).

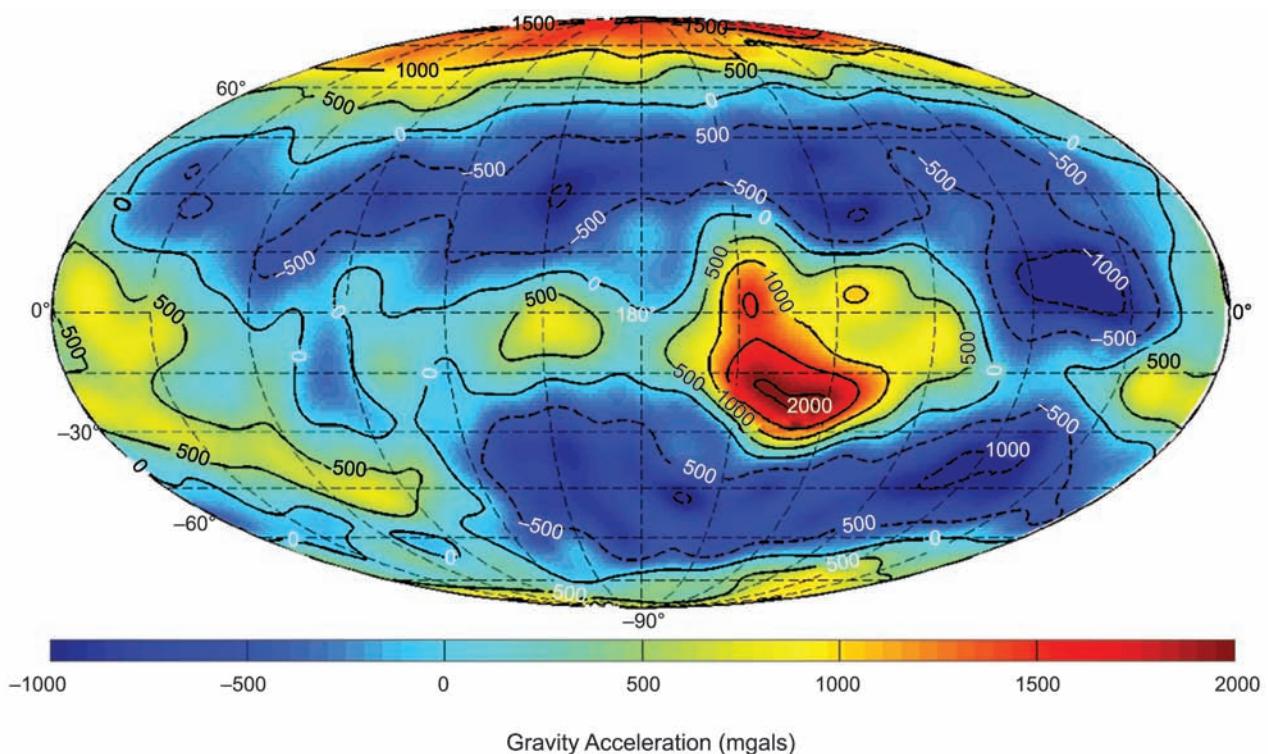

**Plate 12.** BI vs. BII for VIR data and HEDs (De Sanctis et al., 2012a, 2013).

Accompanies chapter by Russell et al. (pp. 419–432).

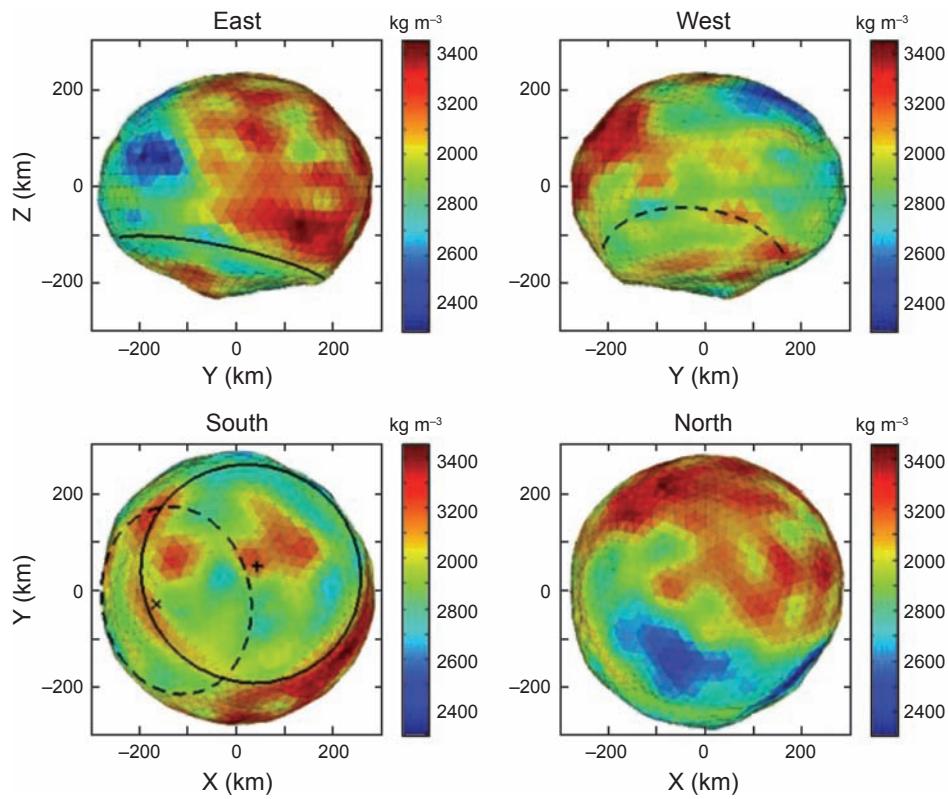

**Plate 13.** Lithologic maps of Vesta remapped in Mollweide projection. (a) Map of HED distribution mapped by VIR (Ammannito et al., 2013). (b) Map of the percentage of eucritic material from GRaND data (Prettyman et al., 2013). Eucritic regions appear as blue, whereas regions that are more diogenitic appear as red.

Accompanies chapter by Russell et al. (pp. 419–432).

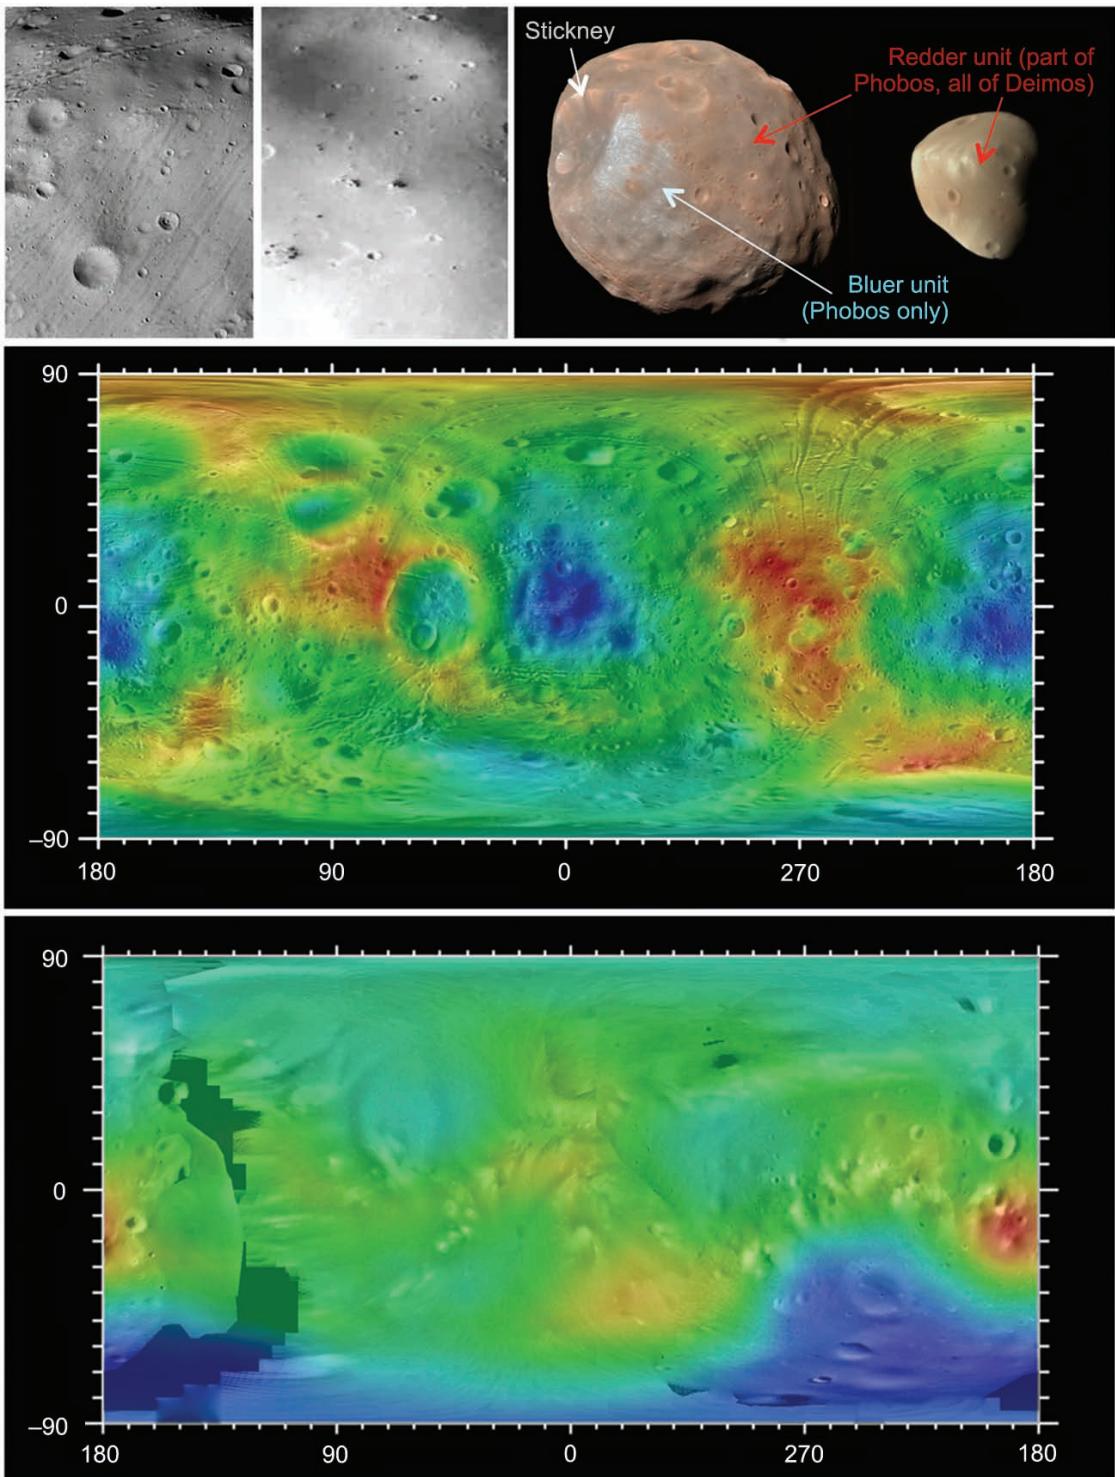

**Plate 14.** The Vesta radial gravity solution mapped to a 290 × 265-km ellipsoid surface through degree 20. The  $J_2$  coefficient has been removed. The maximum and minimum range is given by 2100 mgal at the large equatorial high near 126°W longitude and -1270 mgal, also near the equator at 44°W. From Konopliv et al. (2013).

Accompanies chapter by Russell et al. (pp. 419–432).

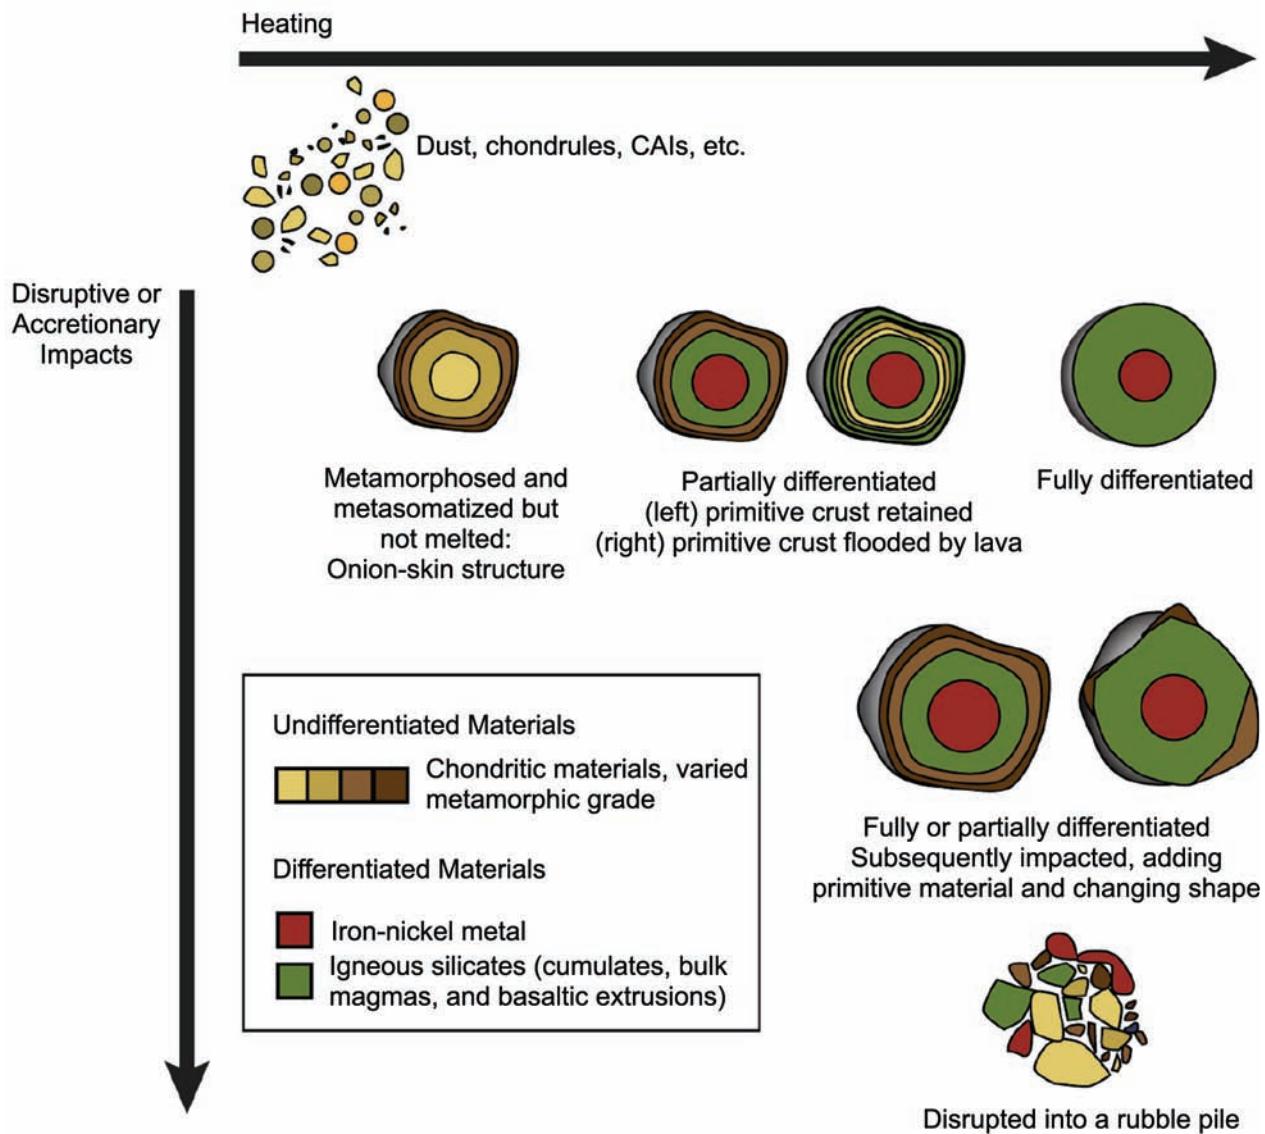

**Plate 15.** The lateral crustal density estimation of the three-layer Vesta (257 × 207-km mantle and 117 × 105-km core). Solid black and dashed black circles represent Rheasilvia and Veneneia impact basins, respectively. The lateral crustal density variation ranges from 2310 to 3440  $\text{kg m}^{-3}$ , which is required to remove the gravity anomaly. From R. S. Park (personal communication, 2014).

Accompanies chapter by Russell et al. (pp. 419–432).

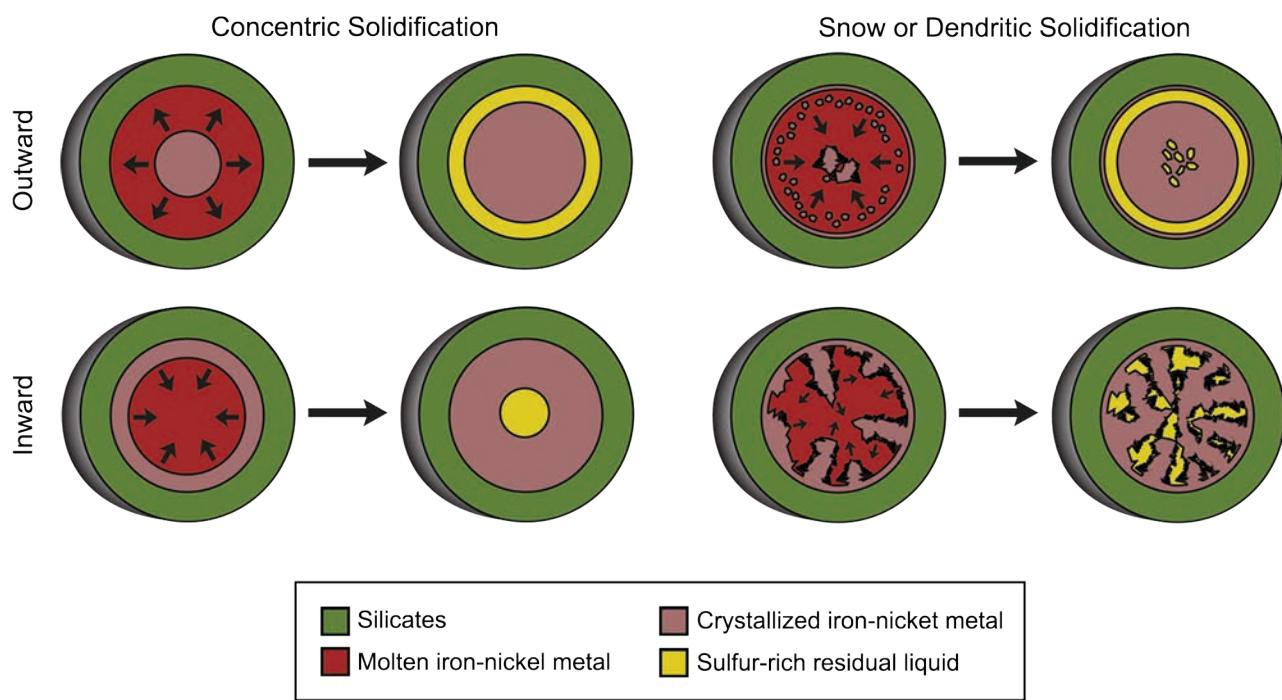

**Plate 16.** Spacecraft exploration reveals global properties of Phobos and Deimos, and basic differences between them. *Top left:* Viking images revealed that Phobos' surface is relatively rough, with well-preserved craters, and parallel topographic grooves. *Top center:* Deimos' surface is smooth with craters infilled by regolith. *Top right:* Multispectral and hyperspectral imaging from Phobos 2, Mars Express, and the Mars Reconnaissance Orbiter (shown, centered on the sub-Mars hemispheres) reveal spatial variations in Phobos' spectral properties, especially associated with Stickney. Deimos' brightness variations are accompanied by less color variation. *Middle:* Phobos simple cylindrical image map and dynamical height, using shape model from Gaskell (2011) and image mosaic from Stooke (2011). Red is high, blue low, with a range of heights of 1.8 km. *Bottom:* Deimos simple cylindrical image map and dynamical heights, using shape model and image mosaic updated from Thomas (1993). Red is high, blue low, with a range of heights of 1.9 km.

Accompanies chapter by Murchie et al. (pp. 451–467).

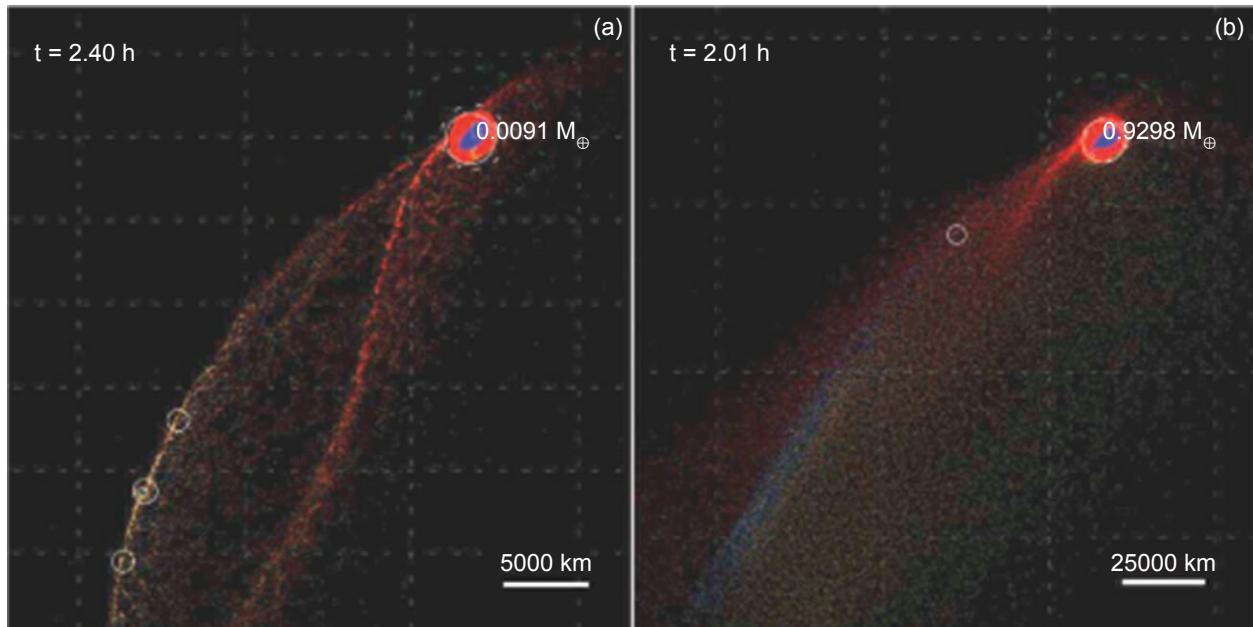

**Plate 17.** Three possible end-states of asteroid differentiation. *Left:* Unmelted but variably metamorphosed and aqueously altered body composed of chondritic materials. *Middle:* Partially differentiated body with melted interior and unmelted surface layer. *Right:* Fully differentiated body with metallic core and igneous silicate mantle. *Bottom:* Partially or fully differentiated bodies disrupted and coated by later impacts, disrupted even to the point of internal disorganization into a rubble pile.

Accompanies chapter by Scheinberg et al. (pp. 533–552).

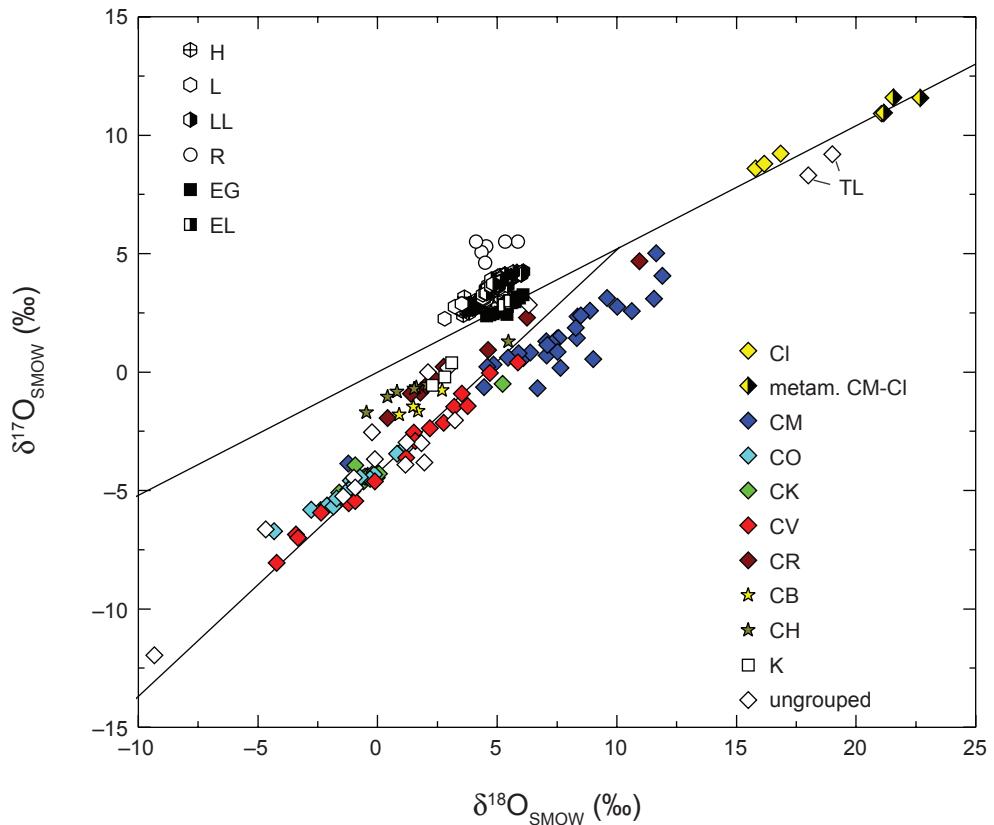

**Plate 18.** Four possible core solidification scenarios and potentially resulting end-states. *Top left:* Outward (Earth-like) solidification. *Bottom left:* Concentric inward solidification. *Top right:* Outward solid core growth due to accumulated iron “snow” and/or destabilized dendrites. *Bottom right:* Dendritic inward solidification.

Accompanies chapter by Scheinberg et al. (pp. 533–552).

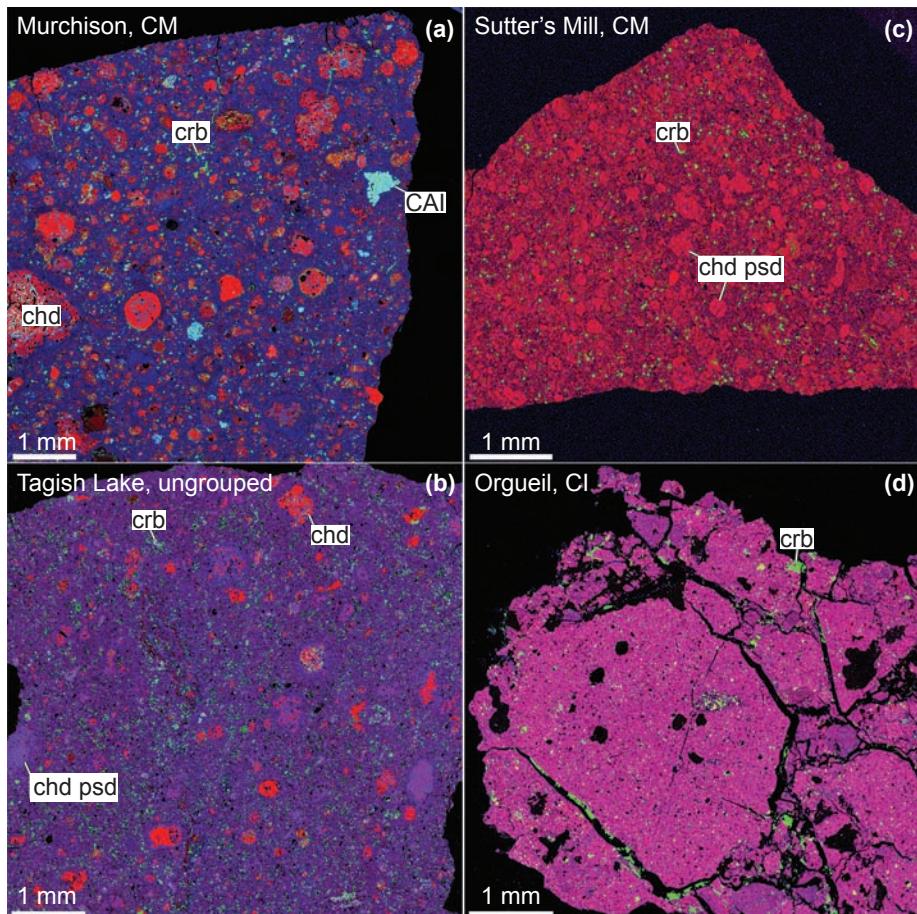

**Plate 19.** Simulations of two collisions with the same  $M_2/M_1 = 0.2$ ,  $\theta = 30^\circ$ ,  $v_{\text{imp}} = 3 v_{\text{esc}}$ , but differing in mass by a factor of 100. Both are shown at  $\sim 10$  collision times,  $\tau_{\text{coll}} = 2(R_1 + R_2)/v_{\text{imp}}$ . Silicates (red) are segregated from metals (blue) in the remnants of  $M_2$  and are dispersed downrange in both hit-and-run collisions. The subsonic collision (left;  $R_1 = 1400$  km,  $R_2 = 800$  km) leads to a chain of iron-dominated clumps (white circles) stripped gravitationally and mechanically from a sheet of lower-density mantle material. The supersonic collision (right;  $M_1 = M_\oplus$ ,  $v_{\text{imp}} \approx 30$  km s $^{-1}$ ), produces intense global shocks and fine dispersal of the plume. After Asphaug and Reufer (2014).

Accompanies chapter by Scott et al. (pp. 573–595).

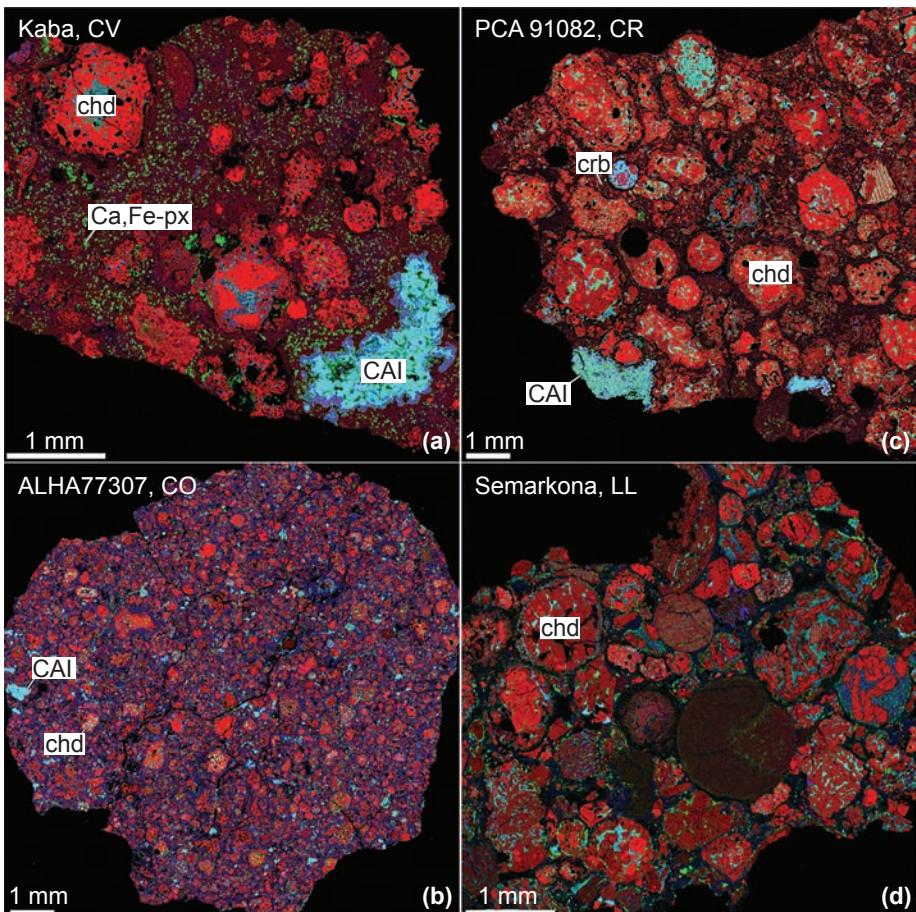

**Plate 20.** Bulk oxygen-isotope compositions of chondrite groups and ungrouped chondrites. Terrestrial fractionation line (TFL) and carbonaceous chondrite anhydrous mineral (CCAM) line are shown for reference. Oxygen-isotopic compositions are reported as  $\delta^{17}\text{O}$  and  $\delta^{18}\text{O}$ , deviations from Vienna Standard Mean Ocean Water (SMOW) [ $^{17}\text{O}/^{16}\text{O}_{\text{SMOW}} = 0.000380$ ;  $^{18}\text{O}/^{16}\text{O}_{\text{SMOW}} = 0.002005$  (*De Laeter et al.*, 2003)] in parts per thousand:  $\delta^{17,18}\text{O}_{\text{SMOW}} = [(^{17,18}\text{O}/^{16}\text{O}_{\text{sample}})/(^{17,18}\text{O}/^{16}\text{O}_{\text{SMOW}})-1] \times 1000$ . Carbonaceous chondrites, except Cls, plot below the TFL; noncarbonaceous chondrites, except EHs and ELs, plot above it. After *Krot et al.* (2014a). Data for Tagish Lake (TL) are from *Brown et al.* (2000).

Accompanies chapter by Krot et al. (pp. 635–660).

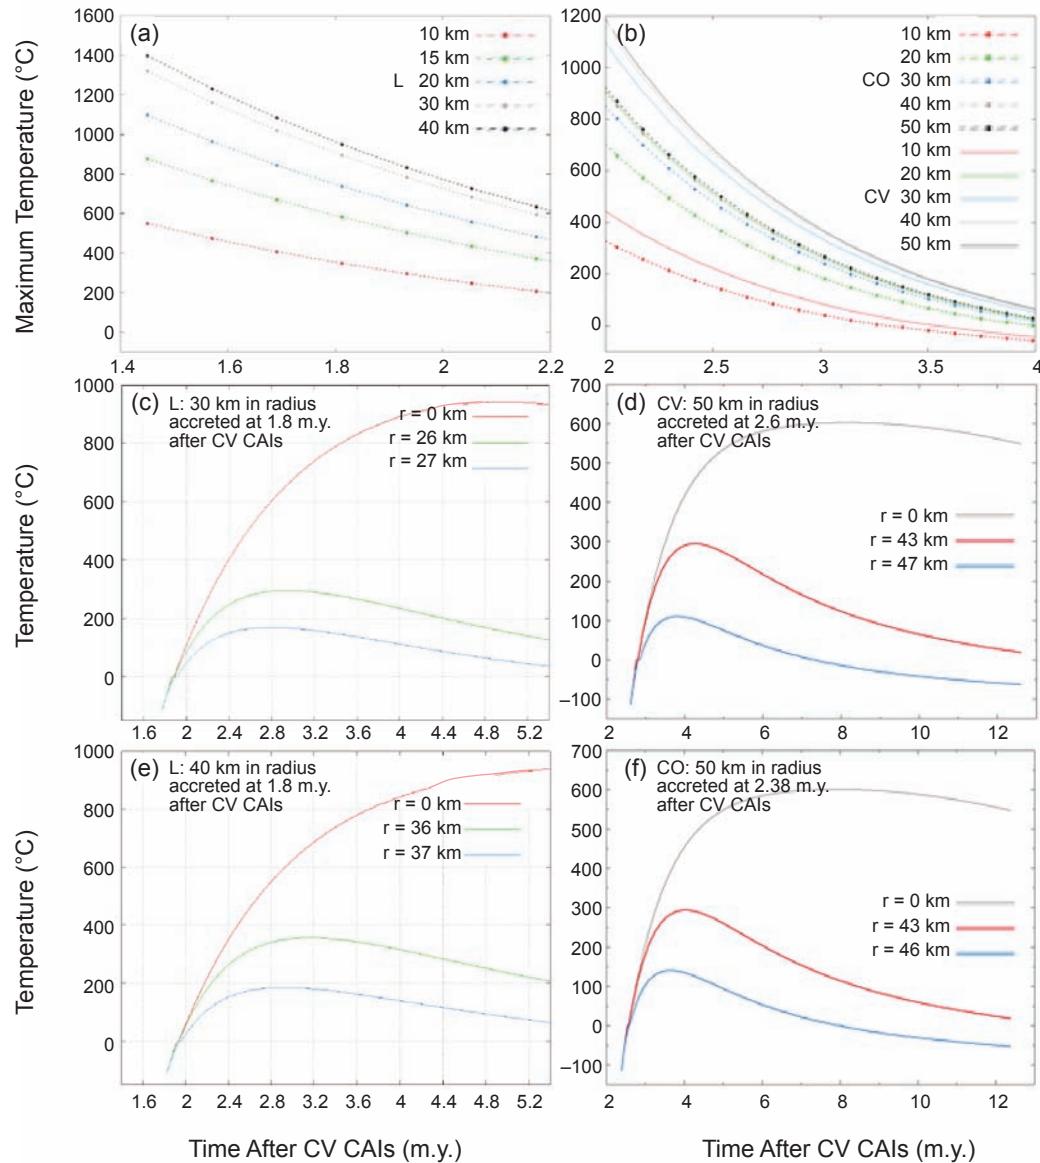

**Plate 21.** Combined elemental maps ( $\text{Mg} = \text{red}$ ,  $\text{Ca} = \text{green}$ ,  $\text{Al} = \text{blue}$ ) of extensively aqueously altered chondrites: **(a)** Murchison (CM2.5), **(b)** ungrouped carbonaceous chondrite Tagish Lake, **(c)** Sutter's Mill (CM2.1), and **(d)** Orgueil (CI1). Murchison contains abundant magnesian chondrules (chd, red), CAIs (bluish), and heavily hydrated matrix (purple) containing relatively rare grains of carbonate (crb, green). In Sutter's Mill, CAIs, chondrules, and matrix are nearly completely replaced by phyllosilicates and carbonates; chondrule pseudomorphs (chd psd) are common. Tagish Lake contains a higher proportion of heavily hydrated matrix and carbonates, and fewer chondrules and CAIs than Murchison; incompletely altered chondrules are common; some chondrules are nearly completely replaced by phyllosilicates. Orgueil consists entirely of hydrated matrix material; chondrule pseudomorphs are absent.

Accompanies chapter by Krot et al. (pp. 635–660).

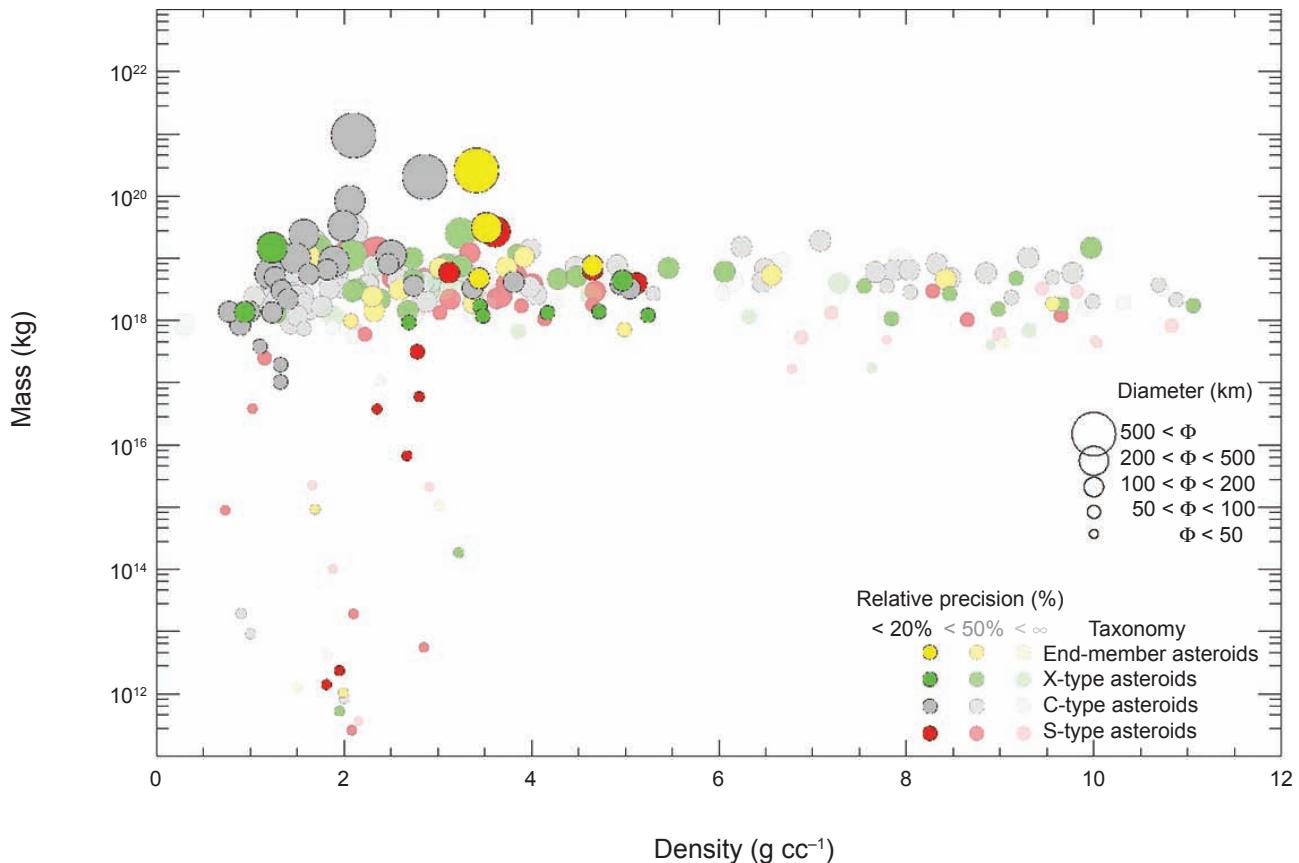

**Plate 22.** Combined elemental maps (Mg = red, Ca = green, Al = blue) of weakly aqueously altered chondrites: (a) Kaba (CV3.1), (b) ALH A77307 (CO3.1), (c) PCA 91082 (CR2), and (d) Semarkona (LL3.0). Chondrules (chd) and CAIs in these meteorites show little evidence for aqueous alteration; matrices are more aqueously altered and contain phyllosilicates, magnetite, and fayalite (except PCA 91082). The Kaba matrix contains abundant Ca,Fe-rich pyroxenes (Ca,Fe-px); the PCA 91082 matrix contains rare carbonate (crb) grains.

Accompanies chapter by Krot et al. (pp. 635–660).

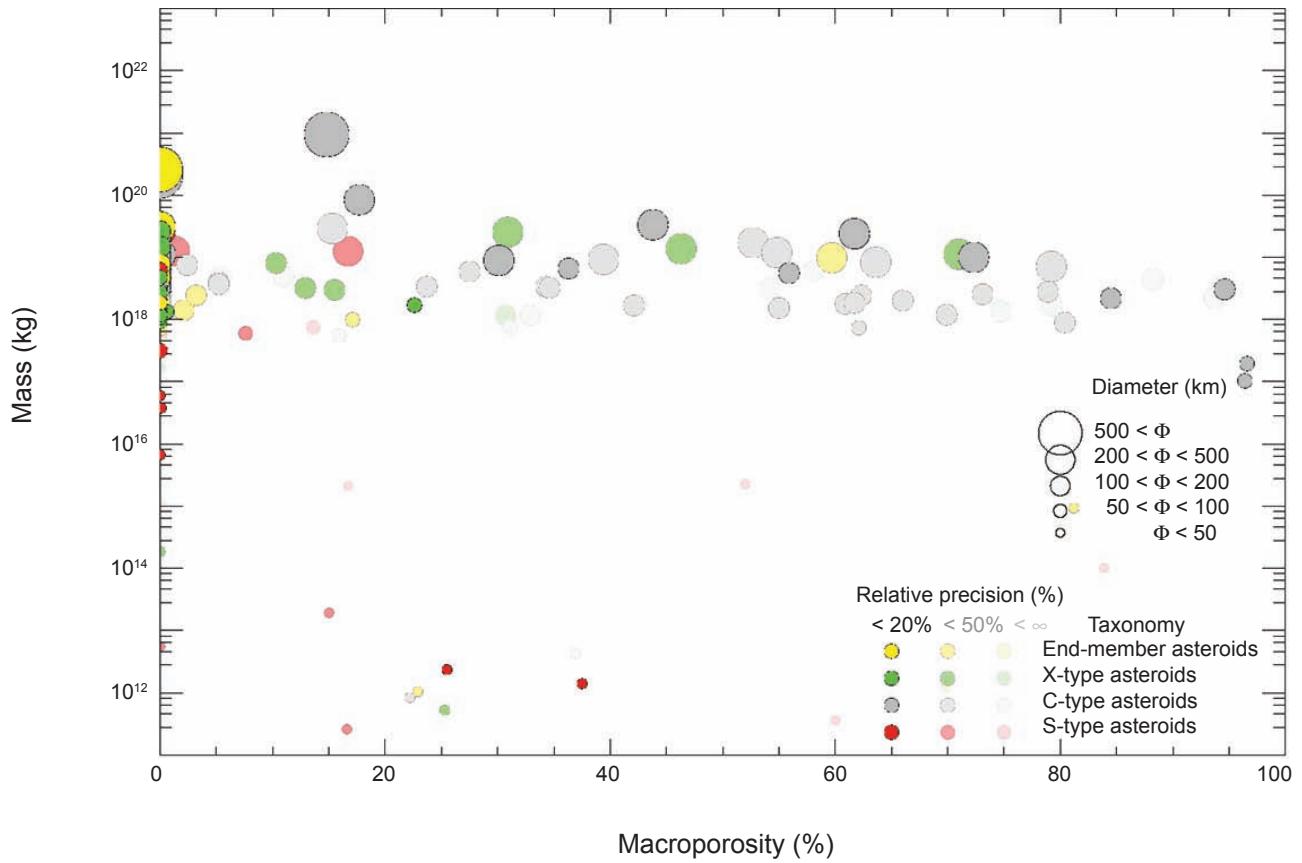

**Plate 23.** **(a,b)** Modeled peak metamorphic temperature for L-, CV-, and CO-like chondrite parent bodies ranging from 10 to 50 km in radius as a function of time after CV CAIs. **(c–f)** Temperature evolution diagrams at different depths shown for **(c,e)** L-like chondrite parent body of 30 and 40 km in radius, **(d)** CV-like chondrite parent body of 50 km in radius, and **(e)** CO-like chondrite parent body of 50 km in radius. Blue and green lines in **(c)** and **(e)** and blue and red lines in **(d)** and **(f)** correspond to regions where thermal conditions ( $\sim 100^\circ\text{--}300^\circ\text{C}$ ) would be suitable for the formation of fayalite at the time inferred from  $^{53}\text{Mn}$ - $^{53}\text{Cr}$  relative chronology. Figure from Doyle *et al.* (2015).

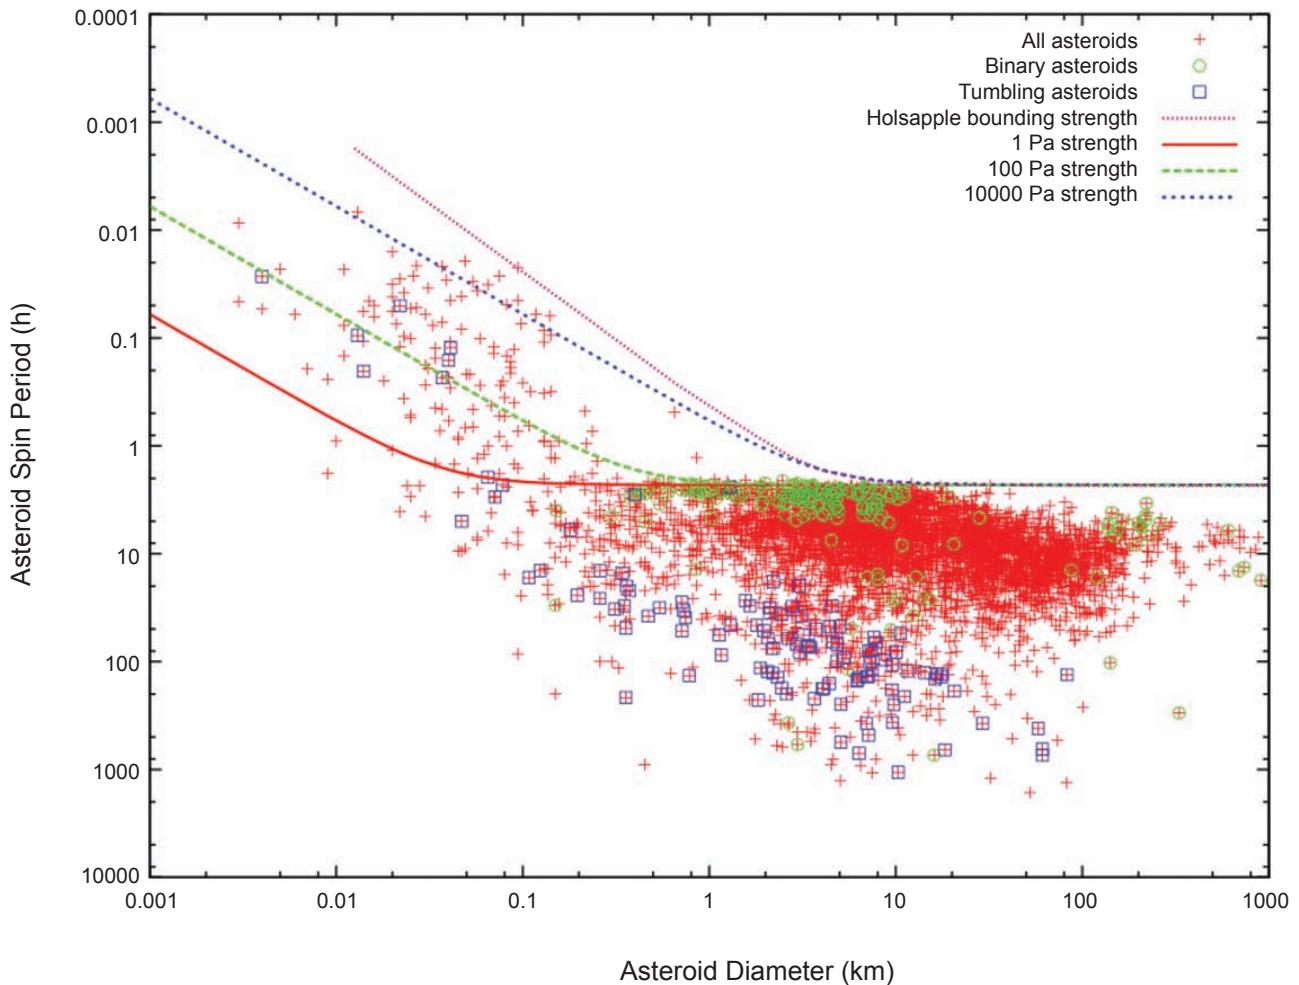

**Plate 24.** Density vs. mass. Asteroids are divided into four taxonomic groups (from DeMeo et al., 2009): S-complex in red, C-complex in gray, X-complex in green, and end members in yellow. The size of the symbols indicates the asteroid diameter, below 50 km, between 50 and 100 km, 100 and 200 km, 200 and 500 km, and above 500 km. The three different levels of contrast correspond to three cuts of relative accuracy: <20%, <50%, and regardless of precision (<∞).

Accompanies chapter by Scheeres et al. (pp. 745–766).

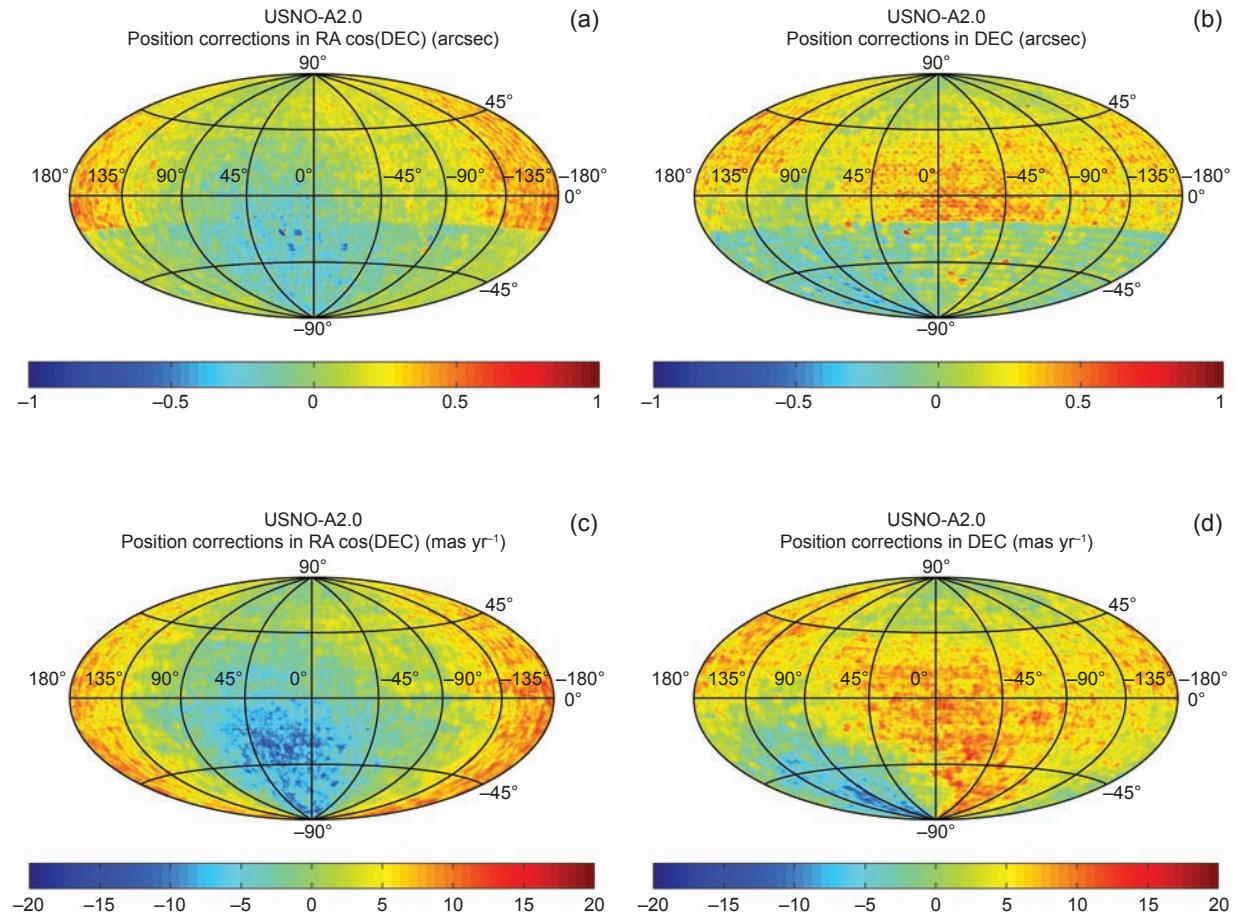

**Plate 25.** Macroporosity vs. mass. See Plate 24 for the explanation of symbols.

Accompanies chapter by Scheeres et al. (pp. 745–766).

**Plate 26.** Asteroid size vs. spin period, with binaries and tumblers called out specifically. All others are assumed to be single, uniform rotators. Only bodies with periods deemed to be reliable (see Warner *et al.*, 2009) are shown. The plot shows distinct structures. No object larger than a kilometer in diameter spins faster than an ~2.4-h period, now known as the gravity spin barrier and that is understood to not be an indicator of cohesionless material by itself. Instead it is simply that at these size scales the gravity effects dominate any strength effect. A number of smaller bodies spin faster; those must experience tensile stress and must have some cohesive strength to hold together. Typically, the observed maximum spins are larger for smaller sizes. Also plotted are spin limits as a function of diameter for levels of asteroid strength. Data shown is as of August 2014.

---

As a complement to experimental and theoretical approaches, numerical modeling has become an important component to study asteroid collisions and impact processes. In the last decade, there have been significant advances in both computational resources and numerical methods. We discuss the present state-of-the-art numerical methods and material models used in “shock-physics codes” to simulate impacts and collisions and give some examples of those codes. Finally, recent modeling studies are presented, focusing on the effects of various material properties and target structures on the outcome of a collision.

## 1. INTRODUCTION

The modeling of impact processes can be based upon mathematical synthesis of experimental results, on direct theoretical application of the principles of physics, or on the use of those principles in numerical codes.

The direct application of experimental results is not usually possible, because the experiments cannot be performed at the actual conditions of interest. To bridge the gap, scaling theories are developed using physical principles to extrapolate experimental results to the actual conditions of interest. For some time, principal scaling theories have been based upon the physical concept of a “point source,” wherein the genesis of an impact process is considered to occur instantaneously at a negligibly small region on the surface of the target object. Prior to 1982, point-source scaling was assumed to be governed by the kinetic energy of the impactor, but *Holsapple and Schmidt* (1982) showed that such an assumption was not warranted, and extended the analysis to arbitrary point sources. Their general approach has been followed in numerous subsequent papers by Holsapple, Housen, and Schmidt; one can refer to the review of those scaling approaches in *Holsapple* (1993). That scaling theory continues with applications to date.

In principle, the physics that govern such processes are known, at least in the continuum approach. Those physics include the balance laws of mass, momentum, and energy, augmented by mathematical descriptions of the material be-

havior. Material behavior commonly includes the “equation of state,” which models the hydrostatic components of the stress histories and the principal thermodynamics, as well as equations describing the deviatoric (shear) components of the response. The latter descriptions include stress-strain-temperature-relations and also include models for failure, flow, and fracture. That material behavior is the source of the primary uncertainties about the correct way to model these processes. However, there has been much progress in the last couple of decades, so that direct numerical solutions using time- and space-stepping increments are becoming increasingly sophisticated and important.

The codes used in those numerical approaches are commonly called “hydrocodes,” a remnant of the early days when they were used in the military industry to make calculations of weapons effects, and the modeling only included the hydrodynamic aspects of the processes. Nowadays those codes are better called “shock-physics codes” (*Pierazzo et al.*, 2008).

Just within the last decade, another approach has been applied to asteroid processes. That approach has been borrowed from the fields of particle mechanics and of “n-body” studies. They model the material of the body as a large number of individual, discrete, usually spherical, usually mono-sized, indestructible particles. With those simplifications the balance of momentum alone determines the motions of the particles. Balance of mass is automatic, and there is no accounting for energy balance and heating. The interactions of the particles are modeled using combinations of concepts of restitution,

friction, and most recently cohesive forces, with a number of interaction parameters. These approaches have only been made possible because of the extensive growth of computing power. However, because of the extreme complications of the interactions of real particles at high energies and stresses, those approaches will most likely be restricted to cases where the stresses remain low, and the discrete particle nature of the process can identify processes not contained in the continuum approaches.

In this chapter, we give an overview of the important asteroid properties that determine the outcome of a collision and discuss the physical processes involved. We then present recent experimental results and the theoretical approaches to describe the outcome of an impact. The main part of this chapter is devoted to a detailed discussion of the current state-of-the-art numerical models — shock-physics codes — which are used in the field to simulate impacts and collisions. Some examples of those codes are presented and the various approaches to model the important properties and processes are detailed here, including hybrid hydrocode-particle code computations. Finally, some examples of recent modeling are presented. In these studies, the effects of various material properties and target structures on the outcome of a collision are discussed.

## 2. IMPORTANT PROPERTIES AND PROCESSES

Asteroids have complex shapes, internal structures, and material properties. The impact response and mechanical behavior of such objects is naturally difficult to model. In this section, we present some of the important internal asteroid properties that determine the outcome of a collision and discuss late-stage processes. Asteroid interiors, morphologies and surface geophysics are further discussed in the chapters by Scheeres et al., Murdoch et al., and Marchi et al. in this volume.

### 2.1. Porosity

The fact that the bulk density of many asteroids is well below the grain density of their likely meteorite analogs indicates that many have significant porosity (Britt et al., 2002). In particular, several lines of evidence point to the presence of a high degree of porosity for asteroids belonging to the C taxonomic class, as indicated by the very low bulk density ( $\sim 1.3 \text{ g cm}^{-3}$ ) estimated for some of them, such as the asteroid (253) Mathilde encountered by the Near Earth Asteroid Rendezvous (NEAR) Shoemaker spacecraft (Yeomans et al., 1997), and as inferred from meteorite analysis (Britt et al., 2006). Porosity might be a result of a rubble-pile structure, as suggested, for instance, by spacecraft observations of asteroid (25143) Itokawa (Fujiwara et al., 2006). The various forms of structures and porosities of asteroids were discussed in *Asteroids III* (Britt et al., 2002; Richardson et al., 2002; Asphaug et al., 2002).

It is useful to distinguish between “microporosity” and “macroporosity.” The distinction is primarily a matter of

scale. The terminology arose in the study of meteorites, wherein porosity not apparent to the naked eye was called microporosity, and visually obvious voids between a grain structure or other identifiable particles was called macroporosity. But in the context of numerical modeling those terms can take on different meanings, because there are three different ways to model void space. In the first way, which is appropriate when the void space is very small compared to any length scale of interest, the porosity is considered a continuum material property and modeled as part of the equations of state. That continuum approach to porosity modeling is discussed below. In the second way, some codes allow a single numerical cell to contain both material and void, and the resulting behavior is determined by a mixture theory. In both of these first two approaches, the porosity scale is smaller than a calculation cell. In the third way, the void can be so large as to encompass an entire numerical zone, and zones without material can be scattered throughout a problem domain in some defined way. The differences between the approaches will depend on the length scale of the modeled phenomena compared to the length scale of the porosity.

The response of an asteroid to an impact is strongly affected by the presence of porosity. In the outgoing shock wave, a porous material can undergo significant permanent compression and become hot, which creates a significant energy sink (see the chapter by Asphaug et al. in this volume) (Davison et al., 2010). That effect will be included in any numerical model where the size scale of the porosity is smaller than the width of the initial outgoing compression pulse. Since it is typical in a code to numerically smear a shock over several calculation zones, even the third of the above porosity models can model significant crush up and energy loss, depending on the resolution of the calculation. In large-scale collisions (say between 100-km bodies), a shock wave can lead to compression of porous bodies even if they contain large (~kilometer-sized) voids, as long as these voids are smaller than the relevant scale (e.g., the impactor size).

In addition to the effects at the shock, porosity and the material’s resulting crushability can also have a dramatic effect on the entire cratering process. Rather than an excavation process, an entire crater can be formed by a downward flow crushing the material beneath the crater floor (K. Housen and K. Holsapple, 2014, in preparation).

Recent experiments and the scaling theory for the regime of cratering dominated by target porosity will be discussed in section 3. The different approaches proposed to model the various effects of porosity described above will be presented in section 4.4.4.

### 2.2. Strength

The outcome of an impact into an asteroid, whether a crater or a disruption, will ultimately be determined by gravity and some strength measure of the material of the object. There are many measures of strength for a geological material, and, over the last decade or so, that variety has

been identified and is often included in our scaling theories and in numerical calculations. Strength measures can include tensile strength, compressive strength, shear strength, crush strength, and others; each governs the ability of a material to withstand a different kind of stress state. In the usual continuum approach, each of those strengths is characterized by a different portion of a single “strength envelope”: a boundary defined in stress space between elastic and inelastic (permanent) deformation. An additional part of the modeling (flow rules) then describes the nature of the inelastic deformation from flow or fracture. In addition, the prior shock history can modify or “damage” the material, and that also must be accounted for. *Holsapple* (2009) presented a review of strength theories appropriate for geological materials. The interested reader can refer to that reference, in addition to further details below (section 4.4).

### 2.3. Late-Stage Processes

Since the time of the early lunar studies it is been observed that large craters and basins have a substantially lower depth-to-diameter ratio than the smaller ones. For the large craters, the slopes of the outer walls are typically well below the angle of repose expected for soils and rocks. These were judged to be puzzling because the angle of repose typically determines the static equilibrium slope angles of soils and rocks. *Melosh* (1979) proposed that the effect was due to the dynamic weakening of rock in the latter stages of crater formation by the action of acoustic vibrations. Since then, many other calculators include a “late-time” period of crater formation using rheological models that suppose the presence of that acoustic fluidization. Those methods are common today. An alternative viewpoint was presented by *Holsapple* (2004a), but his approach has yet to be fully developed.

These approaches are presented below in section 4.4.5. An application of a dynamic weakening model in the case of large-scale collisions on asteroid (4) Vesta (*Jutzi et al.*, 2013) is discussed in the chapter by Asphaug et al. in this volume.

## 3. SCALING LAWS

As mentioned in section 1, the experiments we can make on Earth are not at the size scale, gravity levels, or impact velocities of interest to most solar system impact events. For that reason, the results of experiments in the laboratory must be extrapolated, often over many decades, to predict the results of impacts into asteroids. How does a 10-km asteroid behave compared to a 10-cm laboratory sample?

The physical assumption forming the foundation of modern scaling theories is that of a general “point source.” Any impactor has three fundamental independent measures: radius,  $a$ ; velocity,  $U$ ; and mass density,  $\delta$ . The three independent measures can be taken equally well as the diameter, momentum, and kinetic energy or any other three independent combinations. In any case, they contain the three independent units of length, mass, and time. Then, when that impactor collides at high velocity with an asteroid, it sets

up a highly dynamic event affecting a region much larger than the impactor size, and over a timescale much longer than that of the initial deposition of energy into the surface. Physically, an appropriate assumption is that the deposition of momentum and energy is instantaneous into a region of vanishing dimensions compared to any length scale of interest such as the final crater. Of course, that assumption cannot be made for very low speed impacts or other cases where a final crater may be only slightly larger than the impactor.

For a point source, the governing impactor measures cannot retain a length scale or a timescale. From that assumption it follows that the individual values for the size, velocity, and mass density do not affect the outcome. Instead, there can be at most one single combination of those three variables that “measures” the impactor. That measure is then used in conjunction with those defining the material behavior of the target object to develop the scaling theory.

The earliest point source solutions for impacts simply assumed that the correct measure was the kinetic energy of the impactor that defined what is now called “energy scaling.” *Dienes and Walsh* (1970) noticed in code calculations of impacts into metals that the same crater was obtained for different impacts having the same  $aU^\mu$  where  $\mu = 0.58$ . They did not identify that result as the signature of a point source, nor did they recognize that the general form is quite universal, but with different exponents depending on material type. The Z model of cratering by *Maxwell* (1977) was essentially another early point-source model, but again it was not identified as such, and was only applied to the geometry of the cratering flow field. *Holsapple and Schmidt* (1982) developed crater scaling from the assumption of a general point source, measured by what they called a “coupling parameter.” They showed that it must always have the power-law form  $C = aU^\mu\delta^\nu$ , but the governing exponents  $\mu$  and  $\nu$  cannot be immediately predicted, because they depend in a complicated way on the material of the target. However, it was proved that  $1/3 < \mu < 2/3$  (*Holsapple and Schmidt*, 1982). They also applied the same measure to a variety of outcomes of cratering and determined definite interrelations between the power laws for all outcomes of a given event.

Over the years, the implications of that theory have been applied to many different impact outcomes from both experiments and numerical simulations, including crater size, crater formation time, shock wave propagation time, catastrophic disruptions, ejecta characteristics from the impact, momentum transfer to asteroids, etc. From that variety of applications it is been well determined that the point-source predictions work surprisingly well, and, for moderately porous materials,  $\mu \sim 0.4$ , while for nonporous materials  $\mu \sim 0.55$ , with only small variations found. And in many cases, the use of that assumption leads to simple power-law scaling for many features of interest. Well-known examples are the power laws for crater dimensions when a crater size is determined by the surface gravity (“gravity regime”) or when it is entirely determined by a strength (“strength regime”), power laws for ejecta amounts and velocities, for stress decay, and others.

The reader interested in the details and earlier applications might begin with the scaling review article in *Holsapple* (1993). A review and several applications, including catastrophic disruption cases, were presented in the chapter by *Holsapple et al.* (2002) in the *Asteroids III* volume.

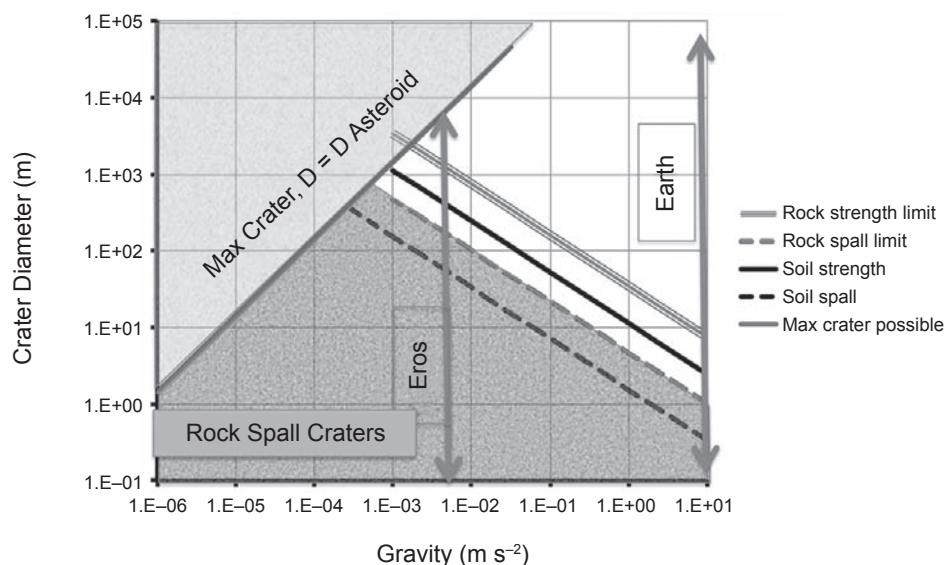

In addition to the now well-known strength and gravity regimes for impacts, two new regimes for cratering have recently been introduced. First, *Holsapple and Housen* (2013b) defined a “spall” cratering regime for small craters on rocky bodies, those dominated by the tensile spall strength, and not the more common shear strength that determines excavation craters. Those have been well known for explosive craters smaller than a meter or so in rocky targets on Earth and in laboratory experiments in competent rocks (e.g., *Gault*, 1973), although that regime has usually been ignored for planetary applications. But at the low gravity on an asteroid, that regime can include much larger craters. The extent of that regime as a function of surface gravity is depicted by the shaded region in Fig. 1 from *Holsapple and Housen* (2013b). For a body such as (433) Eros (16 km) all craters smaller than about 1 km are predicted to be spall craters. They would be flatter and shallower than excavation craters, and would eject blocks, not ejecta with more uniform smaller particles. These analyses are new and require more thorough experimental and numerical investigation.

Second, *Housen and Sweet* (2013) presented experiments and scaling of impacts into highly porous materials. Large porosity also adds a new regime, as illustrated in the schematic shown on a plot of scaled volume vs. the gravity-scaled  $\pi^2$  parameter (Fig. 2).

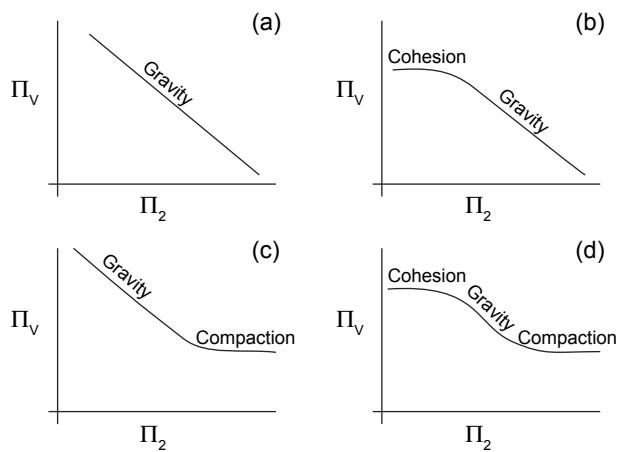

As indicated above, the point-source-scaling theory has also been applied to catastrophic disruptions (e.g., since

*Housen and Holsapple*, 1990). Recently, *Leinhardt and Stewart* (2012) extended this approach to define “general” scaling laws that included collisions between gravity-dominated bodies of comparable sizes. While this approach was shown to work well for some specific regimes (*Leinhardt and Stewart*, 2012), its general applicability still remains to be validated.

A great number of experimental studies in either the cratering or the disruptive regime have been performed since the publication of *Asteroids III*. This chapter is focused on the modeling of collisions, and therefore we will not review this experimental work. We just give a few references to the interested reader, noting that these experiments greatly contributed to our understanding of the collisional process at small laboratory scales and always give a necessary point of reference to test numerical methods (see section 4.6). In particular, various kinds of target materials have been considered, such as targets made of sintered glass beads (e.g., *Setoh et al.*, 2010; *Hiraoka et al.*, 2011); pumice (*Jutzi et al.*, 2009); porous gypsum, sometimes admixed with small pebbles or glass beads (*Okamoto and Arakawa*, 2009; *Leliwa-Kopystynski and Arakawa*, 2014; *Yasui and Arakawa*, 2011); dense (soda lime or quartz) cores and porous (gypsum) mantles (*Okamoto and Arakawa*, 2008); and other porous materials (e.g., *Housen and Sweet*, 2013; *Nakamura et al.*, 2015). Moreover, meteorites (e.g., *Flynn et al.*, 2008; *Kimberley and Ramesh*, 2011) have been used as well as 1-m-diameter granite spheres to check the effect of size on the cratering outcome (*Walker et al.*, 2013). In some cases, scaling parameters allowing an extrapolation at larger scales were also investigated. *Holsapple and Housen* (2012) study experiments and scaling for the momentum coupling of impacts as related to the deflection of

**Fig. 1.** Cratering on rocky asteroids can be dominated by surface spall phenomena when gravity and the crater are small. The lower shaded region of this plot shows the extent of that region; it includes all possible craters on kilometer-sized bodies and all craters smaller than 200 m on Eros.

**Fig. 2.** The scaled-size  $\Pi_V$  depends upon the gravity-scaled-size  $\Pi_2$  in different ways for different materials. **(a)** For a cohesionless soil with low or moderate porosity such as dry sand, standard “gravity scaling” applies at all size scales; for increasing size or gravity, there is a reduction in cratering efficiency. **(b)** For a small or moderately porous material with cohesion, the cohesion is the dominant contribution to the shear strength at small crater-sized scales, so that the cratering efficiency is constant. But for increasing size, there is a transition to the gravity-dominated regime. **(c)** A cohesion-less material with high porosity is gravity scaled at small sizes, but at large sizes is created by compaction, independent of gravity, so  $\Pi_V$  approaches a horizontal asymptote. **(d)** A material with both cohesion and high porosity potentially shows all three of the cohesion, gravity, and compaction regimes.

Earth-threatening asteroids by impacts (see also section 5.2.). A comprehensive review of experiments and ejecta scaling has been published by *Housen and Holsapple* (2011).

The increasingly more sophisticated material modeling in shock-physics code allows “numerical experiments” to be conducted for a much larger parameter space than it is possible to cover experimentally. Moreover, the effect of individual properties such as friction and porosity can be investigated in detail. The first results of this promising approach for the cratering regime have been presented in *Wünnemann et al.* (2010) and are summarized in section 5.1.1. Recent numerical studies of asteroid disruptions will be discussed in section 5.1.2.

## 4. NUMERICAL MODELING

### 4.1. Introduction

As a complement to experimental and theoretical approaches, numerical modeling has become an important component to study the outcome of collisions. In the last decade, advances in both computational resources and numerical methods have allowed the properties and processes involved (see section 2) to be modeled more and more realistically.

Here we present the principles of numerical impact modeling. We show some examples of codes used in the field and discuss the various model approaches.

### 4.2. Numerical Techniques

The two most common approaches to simulate impacts and collisions use shock-physics codes (“hydrocodes”) and particle codes.

Shock-physics computer programs use continuum theory, and can calculate the entire dynamical process including the propagation of shock waves and resulting fields of displacement, velocity, strain, stress, etc., as function of time and position (e.g., *Anderson*, 1987). They rely on mathematical constitutive models for the thermodynamics, which often includes melt and vaporization; for the deformation processes; and for the failure, fracture, and flow. Those material equations are the outcomes of testing of materials at the various states of interest. The equations are solved in a time-stepping manner on a geometrical computational grid (or interpolation points), usually with zones much smaller than the impactor dimension. The allowable timestep size must be shorter than the time for the passage of a shock wave across the smallest zone (“Courant-Friedrichs-Levy” stability criterion). Depending on the numerical method used, additional timestep restrictions are required (e.g., *Anderson*, 1987). It is not uncommon in two-dimensional applications to include hundreds ( $n$ ) of space zones in each direction, for a total of  $n^2 \sim 10^5$  and runs for several  $10^6$  timesteps. In three-dimensional problems, many more zones ( $n^3$ ) are required, so generally  $n$  must be much smaller. That illustrates the great advantage of codes that can calculate in two dimensions. However, many problems are inherently three-dimensional.

In contrast, particle codes (including “discrete element codes”) assume a collection of simple interacting particles. These codes generally only perform three-dimensional calculations. Their collisions are modeled using heuristic descriptions for restitution, friction, and viscosity, and their interactions include mutual interparticle gravitational forces. The balance of linear and angular momentum is all that is required to calculate their motions and rotations, so there is no use of mass balance or energy balance concepts. They do not include crushing, melting, vaporization, or other phenomena occurring in high-speed impacts, so these models are limited to low-velocity, low-stress events. The number of particles might be millions, but that is still many orders of magnitude less than the actual number in a soil-like structure in any problem of interest. Thus, it is inherently assumed that there are “enough” particles to approach the “infinite number” continuum limit. And, to date, it appears that the governing parameters need be chosen on a case-by-case basis.

There are two classes of particle models. The simpler and earlier approaches are the so-called “hard sphere” models in which particle collisions, which are assumed to occur instantaneously, are predicted in advance and are governed entirely by coefficients of restitution chosen by the user.

Such a model has been implemented in the N-body hard-sphere discrete element code *pkdgrav* (*Richardson et al.*, 2000), which has been used for different applications in planetary science (see the chapter by Michel et al. in this volume for an application to asteroid family formation) and which has been adapted to enable dynamic modeling of granular materials in the presence of a variety of boundary conditions (*Richardson et al.*, 2011). Other examples of such codes are polyhedral rubble-pile codes (*Korycansky and Asphaug*, 2006; *Movshovitz et al.*, 2012).

The hard-sphere approach is equivalent to the early attempts to model fluid mechanics by a collection of very sparse interacting atoms or molecules. It works well for rarefied gas dynamics, and it is well known that averaging across many particles leads to the classical continuum equations of perfect fluids. However, dense systems involving multiple collisions and enduring contacts require another approach, such as the “soft-sphere” discrete element method. In this approach, the particles are allowed to have finite interaction times governed by elastic concepts, and in principle even static cases of enduring contact can be included, relying upon modest penetration between particles. The soft-sphere approach was recently included in the code *pkdgrav* (*Schwartz et al.*, 2012); it is also used in other codes (e.g., *Sanchez and Scheeres*, 2011). Moreover, these discrete approaches can include bonding forces between particles, as a first analog of cohesive materials (see, e.g., *Schwartz et al.*, 2013; *Sanchez and Scheeres*, 2014). Such capability is also now available in the commercial finite-element code, LS-Dyna.

But this soft-sphere extension generally comes at a price. In effect, although the soft-sphere approach has the advantage of not requiring collisions to be predicted in advance, it comes at the expense of much smaller integration timesteps than the hard-sphere approach, which can limit the integration timescale. That is similar to the timestep restrictions for the continuum codes. On the other hand, because it can be implemented into codes, like *pkdgrav*, that are fully and efficiently parallelized, it is currently possible to follow the evolution of millions of particles over a fairly large range of conditions. The chapter by Murdoch et al. in this volume provides a review of discrete element methods and continuum approaches applied to the dynamics of granular materials at the surface of asteroids.

The use of particle codes to simulate rubble-pile collisions at low speeds (below the sound speed of the materials) was discussed in *Asteroids III* (*Richardson et al.*, 2002). In a recent study, *Ballouz et al.* (2014, 2015) used the particle code *pkdgrav* to simulate low-velocity collisions between rotating rubble piles in order to measure the effect of the initial rotation of colliding bodies on the outcome.

In situations where the whole process of a large-scale asteroid collision is investigated, including both the initial shock passages, heating, fragmentation, and the subsequent reaccumulation of fragments, a hybrid approach is often used (e.g., *Michel et al.*, 2001) (see the chapter by Michel et al. in this volume). There the fragmentation is computed with a shock-physics code and the gravitational reaccumulation

with a particle code. This approach is limited by the numerical resolution that fixes the minimum size of tractable fragments (typically down to  $\sim 10$  m for simulations involving kilometer-sized bodies).

In the fragmentation phase of a hypervelocity asteroid collision, self-gravity can usually be neglected because (1) the overburden pressure is small compared to the amplitude of the shock wave, and (2) the fragmentation timescale is much smaller than the reaccumulation timescale. (For large asteroids, however, it may be important to include fracture shielding due to compression.) The fragmentation timescale is given by the time it takes for a shock wave to travel through the whole target  $\tau_f \sim R_t/c_s$ , where  $R_t$  is the target radius and  $c_s$  a wave speed. On the other hand, gravitational reaccumulation proceeds on a timescale of  $\tau_{dyn} \sim (G_p)^{-1/2} \sim 2200$  s (for a bulk density  $\rho = 3000$  kg m $^{-3}$  and the gravitational constant  $G = 6.67 \times 10^{-11}$  m $^3$  kg $^{-1}$  s $^{-2}$ ). For small bodies ( $R_t \lesssim$  a few 100 km),  $\tau_f \ll \tau_{dyn}$  and gravity does not affect the dynamics of the fragments during the fragmentation phase. However, it is important to note that for very low velocity collisions, gravity has to be computed during the whole process, even for small bodies. This is typically the case in accretionary collisions (see the chapter by Asphaug et al. in this volume) where the impact velocity  $v_{imp}$  is on the order of the mutual escape velocity  $v_{esc} = \sqrt{2G(M_p + M_t)/(R_p + R_t)}$ , where  $M_p$  is the mass of the projectile,  $M_t$  the mass of the target, and  $R_p$  the projectile radius. For 10 (100)-km-diameter bodies,  $v_{esc} \sim 5$  (50) m s $^{-1}$  (assuming a density of  $\rho = 3000$  kg m $^{-3}$ ).

The hybrid hydrocode-particle code approach is detailed in the chapter by Michel et al. in this volume, which presents the newest collision models in particle codes. Here we focus on shock-physics codes.

#### 4.3. Basic Equations

Shock-physics codes solve the system of partial differential equations that describe the conservation of mass, momentum and energy for a continuous, compressible medium (see e.g., *Collins et al.*, 2013 for a recent review). Examples and a description of such codes used in the field [smoothed particle hydrodynamics (SPH), CTH, iSALE, SOVA] will be given in section 4.5.

The stress tensor is symmetric and is often divided into isotropic (hydrostatic) and deviatoric parts

$$\sigma^{ij} = S^{ij} - P\delta^{ij} \quad (1)$$

where the pressure  $P$  is the hydrostatic pressure,  $S^{ij}$  is the (traceless) deviatoric stress tensor, and  $\delta^{ij}$  is the Kronecker symbol. Using a Lagrangian reference frame, the conservation equations (mass, momentum, and internal specific energy) can then be written using an indicial summation convention as

$$\frac{dp}{dt} + p \frac{\partial v^i}{\partial x^i} = 0 \quad (2)$$

$$\frac{dv^i}{dt} = \frac{1}{\rho} \frac{\partial \sigma^{ij}}{\partial x^j} + g^i \quad (3)$$

$$\frac{dE}{dt} = -\frac{P}{\rho} \frac{\partial}{\partial x^i} v^i + \frac{1}{\rho} S^{ij} \bar{\epsilon}^{ij} \quad (4)$$

where  $d/dt$  is the Lagrangian time derivative,  $\rho$  the density,  $v$  the velocity,  $E$  the specific internal energy,  $x$  the position, and  $\bar{\epsilon}$  the deviatoric part of the strain rate tensor. The term  $g$  on the righthand side of equation (3) accounts for any external acceleration, e.g., due to gravity forces.

To complete the set of equations, equations describing the material response are required. For the hydrostate components an equation of state (EOS) is required, which relates pressure, density, and internal energy (or temperature, if its inclusion is convenient). And constitutive equations relating the deviatoric components are used. Both of these can be very complex, but have been developed over the years, often by the military community. The specifics are discussed in section 4.4.

For many problems, the acceleration due to self-gravity is important and has to be taken into account in equation (3). The components of the gravity acceleration can be computed by solving the Poisson equation for the gravitational potential. In particle-based approaches (including SPH), the gravity acceleration for a particle  $k$  is directly given by

$$\vec{g}_k = -G \sum_{k \neq l} \frac{m_l \vec{r}_{kl}}{r_{kl}^2} \quad (5)$$

where  $G$  is the gravity constant,  $m$  the mass of the particles, and  $r = |\vec{r}|$  the distance between the particles. For  $N$  particles, the direct summation method leads to a complexity of  $O(N^2)$  and is only practical when computers that are designed to solve such problems [e.g., graphics processing units (GPUs)] are used. A method often applied for the self-gravity computation is the Barnes-Hut tree algorithm (Barnes and Hut, 1986), which allows reduction of the complexity to  $O(N \log N)$ .

#### 4.4. Material Models

An EOS relates density, internal energy, and pressure, and may also include porosity effects. A stiffness and strength model is needed to determine the deviatoric stress due to strains and possible material failure (sections 4.4.2 and 4.4.3).

Various processes occur during an impact on an asteroid and these have to be modeled in a suitable way. Those may include (1) effects due to porosity and other nonlinearities (including energy dissipation by compaction, damping of shock wave, and reduction of wave speed in highly porous materials); (2) (post-impact) flow of granular material in the case of shattered asteroids or rubble piles; and (3) dynamical state weakening (e.g., important to model the collapse of large craters).

**4.4.1. Equations of state.** An often-used form for the EOS is

$$P = P(\rho, E) \quad (6)$$

This form is convenient because in most hydrocodes, the specific internal energy (rather than the temperature) is computed directly. In fact, temperature is not required to solve the conservation equations. However, it may be useful to account for phase transitions and the thermal softening when deviatoric stresses are included (section 4.4.2).

The most simple EOSs have no thermodynamic coupling and the pressure is solely a function of density (e.g., the Murnaghan EOS). A more sophisticated and widely used analytical equation is the Tillotson EOS, which was derived for high-speed impact computations (Tillotson, 1962). One of the major advantages of this EOS is its efficiency. However, the Tillotson EOS does not provide information about how to compute the temperature or the entropy of a material. Furthermore, the treatment of vaporization is not very sophisticated. For these reasons, the Tillotson EOS is mostly used to study impacts involving specific energies that do not lead to significant melting or vaporization.

A more complex and thermodynamically consistent analytical EOS model is ANEOS (M-ANEOS) (Thompson and Lauson, 1972; Melosh, 2007). In this model, the thermodynamics variables are derived from the Helmholtz free energy. ANEOS includes a more accurate treatment of both melting and vaporization than the Tillotson approach and allows for other polymorphic and liquid/solid phase transitions.

There are also complete tabular databases such as the SESAME library, developed by the Livermore National Laboratory. Those are efficient to use, valid over vast density ranges, and commonly include complete thermodynamics, including phase changes of melt and vapor. Often those are tabular compilations of the analytical forms.

**4.4.2. Strength models.** The strength model is fundamental for modeling impacts and collisions involving small bodies. It determines the “impact strength” in disruptive collisions; the size, final shape, and characteristics of the crater in an impact; and so on.

It is important to note that, depending on the loading conditions, various forms of “strength” exist (section 2). Here we give an overview of some strength models that are included in impact codes used in the field.

A simple strength model commonly used is the von Mises model developed for ductile metals. In this model, plastic flow occurs at stresses larger than a single constant yield strength  $Y_0$ . The von Mises criterion is implemented in shock codes by reducing the deviator stress (see, e.g., Benz and Asphaug, 1994; 1995) by

$$S^{ij} \rightarrow f S^{ij} \quad (7)$$

where  $f$  is computed by

$$f = \min \left[ \frac{Y_0^2}{3J_2}, 1 \right] \quad (8)$$

This is commonly called the “radial return method” and is also, for the von Mises case, the direction of the “associated flow rule” of plasticity theories. Here, the second invariant of the deviatoric stress tensor  $J_2 = \frac{1}{2}S^{ij}S_{ij}$  is used as a scalar measure of the maximal shear stress.

Although this model was developed for ductile materials, it was commonly used in impact calculations in geological materials in the past. In combination with a tensile fracture model (see section 4.4.3), it gives reasonably accurate results in disruptive collisions. *Jutzi* (2015) gives a comparison between this approach and more sophisticated strength models in simulations of disruptive collisions.

However, common geological materials such as soils, rocks, and ices have more complex behavior than ductile metals. An important characteristic of their strength is a substantial increase of shear strength with increasing confining pressure. That is the common feature of more sophisticated failure criterion used for geologic materials. The general form for geological strength models is as indicated in Fig. 1 of *Holsapple* (2009). There is a region in “shear-pressure” space delimited by a closed curve at which “failure” or “flow” can occur. The “shear” can either be measured by the maximum shear stress  $\tau$  on any plane, or by the average shear given by the stress invariant  $\sqrt{J_2}$ . The “pressure” can as well be the actual average normal stress  $P$  or the maximum normal stress  $\sigma$  on any plane. The Drucker-Prager model uses  $P$  and  $\sqrt{J_2}$ , while the Mohr-Coulomb model uses  $\sigma$  and  $\tau$ . For small pressure, failure occurs at the upper-limit pressure-dependent shear envelope defining the largest admissible shear. For large pressures, that shear envelope flattens. Then, at the right is a constraint for the maximum pressure where compaction can occur with compressive pressure. This limit is particularly important for porous material for which “crushing” can start at very low pressures. Models for that rightmost porous limit are described below.

The initial slope of the shear envelope at low or tensile pressures is commonly called the “friction coefficient,” because the form is similar to that used for friction between solid sliding blocks. But that is in fact a misnomer; the actual mechanism is a result of the fact that a pressure impedes the movement of irregular-shaped grains up and over each other in a shearing flow. That slope then reduces at larger pressures.

The Mohr-Coulomb and Drucker-Prager models include that pressure-dependent yield strength and are the simplest failure models commonly used in soil and rock mechanics (e.g., *Holsapple*, 2009).

One strength model (*Collins et al.*, 2004) uses the following pressure-dependent shear strength for the intact material  $Y_i$

$$Y_i = Y_0 + \frac{\mu_i P}{1 + \mu_i P / (Y_M - Y_0)} \quad (9)$$

where  $Y_0$  is the shear strength at  $P = 0$ ,  $Y_M$  is the shear strength at  $P = \infty$ , and  $\mu_i$  is related to the coefficient of internal friction for the intact material. Here the “shear” is measured by  $\sqrt{J_2}$ . This model is implemented in a number

of codes (e.g., *Collins et al.*, 2004; *Senft and Stewart*, 2007; *Jutzi*, 2015). Other nonlinear functions including powers and exponentials are common (e.g., *Hoek and Brown*, 1980).

To describe the yield strength of fully damaged rock, which includes granular material

$$Y_d = \mu_d P \quad (10)$$

is used, where  $\mu_d$  is related to the coefficient of friction of the damaged material. [For modeling regoliths in low-gravity environments, it is not uncommon to add a (small) cohesion.]

In addition, the model must specify how a stress exceeding the limit is mapped back to the failure surface in each timestep (the “return method”) and also the resulting plastic flow increment during the timestep (the “flow rule”). The yield strength  $Y$  is often used to simply reduce the deviatoric stress (represented by  $\sqrt{J_2}$ ) by a factor of  $Y/\sqrt{J_2}$ . That is again the “radial return method.” The plastic strain increment is often assumed to be in shear only (no volume change). But in general plasticity theories, the “associated flow rule” is more common; it is assumed to be in the direction perpendicular to the failure envelope. That case includes the important phenomena of the dilatancy of a granular material when flowing. Such details are not yet included in most planetary code simulations, although such an approach has been implemented recently in the iSALE code (*Collins*, 2014). Much more study and use of such models is warranted.

One might note the occurrence of two characteristic strength measures in such equations. The strength  $Y_0$  at zero pressure is commonly called the cohesion. It may be zero for dry sands, or on the order of a few kilopascals to several megapascals or more for cohesive materials, and even hundreds of megapascals for small solid rocks. Then the shear strength increases with pressure to a maximum value of  $Y_M$ , a characteristic of the strength of individual grains, which may be as much as a few gigapascals. The importance of these values depends on the other pressure scales in the problem, and especially on the gravity-induced lithostatic stress  $\rho gh$  at a depth  $h$ . If that gravitational stress is much larger than the cohesion, but still less than  $Y_M$ , then the cohesion can be ignored, but a dependence on the angle of friction will still occur. That is the case in what is called the “gravity regime” of cratering, which holds, e.g., for large craters on Earth. In the gravity regime, there remains a dependence on that angle of friction, but not on any other strength measure. That dependence will emerge from any calculation including the strength equation. But for extremely large events, the gravity stress will be larger even than  $Y_M$ . For example, for collisions between planetary-sized bodies, that will be the case. Therefore, in giant impact simulations, e.g., to study the Moon-forming impact (e.g., *Benz et al.*, 1989; *Canup and Asphaug*, 2001; *Reufer et al.*, 2012), any form of strength is typically ignored.

There are additional factors that must be accounted for in the construction of any strength envelope. It is not static, but changes according to the present state of the material at any point. For example, it can depend on the instantaneous strain

rate, or on the temperature, and can change size and shape as the material is strained. The community is just beginning to include all known effects in our mathematical models.

For example, to account for the thermal softening of geologic materials for extreme impacts,  $Y$  may be further reduced according to

$$Y \rightarrow Y \tanh \left\{ \xi \left( \frac{T_{melt}}{T} - 1 \right) \right\} \quad (11)$$

(Collins et al., 2004), or using a similar function of specific internal energy  $E$

$$Y \rightarrow Y \left( 1 - \frac{E}{E_{melt}} \right) \quad (12)$$

where  $E$  is the specific internal energy and  $E_{melt}$  the specific melting energy. It is important to note that the temperature and energy at which melt occurs are strongly pressure dependent and not simply a constant, and that fact should be included in any thermal softening equation. A possible approach is to use the location of the present thermodynamic state compared to the melt boundary in the EOS space to soften the material.

**4.4.3. Fracture (or damage) models.** There is an additional complexity when a rock fractures. When a rock is stressed to failure, it breaks and becomes granular; the failure envelope should then ultimately change from one with cohesion to one appropriate for a fully granular material such as a dry sand or gravel. Some approaches in the past did not do that, but simply assumed zero strength (as water) when damaged. A scalar damage parameter  $D$  describing the accumulation of tensile and/or shear fractures and/or pore crushing from undamaged ( $D = 0$ ) to totally damaged ( $D = 1$ ) is often used to interpolate between the intact (equation (9)) and the damaged (equation (10)) strength

$$Y = (D - 1) Y_i + D Y_d \quad (13)$$

where  $Y$  is limited such that  $Y \leq Y_i$ . The damage parameter is computed using a fracture model and it may also be related to porosity models (e.g., Jutzi et al., 2008).

Continuum fracture models (e.g., Grady and Kipp, 1980) often use an underlying structure with a preexisting Weibull distribution (Weibull, 1939) of cracks that grow and coalesce under tensile loading. In these models, cracks grow at a fixed speed  $c_g$  once a flaw becomes active. This finite speed of crack growth naturally leads to a rate-dependent failure of the material, as is observed for rocks [see, e.g., Housen and Holsapple (1990) for the application to disruptions]. In *Asteroids III* (Asphaug et al., 2002), various aspects of the rate- and size-dependent fracture models were discussed. The implementation of the fracture models in shock-physics codes are discussed in, e.g., Benz and Asphaug (1994, 1995), Collins et al. (2004), and Jutzi et al. (2008). These models are generally overlaid in addition to the strength envelopes discussed above.

Damage can also increase due to pore crushing during the compression of a porous material. This effect can be taken into account using a (linear) relation between distension  $\alpha$  and damage  $D$  (e.g., Jutzi et al., 2008).

Damage is usually treated as a scalar parameter. However, others have introduced tensor measures of damage (e.g., Lubarda and Krajcinovic, 1993). Due to their complexity, those have not yet made their way into impact studies, although tensor damage has been included in some recent codes (e.g., Owen, 2010).

**4.4.4. Porosity models.** In section 2 we discussed the various scales of porosity and the effects of porosity during an impact, such as the absorption of energy due to compaction or the reduction of the wave speed.

Depending on the scale of porosity, it can be modeled as either macroscopic voids (macroporosity) or by using a continuum, subresolution material model (microporosity), or as a combination of both as discussed in section 2. Here the size scale for demarcation is a computational cell size.

A widely used continuum model is the “P- $\alpha$ ” model (Herrmann, 1969; Carroll and Holt, 1972), which uses the distension  $\alpha$  defined by

$$\alpha = \rho_s / \rho \quad (14)$$

where  $\rho$  is the bulk density of the porous material and  $\rho_s$  is the density of the corresponding solid (matrix) material. A crucial assumption in this model is that it is the density and specific internal energy of the matrix material that determines the pressure. That is true when ignoring any energy content related to the porosity such as surface energy. Therefore, the bulk pressure of the porous material  $P$  is then related to the pressure in the solid component (matrix)  $P_s$

$$P = \frac{1}{\alpha} P_s (\rho_s, E_s) = \frac{1}{\alpha} P_s (\alpha \rho, E) \quad (15)$$

A significant feature of this model is that any existing EOS for a nonporous material  $P_s(\rho_s, E_s)$  can be used as the solid component of a porous material of the same composition.

A compaction model is required to determine the history of distension as a function of the history of pressure change. It is often assumed that the crush-up is independent of shear stress, although Jutzi et al. (2008) relate the changing rate of the distension and of the deviatoric stress tensor. The form of the model for the historic P- $\alpha$  Herrmann form includes a crush curve  $\alpha = \alpha_c(P)$ , at which pressure increases will decrease the distension, defining the crush-up of the material. In addition, the porous model defines unloading elastic curves. Those apply until the stress state again reaches a failure boundary. Herrmann (1969) does not discuss that feature. The curves for loading and unloading are obtained by pressure tests that load and unload the material and are defined in the model with appropriate algebraic forms. The quadratic form assumed by Herrmann (1969) is not well suited to geological materials, but is easily changed. For instance, Jutzi et al. (2008, 2009) use a combination of two power-law functions to successfully reproduce the crush curve of pumice (Fig. 1 in Jutzi et al., 2009).

Since the EOS has the underlying density as a function of both the pressure and the internal energy, the crush curve should include that also, so *Holsapple* (2008) suggests that  $\alpha = \alpha_c(P, E)$ . In particular, the crush strength should become zero when the thermodynamic state is at melt. That feature is not yet common in models.

Elastic unloading only occurs until the stress state reaches some other point on the enclosing failure envelope. When shear stress is present, that can occur at positive pressure, but it will be at pure tensile pressure if the shear is zero and cohesion is present. At those states, increasing porosity will occur: The occurrence with shear is the physical process of dilation in shear flow. Such an approach has been implemented recently in the iSALE code (*Collins*, 2014).

The Herrmann approach to solving the history of distension following these paths used a time subcycling that was essentially a forward differencing. The difficulties in that numerical method motivated an alternative model that determines the distension as a function of volumetric strain; it was presented by *Wünnemann et al.* (2006). The so-called “ $\epsilon$ - $\alpha$ ” model addresses the above-mentioned problem of the iterations in the “P- $\alpha$ ” model due to the interdependency of pressure P and distension  $\alpha$ . When implementing equation (15) and the crushing curve  $\alpha = \alpha(P)$  into a hydrocode for a given timestep t,  $\alpha_{t+1}$  must be known to derive  $P_{t+1}$ , but  $\alpha_{t+1} = f(P_{t+1})$ . A common solution is to use small subcycles to iterate the new  $P(t+1)$  value. This method requires extra computation time and may be numerically unstable under certain circumstances. The problem is solved in the “ $\epsilon$ - $\alpha$ ” model using the volumetric strain  $\epsilon_V$  to determine the crushing of pore space:  $\alpha = \alpha(\epsilon_V)$ . The “ $\epsilon$ - $\alpha$ ” model distinguishes four compaction regimes, where the rate of compaction  $d\alpha/d\epsilon_V$  is calculated according to elastic compaction ( $\epsilon_V < \epsilon_e$ ), exponential compaction ( $\epsilon_e < \epsilon_V < \epsilon_x$ ), power-law compaction ( $\epsilon_x < \epsilon_V < \epsilon_c$ ), and the fully consolidated state ( $\epsilon_V > \epsilon_c$ ).

The improved model (*Collins et al.*, 2011) removed two shortcomings of the initial model. First, it accounts for the fact that the speed of sound of the pristine porous material can be substantially lower than the elastic wave speed in the solid material. A simple linear relationship for  $c(\alpha)$  interpolating between the speed of sound of the fully compacted material and the initial porous material is assumed. Second, the improved version distinguishes between thermal and mechanical strains. The improvement uses an approximation about the EOS, so further calls to the EOS subroutine are not needed. In contrast to the original “ $\epsilon$ - $\alpha$ ” model the improved version is also applicable for highly porous material where material is heated extremely due to the compaction of pore space (PdV-work) resulting in thermal expansion of the solid component.

An alternative idea that retains the P- $\alpha$  form was outlined in *Holsapple* (2008). It is based on a Newton-Raphson approach rather than the forward differencing and eliminates the numerical problems in the original formulation.

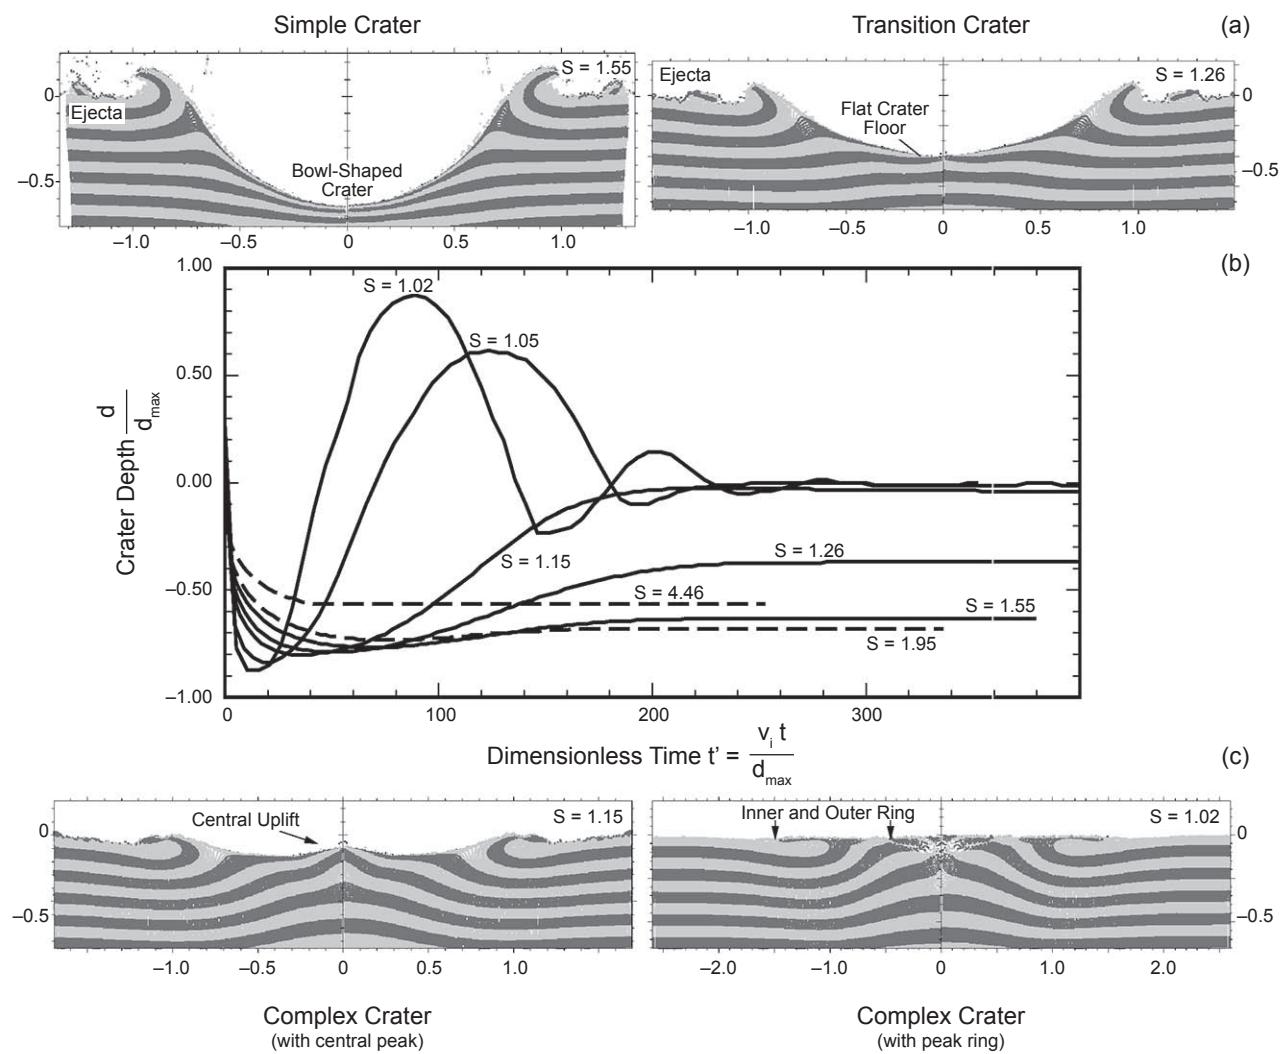

**4.4.5. Fluidization models.** In the opinion of some researchers, the constitutive models describing the strengths of rocks cannot explain the formation of complex crater

structures with central peaks, where originally deep-seated material was uplifted several kilometers. And they do not explain the shallow outer wall slopes that are well below the angle of repose of the models. It is assumed that an almost fluid-like rheology of matter during crater formation is required, and it is from some weakening mechanism that lasts only temporarily. The latter is an important constraint as steep, almost vertically standing flanks of central peaks can only be explained if rocks almost return to their initial strength.

A successful approach to solve the problem of a temporary fluid-like rheology of rocks during crater formation was suggested by *Melosh* (1979). He proposed that heavily fractured and brecciated rocks behave like a granular flow excited by acoustic vibrations that have been interpreted to be observed in the ground motions generated by nuclear explosions. The fluid-like nonlinear rheology decays as the amplitude of the vibration attenuates. The model requires that the wavelength of the acoustic signal is comparable to the size of the fragments. The original acoustic fluidization model has been simplified in the so-called block model where the acoustically fluidized material behavior is described by a Bingham model (*Melosh and Ivanov*, 1999). The Bingham viscosity is proportional to the block size and the Bingham cohesion depends on the amplitude of the vibration. The latter is a function of time as the amplitude of the acoustic wave decays. A shortcoming of the acoustic fluidization or block model is the fact that neither block size nor decay time are known and can only be estimated for the size of a given structure. *Wünnemann and Ivanov* (2003) suggested a heuristic linear relationship for both block size and decay time with the size of the impactor. They assume that larger impactors produce larger blocks and longer waves that attenuate slower than in case of smaller impacts where material is fractured into smaller fragments and the acoustic signal vanishes much quicker. The linear scaling of the block model parameters has been calibrated against the observed depth-to-diameter ratios of the cratering record of the Moon (*Wünnemann and Ivanov*, 2003) and on satellites (*Bray et al.*, 2014).

Figure 3 shows a simulation of the gradual transition with increasing crater size from simple to complex crater morphology, using that model. The parameter S is given by the ratio between strength Y and the hydrostatic pressure at maximum crater depth  $d_{max}$ :  $S = Y/(pgd_{max})$ . The diagram illustrates the increasing crater depth while the transient cavity is growing and the decrease of crater depth when the crater floor collapses and starts to rise, forming a complex crater with a central peak. According to some simple estimates by *Melosh* (1979), the critical value for crater collapse is given by  $S = 0.25$ , which corresponds to strength of the rocks of a few megapascals, approximately one order of magnitude smaller than typical values for rocks. The application of the block model allows the assumption of realistic strength values for crater collapse at the observed transition diameter between simple and complex crater morphology on different planets.

The approach described above is well established and was successfully applied in many studies in the past to model the formation of complex craters. However, there is an ongoing

**Fig. 3.** Crater depth vs. time for different impact conditions ( $S = 1.02\text{--}4.46$ ). The length parameter is normalized by the maximum crater depth  $d_{\max}$ ; time is scaled by the ratio of impact velocity  $v_i$  and  $d_{\max}$ . The no-fluidized rheology is given by a Drucker-Prager yield strength envelope where  $Y = Y_0 + \phi p$ , with  $Y_0 = 25$  GPa and  $\phi = 0.1$ . Examples of the resulting crater morphology for different  $S$  values (different projectile sizes) are shown above and below the diagram. Note: All length scales are normalized by  $d_{\max}$  (taken from Wünnemann and Ivanov, 2003).

debate about the actual underlying physical mechanism that causes the temporary weakening. Holsapple (2004a, 2013) suggested that existing strength theories, in their complete form, can model the late-time readjustments discussed above, but his approach has not yet been fully vetted. Some important evidence for the related problem of the collapse and runout of a granular cliff is given in section 4.6.3 below.

#### 4.5. Examples of Hydrocodes

Various approaches are used in shock-physics codes to solve the continuum system of partial differential equations detailed in section 4.3. The equations may be cast in a “Lagrangian” reference frame that follows the material or in an “Eulerian” reference frame that is fixed in space. The continuum codes include finite-difference, finite-element,

and SPH methods. Each numerical method has its own strengths and weaknesses. In a recent review by Collins *et al.* (2013), the various methods are presented and numerical issues such as resolution, the treatment of shocks, multi-material approaches, etc., are discussed. Here we present a few examples of commonly used hydrocodes. For each method, the specific material models used and the pros and cons are indicated.

**4.5.1. Grid-based codes.** Most numerical simulations of planetary collision processes use Eulerian grids, because large deformations are difficult to track in the Lagrangian approach.

Grid-based codes typically use a two-step approach, where the first step is the Lagrangian step where the deformation of the grid according to a given velocity field is calculated, and then there is a second step that maps the grid back on its original location in space. The remapping

requires special treatment of material boundaries, which is usually solved by tracking or reconstructing the interface between different matter [for a discussion of different methods of interface tracking/reconstruction see *Elbeshausen and Wünnemann (2010)*]. There are several advantages to grid-based codes: (1) Lagrangian, Eulerian, or an arbitrary spatiotemporal transition between both reference frames is possible; (2) high resolution, which may be increased locally by the adaptive mesh refinement (AMR) method (*Berger and Oliger, 1984; Berger and Colella, 1989*) employed in CTH; (3) adequate treatment of solid-state deformation, liquid flow, and gas expansion including appropriate rheology models; (4) coupling of the grid-based methods with massless Lagrangian tracer particles to track the spatiotemporal thermodynamic history of matter; and (5) relatively straightforward implementation of a variety of EOS models.

Grid-based models come also with some disadvantages: (1) In Eulerian mode, material interfaces are not tracked perfectly and bulk properties must be defined for mixed cells. (2) Matter is treated as continuum, which makes it difficult to treat fragmentation properly. Separate fragments tend to be underresolved unless AMR is employed. (3) Although multi-material handling is possible, mostly the codes do not deal with multi-phase processes where each phase moves at its own speed resulting in mixing of matter. Such processes are in particular important for the interaction of solid-state fragments with an expanding vapor plume.

In this paper we mention three shock-physics codes widely used in planetary science. A much more complete overview of available hydrocodes is given in *Pierazzo et al. (2008)*.

The most advanced software package among those is the Sandia National Laboratories CTH code (*McGlaun et al., 1990*); however, because of its military uses, this code is limited in its availability to U.S. citizens. Besides highly advanced material models, it also includes AMR and self-gravity. For disruptive large-scale collision processes such as the Moon-forming impact event, self-gravity is essential (*Canup et al., 2013*). Canup et al. also compare results produced by different approaches such as grid-based models (CTH) and mesh-free codes (SPH, see below). Other widely used hydrocodes are SOVA (*Shuvalov, 1999*) and iSALE (*Amsden et al., 1980; Collins et al., 2004; Wünnemann et al., 2006; Elbeshausen et al., 2009*), which are (with some limitations) freely available for scientific purpose. SOVA contains a specific routine to deal with the interaction of lithic and molten ejecta and the vapor plume. As mixing of all phases occurs, it may be better called ejecta plume. This process requires so-called multi-phase hydrodynamics where at least two different phases (ejecta and vapor) travel at different speeds, interacting and mixing with each other. SOVA addresses this problem by introducing representative tracer particles where each tracer represents a certain number of fragments of a given size. The tracers exchange momentum and energy with the surrounding gas, but not with each other. The approach only works if the volume of fragments is small relative to the volume of the gas. The method has been successfully applied to model dusty flows (*Shuvalov,*

*1999*), tektite formation and deposition (*Stöffler et al., 2002*), and the development of Chicxulub distal ejecta (*Artemieva and Morgan, 2009*). The iSALE hydrocode is based on the SALE hydrocode solution algorithm (*Amsden et al., 1980*). To simulate hypervelocity impact processes in solid materials, SALE was modified to include an elastoplastic constitutive model, fragmentation models, various EOSs (Tillotson and ANEOS), and multiple materials (*Melosh et al., 1992; Ivanov et al., 1997*). More recent improvements include a modified strength model (*Collins et al., 2004*) and a porosity compaction model (*Wünnemann et al., 2006; Collins et al., 2011*). The three-dimensional version uses a numerical solver as described in *Hirt et al. (1974)*. The development history of iSALE-3D is described in *Elbeshausen et al. (2009)*. iSALE has been used to model the collision of highly porous planetesimals (*Davison et al., 2012*), impacts on the surface of (4) Vesta (*Krohn et al., 2014*), and the formation of large craters on (21) Lutetia (*Cremonese et al., 2012*), as well as the effect of an oblique impact angle on crater formation (*Elbeshausen et al., 2009, 2013*).

**4.5.2. Smoothed particle hydrodynamics codes.** Smoothed particle hydrodynamics is a meshless continuum Lagrangian approach (and in spite of its name is not a “particle” code). In the basic SPH method, approximate numerical solutions of the fluid-dynamics equations are obtained by replacing the fluid with a set of particles (see, e.g., *Gingold and Monaghan, 1977; Monaghan, 2012*). The properties of these particles are smoothed over a certain length  $h$  by a kernel function. That provides the link to a continuum approach. As the flow evolves, material mass moves with the particle and local density is calculated based on the proximity of nearby particles. The main advantages of this mesh-free method are: (1) SPH is a very robust scheme, and it is “straightforward” to add new physics. (2) Large deformations of the simulated objects are handled easily. (3) The description of free surfaces is trivial. (4) Due to the particle nature of the method, fragmentation is modeled naturally by the separation of particle clusters.

Disadvantages of the SPH method include: (1) The spatial resolution is typically lower than in grid-based simulations. (2) Boundary conditions and discontinuities (e.g., material interfaces) are complicated to handle. (3) It is mostly applied in three dimensions, which often requires computationally expensive million-particle calculations.

In the past years, the range of applications of the SPH algorithm has increased significantly. A number of SPH codes have been recently developed to study problems in planetary sciences. Examples are a SPH code for the modeling of pre-planetesimals (*Geretschauser et al., 2011*), SPHERAL (*Shapiro et al., 1996; Owen, 2010*), GADGET (*Springel, 2005; Marcus et al., 2009*), SPHLATCH (*Reufer et al., 2012*), or a GPU-based SPH code (*Kaplinger et al., 2013*).

A widely used SPH code to model collisions among rocky bodies was developed by *Benz and Asphaug (1994, 1995)*. This code was further extended by *Jutzi et al. (2008, 2013)* with the goal of realistically modeling rocky bodies with various internal structures (see section 4.5 for a comparison

to laboratory experiments). The most recent version of this code (see *Jutzi*, 2015) includes a pressure-dependent strength model as outlined in section 4.4.2, a tensile fracture model (section 4.4.3), and a porosity model based on the P- $\alpha$  model (section 4.4.5) and self-gravity. Friction is modeled either using the Coulomb dry friction law (equation (10)) or the rate-dependent model suggested by *Jop et al.* (2006). Self-gravity (section 4.3) is included as well. Recent applications of this code in asteroid studies are presented in section 5 and in the chapter by Asphaug et al. in this volume.

#### 4.6. Comparison to Laboratory Experiments

An important step in the development of numerical methods (which includes the implementation of complex material models) is the validation against laboratory experiments. As rigorous testing is limited by the availability of appropriate experiments, including measurements during the highly dynamic processes, a preliminary step is benchmarking of different codes against each other. An example for a very successful benchmark and validation study is given in *Pierazzo et al.* (2008), in which the modeling results of specific test problems from eight different hydrocodes were compared against each other and validated against laboratory cratering experiments, but only for water and aluminum.

Here we provide some additional examples dealing with the fracturing and fragmentation resulting from collisional processes, as well as a granular flow problem.

##### 4.6.1. Modeling the fragmentation of porous pumice.

Figure 4 shows a comparison of an SPH code calculation (using the SPH method as described in section 4.5.2) to laboratory impact experiments. The target used in the experiments is porous pumice with a porosity of ~70%. The fragment-sized distributions resulting from the impacts with velocities ranging from 2–4 km s<sup>-1</sup> could be well reproduced in the SPH code calculations (see *Jutzi et al.*, 2009, for details). This example illustrates the capabilities of the SPH method to model impact fragmentation.

**4.6.2. Fracturing in cratering experiments.** Fracturing caused by hypervelocity impact does not necessarily result in a complete disruption of the target. Figure 5 shows the cross-section of the crater that was formed by the 5.4 km s<sup>-1</sup> impact of a 1-cm-diameter iron projectile in ~20% porous sandstone. The experiment was carried out in the framework of the so-called Multidisciplinary Experimental and Modeling Impact Research Network (MEMIN) project, aiming at the validation of hydrocode modeling of hypervelocity impact processes (see *Kenkmann et al.*, 2013, and references therein). Figure 5a shows a snapshot of the iSALE cratering model at 750  $\mu$ s. The model includes the  $\epsilon$ - $\alpha$  porosity compaction model and a strength and damage model as described in *Collins et al.* (2004). Some static strength parameters of the sandstone were available (*Kenkmann et al.*, 2011); others, such as the crushing strength of the porous sandstone, were estimated or adjusted to match the observed crater depth.

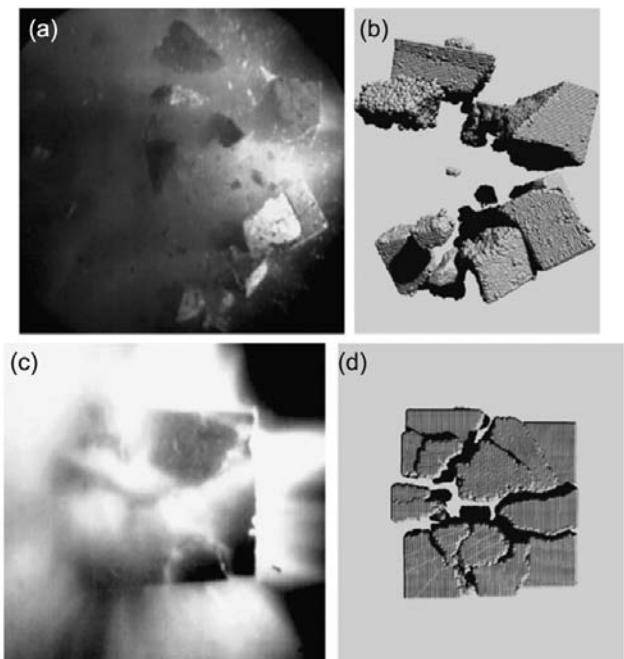

A more detailed calibration and validation of the crushing of pore space and sandstone is presented in *Güldemeister et*

*al.* (2013) and *Kowitz et al.* (2013). The crater in the experiment is enlarged by spallation. Modeling of the actual spall of material from the surface is not included in the iSALE model; however, the spall zone is indicated by cells that have experienced failure.

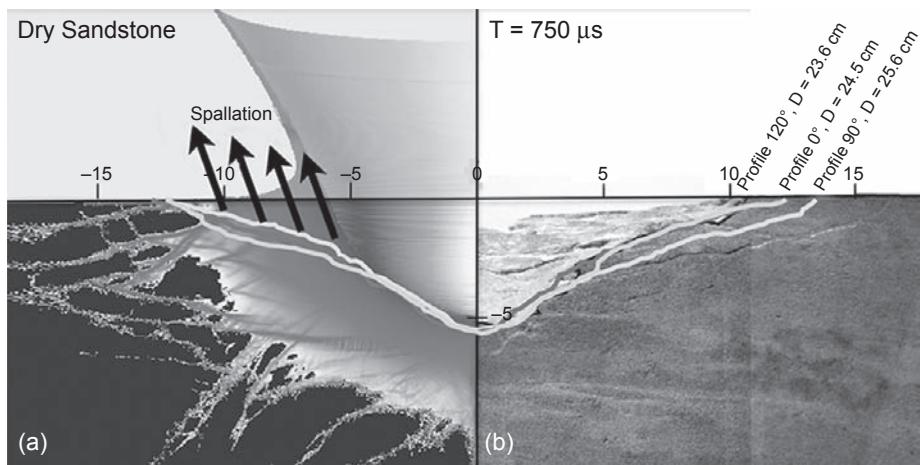

The damage zone in the model (gray contours represent the damage parameter as introduced above) underneath the crater shows some qualitative similarities with the flaws indicated by the thin gray lines on the cross-section of the cratering experiment. On the scale of individual grains it was shown that the zone where pore space was crushed or fracturing occurs in grains extends approximately to the same distance as in the model.

**4.6.3. Cliff collapse problem.** The cliff collapse problem is a useful test case for the pressure-dependent models used in code calculations, at least for low pressure. In that problem, an initial vertical “cliff” of material is suddenly released, and the mass falls and flows out to considerable lengths. This problem is of special interest for cratering because the same requirements of temporary fluidization mechanisms have been asserted as necessary for the mechanics of landslides. The final angles of the runouts are typically <10°, far below the angle of repose of geological materials.

*Holsapple* (2013) presented detailed theoretical arguments and numerical calculations of that landslide problem, using only the standard Drucker-Prager soil model with a

**Fig. 4.** Comparison between (a,c) laboratory impact experiments and (b,d) SPH code calculations. The targets are pumice cubes 7 cm in size with a porosity of ~70%. The impact experiments were performed at the Institute of Space and Astronautical Science (ISAS) of the Japan Aerospace Exploration Agency (JAXA) using a two-stage light-gas gun. Two impacts are shown at different times: (a,b)  $t = 8$  ms and (c,d)  $t = 1.5$  ms. From *Jutzi et al.* (2009).

**Fig. 5.** Comparison between (a) iSALE simulation and (b) laboratory cratering experiments. The target was a  $100 \times 100 \times 50$ -cm sandstone block with 20% porosity. The so-called Seeberger sandstone is composed of 97 wt.% SiO<sub>2</sub> with an unconfined compressive strength of  $\sim 60$  MPa. The projectile was a 1-cm iron sphere impacting at  $5.4 \text{ km s}^{-1}$  (for further details see Kenkmann *et al.*, 2011). (a) A snapshot of the numerical model showing contours of the damage parameter. The black lines indicate the zone where tensile failure occurs and material spalls off the surface. (b) The thin gray lines indicate macroscopic flaws; the thick gray lines indicate crater profiles in different directions. Courtesy of the Multidisciplinary Experimental and Modeling Impact Crater Research Network (MEMIN) Team.

35° angle of friction. He concludes that no additional *ad hoc* models are required to reproduce observed laboratory results. Specifically, his numerical simulations correctly reproduce laboratory experiments with final slopes  $< 10^\circ$ . A detailed investigation of those simulations explains the reason. It lies in the fact that the “slopes” allowed by the angle of repose argument are not violated, it is just that during the highly dynamic flows, the “slopes” must be measured relative to the combination of the local gravity direction and the direction of the inertial forces.

Jutzi (2015) also presented SPH calculations of that problem. He compared two models, one with a constant coefficient of friction (equation (10)) and one using a rate-dependent and particle-size-dependent relation defined in an “inertial number” as suggested by Jop *et al.* (2006). It was found that both models reproduce the experiments very well. The two models lead to the same results because in this granular flow regime, the inertial number stays small and therefore the rate dependency is negligible. This finding provides further evidence that the global outcome of such events is well reproduced by using a simple Coulomb dry friction law with a single parameter  $\mu_d$ , although at higher pressures a nonlinear model is undoubtedly necessary.

These examples show that the cliff-collapse problem and the resulting runouts (at laboratory conditions) can be well reproduced with continuum codes using conventional rock mechanics. However, there is evidence that additional weakening mechanisms (section 4.4.6) are necessary to explain other cases, such as the very long runout slides observed on Mars (e.g., Lucas and Mangeney, 2007; Harrison and Grimm, 2003).

## 5. APPLICATIONS

In this section, some examples of recent modeling are presented that illustrate the various the effects of the material properties, target structures, and impact conditions on the outcome of a collision.

### 5.1. Scaling Laws from Numerical Modeling
